Here, both  $f_m(\mathbf{x} | \mu_1, \sigma^2)$  and  $f_n(\mathbf{y} | \mu_2, \sigma^2)$  have the form given in Eq. (9.5.9), and the value of  $\sigma^2$  is the same in both terms. In this case,  $\Omega_0 = \{(\mu_1, \mu_2, \sigma^2) : \mu_1 \leq \mu_2\}$ . The likelihood ratio statistic is

$$\Lambda(\mathbf{x}, \mathbf{y}) = \frac{\sup_{\{(\mu_1, \mu_2, \sigma^2) : \mu_1 \leq \mu_2\}} g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma^2)}{\sup_{(\mu_1, \mu_2, \sigma^2)} g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma^2)}. \quad (9.6.10)$$

The likelihood ratio test procedure then specifies that  $H_0$  should be rejected if  $\Lambda(\mathbf{x}, \mathbf{y}) \leq k$ , where  $k$  is typically chosen so that the test has a desired level  $\alpha_0$ .

To facilitate the maximizations in (9.6.10), let

$$s_x^2 = \sum_{i=1}^m (x_i - \bar{x}_m)^2, \text{ and } s_y^2 = \sum_{i=1}^n (y_i - \bar{y}_n)^2.$$

Then we can write

$$\begin{aligned} g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma^2) \\ = \frac{1}{(2\pi\sigma^2)^{(m+n)/2}} \exp\left(-\frac{1}{2\sigma^2}\left[m(\bar{x}_m - \mu_1)^2 + n(\bar{y}_n - \mu_2)^2 + s_x^2 + s_y^2\right]\right). \end{aligned}$$

The denominator of (9.6.10) is maximized by the overall M.L.E.'s, that is, when

$$\mu_1 = \bar{x}_m, \quad \mu_2 = \bar{y}_n, \quad \text{and} \quad \sigma^2 = \frac{1}{m+n}(s_x^2 + s_y^2). \quad (9.6.11)$$

For the numerator of (9.6.10), when  $\bar{x}_m \leq \bar{y}_n$ , the parameter vector in (9.6.11) is in  $\Omega_0$ , and hence the maximum also occurs at the values in Eq. (9.6.11). Hence,  $\Lambda(\mathbf{x}, \mathbf{y}) = 1$  if  $\bar{x}_m \leq \bar{y}_n$ .

For the other case, when  $\bar{x}_m > \bar{y}_n$ , it is not difficult to see that  $\mu_1 = \mu_2$  is required in order to achieve the maximum. In these cases, the maximum occurs when

$$\begin{aligned} \mu_1 = \mu_2 &= \frac{m\bar{x}_m + n\bar{y}_n}{m+n}, \\ \sigma^2 &= \frac{mn(\bar{x}_m - \bar{y}_n)^2 / (m+n) + s_x^2 + s_y^2}{m+n}. \end{aligned}$$

Substituting all of these values into (9.6.10) yields

$$\Lambda(\mathbf{x}, \mathbf{y}) = \begin{cases} 1 & \text{if } \bar{x}_m \leq \bar{y}_n, \\ (1+v^2)^{-(m+n)/2} & \text{if } \bar{x}_m > \bar{y}_n, \end{cases}$$

where

$$v = \frac{(\bar{x}_m - \bar{y}_n)}{\left(\frac{1}{m} + \frac{1}{n}\right)^{1/2} (s_x^2 + s_y^2)^{1/2}}. \quad (9.6.12)$$

If  $k < 1$ , it is straightforward to show that  $\Lambda(\mathbf{x}, \mathbf{y}) \leq k$  is equivalent to  $v \geq k'$  for some other constant  $k'$ . Finally, note that  $(m+n-2)^{1/2}v$  is the observed value of  $U$ , so

the likelihood ratio test is to reject  $H_0$  when  $U \geq c$ , for some constant  $c$ . This is the same as the two-sample  $t$  test. The preceding argument can easily be adapted to handle the other one-sided hypotheses and the two-sided case. (See Exercise 13 for the two-sided case.)

## ◆ Unequal Variances

**Known Ratio of Variances** The  $t$  test can be extended to a problem in which the variances of the two normal distributions are not equal but the ratio of one variance to the other is known. Specifically, suppose that  $X_1, \dots, X_m$  form a random sample from the normal distribution with mean  $\mu_1$  and variance  $\sigma_1^2$ , and  $Y_1, \dots, Y_n$  form an independent random sample from another normal distribution with mean  $\mu_2$  and variance  $\sigma_2^2$ . Suppose also that the values of  $\mu_1, \mu_2, \sigma_1^2$ , and  $\sigma_2^2$  are unknown but that  $\sigma_2^2 = k\sigma_1^2$ , where  $k$  is a known positive constant. Then it can be shown (see Exercise 4 at the end of this section) that when  $\mu_1 = \mu_2$ , the following random variable  $U$  will have the  $t$  distribution with  $m + n - 2$  degrees of freedom:

$$U = \frac{(m+n-2)^{1/2}(\bar{X}_m - \bar{Y}_n)}{\left(\frac{1}{m} + \frac{k}{n}\right)^{1/2} \left(S_X^2 + \frac{S_Y^2}{k}\right)^{1/2}}. \quad (9.6.13)$$

Hence, the statistic  $U$  defined by Eq. (9.6.13) can be used for testing either the hypotheses (9.6.1) or the hypotheses (9.6.9).

**The Behrens-Fisher Problem** If the values of all four parameters  $\mu_1, \mu_2, \sigma_1^2$ , and  $\sigma_2^2$  are unknown, and if the value of the ratio  $\sigma_1^2/\sigma_2^2$  is also unknown, then the problem of testing the hypotheses (9.6.1) or the hypotheses (9.6.9) becomes very difficult. Even the likelihood ratio statistic  $\Lambda$  has no known distribution. This problem is known as the *Behrens-Fisher problem*. Some simulation methods for the Behrens-Fisher problem will be described in Chapter 12 (Examples 12.2.4 and 12.6.10). Various other test procedures have been proposed, but most of them have been the subject of controversy in regard to their appropriateness or usefulness. The most popular of the proposed methods was developed in a series of articles by Welch (1938, 1947, 1951). Welch proposed using the statistic

$$V = \frac{\bar{X}_m - \bar{Y}_n}{\sqrt{\frac{S_X^2}{m(m-1)} + \frac{S_Y^2}{n(n-1)}}}. \quad (9.6.14)$$

Even when  $\mu_1 = \mu_2$ , the distribution of  $V$  is not known in closed form. However, Welch approximated the distribution of  $V$  by a  $t$  distribution as follows. Let

$$W = \frac{S_X^2}{m(m-1)} + \frac{S_Y^2}{n(n-1)}, \quad (9.6.15)$$

and approximate the distribution of  $W$  by a gamma distribution with the same mean and variance as  $W$ . (See Exercise 12.) If we were now to assume that  $W$  actually had this approximating gamma distribution, then  $V$  would have the  $t$  distribution with

degrees of freedom

$$\frac{\left(\frac{\sigma_1^2}{m} + \frac{\sigma_2^2}{n}\right)^2}{\frac{1}{m-1} \left(\frac{\sigma_1^2}{m}\right)^2 + \frac{1}{n-1} \left(\frac{\sigma_2^2}{n}\right)^2}. \quad (9.6.16)$$

Next, substitute the unbiased estimates  $s_x^2/(m-1)$  and  $s_y^2/(n-1)$  for  $\sigma_1^2$  and  $\sigma_2^2$ , respectively, in (9.6.16) to obtain the degrees of freedom for Welch's  $t$  distribution approximation:

$$\nu = \frac{\left(\frac{s_x^2}{m(m-1)} + \frac{s_y^2}{n(n-1)}\right)^2}{\frac{1}{(m-1)^3} \left(\frac{s_x^2}{m}\right)^2 + \frac{1}{(n-1)^3} \left(\frac{s_y^2}{n}\right)^2}. \quad (9.6.17)$$

In Eq. (9.6.17),  $s_x^2$  and  $s_y^2$  are the observed values of  $S_X^2$  and  $S_Y^2$ . To summarize Welch's procedure, act as if  $V$  in Eq. (9.6.14) had the  $t$  distribution with  $\nu$  degrees of freedom when  $\mu_1 = \mu_2$ . Tests of one-sided and two-sided hypotheses are then constructed by comparing  $V$  to various quantiles of the  $t$  distribution with  $\nu$  degrees of freedom. If  $\nu$  is not an integer, round it to the nearest integer or use a computer program that can handle  $t$  distributions with noninteger degrees of freedom.

**Example  
9.6.6**

Comparing Copper Ores. Using the data from Example 9.6.5, we compute

$$V = \frac{2.6 - 2.3}{\left(\frac{0.32}{8 \times 7} + \frac{0.22}{10 \times 9}\right)^{1/2}} = 3.321,$$

$$\nu = \frac{\left(\frac{0.32}{8 \times 7} + \frac{0.22}{10 \times 9}\right)^2}{\frac{1}{7^3} \left(\frac{0.32}{8}\right)^2 + \frac{1}{9^3} \left(\frac{0.22}{10}\right)^2} = 12.49.$$

The  $p$ -value associated with the observed data for the hypotheses (9.6.9) is  $2[1 - T_{12.49}(3.321)] = 0.0058$ , not much different than what we obtained in Example 9.6.5. ◀

**Likelihood Ratio Test** An alternative to the Welch approximation described above would be to apply the large-sample approximation of Theorem 9.1.4. Using the same notation as earlier in the section, we can write the likelihood function as

$$\begin{aligned} g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma_1^2, \sigma_2^2) & \quad (9.6.18) \\ &= \frac{1}{(2\pi\sigma_1^2)^{m/2} (2\pi\sigma_2^2)^{n/2}} \exp\left(-\frac{m(\bar{x}_m - \mu_1)^2 + s_x^2}{2\sigma_1^2} - \frac{n(\bar{y}_n - \mu_2)^2 + s_y^2}{2\sigma_2^2}\right). \end{aligned}$$

The overall M.L.E.'s are

$$\hat{\mu}_1 = \bar{x}_m, \quad \hat{\mu}_2 = \bar{y}_n, \quad \hat{\sigma}_1^2 = \frac{s_x^2}{m}, \quad \hat{\sigma}_2^2 = \frac{s_y^2}{n}. \quad (9.6.19)$$

Under  $H_0: \mu_1 = \mu_2$ , we cannot find formulas for the M.L.E.'s. However, if we let  $\hat{\mu}$  stand for the common value of  $\hat{\mu}_1 = \hat{\mu}_2$ , we find that the M.L.E.'s satisfy the following equations:

$$\hat{\sigma}_1^2 = \frac{1}{m} \left[ s_x^2 + m(\bar{x}_m - \hat{\mu})^2 \right], \quad (9.6.20)$$

$$\hat{\sigma}_2^2 = \frac{1}{n} \left[ s_y^2 + n(\bar{y}_n - \hat{\mu})^2 \right], \quad (9.6.21)$$

$$\hat{\mu} = \frac{\frac{m\bar{x}_m}{\hat{\sigma}_1^2} + \frac{n\bar{y}_n}{\hat{\sigma}_2^2}}{\frac{m}{\hat{\sigma}_1^2} + \frac{n}{\hat{\sigma}_2^2}}. \quad (9.6.22)$$

These equations can be solved recursively even though we do not have a closed-form solution. One algorithm is the following:

1. Set  $k = 0$  and pick a starting value  $\hat{\mu}^{(0)}$ , such as  $(m\bar{x}_m + n\bar{y}_n)/(m + n)$ .
2. Compute  $\hat{\sigma}_1^{2(k)}$  and  $\hat{\sigma}_2^{2(k)}$  by substituting  $\hat{\mu}^{(k)}$  into Eqs. (9.6.20) and (9.6.21).
3. Compute  $\hat{\mu}^{(k+1)}$  by substituting  $\hat{\sigma}_1^{2(k)}$  and  $\hat{\sigma}_2^{2(k)}$  into Eq. (9.6.22).
4. If  $\hat{\mu}^{(k+1)}$  is close enough to  $\hat{\mu}^{(k)}$  stop. Otherwise, replace  $k$  by  $k + 1$  and return to step 2.

**Example  
9.6.7**

**Comparing Copper Ores.** Using the data in Example 9.6.5, we will start with  $\hat{\mu}^{(0)} = (8 \times 2.6 + 10 \times 2.3)/18 = 2.433$ . Plugging this value into Eqs. (9.6.20) and (9.6.21) gives us  $\hat{\sigma}_1^{2(0)} = 0.068$  and  $\hat{\sigma}_2^{2(0)} = 0.0398$ . Plugging these into Eq. (9.6.22) gives  $\hat{\mu}^{(1)} = 2.396$ . After 13 iterations the values stop changing and our final M.L.E.'s are  $\hat{\mu} = 2.347$ ,  $\hat{\sigma}_1^2 = 0.1039$ , and  $\hat{\sigma}_2^2 = 0.0242$ . We can then substitute these M.L.E.'s into the likelihood function (9.6.18) to get the numerator of the likelihood ratio statistic  $\Lambda(\mathbf{x}, \mathbf{y})$ . (Remember to substitute  $\hat{\mu}$  for both  $\mu_1$  and  $\mu_2$ .) We can also substitute the overall M.L.E.'s (9.6.19) into (9.6.18) to get the denominator of  $\Lambda(\mathbf{x}, \mathbf{y})$ . The result is  $\Lambda(\mathbf{x}, \mathbf{y}) = 0.01356$ . Theorem 9.1.4 says that we should compare  $-2 \log \Lambda(\mathbf{x}, \mathbf{y}) = 8.602$  to a critical value of the  $\chi^2$  distribution with one degree of freedom. The  $p$ -value associated with the observed statistic is the probability that a  $\chi^2$  random variable with one degree of freedom is greater than 8.602, namely, 0.003. This is the same as the  $p$ -value that we obtained in Example 9.6.5 when we assumed that the two variances were the same.  $\blacktriangleleft$

For the cases of one-sided hypotheses such as (9.6.1) and (9.6.7), the likelihood ratio statistic is a bit more complicated. For example, if  $\mu_1 = \mu_2$ ,  $-2 \log \Lambda(\mathbf{X}, \mathbf{Y})$  converges in distribution to a distribution that is neither discrete nor continuous. We will not discuss this case further in this book.

## Summary

Suppose that we observe independent random samples from two normal distributions:  $X_1, \dots, X_m$  having mean  $\mu_1$  and variance  $\sigma_1^2$ , and  $Y_1, \dots, Y_n$  having mean  $\mu_2$  and variance  $\sigma_2^2$ . For testing hypotheses about  $\mu_1$  and  $\mu_2$ ,  $t$  tests are available if we assume that  $\sigma_1^2 = \sigma_2^2$ . The  $t$  tests all make use of the statistic  $U$  defined in Eq. (9.6.3). To test  $H_0: \mu_1 = \mu_2$  versus  $H_1: \mu_1 \neq \mu_2$  at level  $\alpha_0$ , reject  $H_0$  if  $|U| \geq$

$T_{m+n-2}^{-1}(1 - \alpha_0/2)$ , where  $T_{m+n-2}^{-1}$  is the quantile function of the  $t$  distribution with  $m + n - 2$  degrees of freedom. To test  $H_0: \mu_1 \leq \mu_2$  versus  $H_1: \mu_1 > \mu_2$  at level  $\alpha_0$ , reject  $H_0$  if  $U > T_{m+n-2}^{-1}(1 - \alpha_0)$ . To test  $H_0: \mu_1 \geq \mu_2$  versus  $H_1: \mu_1 < \mu_2$  at level  $\alpha_0$ , reject  $H_0$  if  $U < -T_{m+n-2}^{-1}(1 - \alpha_0)$ . The power functions of these tests can be computed using the family of noncentral  $t$  distributions. Approximate tests are available if we do not assume that  $\sigma_1^2 = \sigma_2^2$ .

## Exercises

---

**1.** In Example 9.6.3, we discussed Roman pottery found at two different locations in Great Britain. There were samples found at other locations as well. One other location, Island Thorns, had five samples  $X_1, \dots, X_n$  with an average aluminum oxide percentage of  $\bar{X} = 18.18$  with  $\sum_{i=1}^5 (X_i - \bar{X})^2 = 12.61$ . Let  $Y_1, \dots, Y_5$  be the five sample measurements from Ashley Rails in Example 9.6.3. Test the null hypothesis that the mean aluminum oxide percentages at Ashley Rails and Island Thorns are the same versus the alternative that they are different at level  $\alpha_0 = 0.05$ .

**2.** Suppose that a certain drug  $A$  was administered to eight patients selected at random, and after a fixed time period, the concentration of the drug in certain body cells of each patient was measured in appropriate units. Suppose that these concentrations for the eight patients were found to be as follows:

1.23, 1.42, 1.41, 1.62, 1.55, 1.51, 1.60, and 1.76.

Suppose also that a second drug  $B$  was administered to six different patients selected at random, and when the concentration of drug  $B$  was measured in a similar way for these six patients, the results were as follows:

1.76, 1.41, 1.87, 1.49, 1.67, and 1.81.

Assuming that all the observations have a normal distribution with a common unknown variance, test the following hypotheses at the level of significance 0.10: The null hypothesis is that the mean concentration of drug  $A$  among all patients is at least as large as the mean concentration of drug  $B$ . The alternative hypothesis is that the mean concentration of drug  $B$  is larger than that of drug  $A$ .

**3.** Consider again the conditions of Exercise 2, but suppose now that it is desired to test the following hypotheses: The null hypothesis is that the mean concentration of drug  $A$  among all patients is the same as the mean concentration of drug  $B$ . The alternative hypothesis, which is two-sided, is that the mean concentrations of the two drugs are not the same. Find the number  $c$  so that the level 0.05 two-sided  $t$  test will reject  $H_0$  when  $|U| \geq c$ , where  $U$  is defined by Eq. (9.6.3). Also, perform the test.

**4.** Suppose that  $X_1, \dots, X_m$  form a random sample from the normal distribution with mean  $\mu_1$  and variance  $\sigma_1^2$ , and

$Y_1, \dots, Y_n$  form an independent random sample from the normal distribution with mean  $\mu_2$  and variance  $\sigma_2^2$ . Show that if  $\mu_1 = \mu_2$  and  $\sigma_2^2 = k\sigma_1^2$ , then the random variable  $U$  defined by Eq. (9.6.13) has the  $t$  distribution with  $m + n - 2$  degrees of freedom.

**5.** Consider again the conditions and observed values of Exercise 2. However, suppose now that each observation for drug  $A$  has an unknown variance  $\sigma_1^2$ , and each observation for drug  $B$  has an unknown variance  $\sigma_2^2$ , but it is known that  $\sigma_2^2 = (6/5)\sigma_1^2$ . Test the hypotheses described in Exercise 2 at the level of significance 0.10.

**6.** Suppose that  $X_1, \dots, X_m$  form a random sample from the normal distribution with unknown mean  $\mu_1$  and unknown variance  $\sigma^2$ , and  $Y_1, \dots, Y_n$  form an independent random sample from another normal distribution with unknown mean  $\mu_2$  and the same unknown variance  $\sigma^2$ . For each constant  $\lambda$  ( $-\infty < \lambda < \infty$ ), construct a  $t$  test of the following hypotheses with  $m + n - 2$  degrees of freedom:

$$H_0: \mu_1 - \mu_2 = \lambda,$$

$$H_1: \mu_1 - \mu_2 \neq \lambda.$$

**7.** Consider again the conditions of Exercise 2. Let  $\mu_1$  denote the mean of each observation for drug  $A$ , and let  $\mu_2$  denote the mean of each observation for drug  $B$ . It is assumed, as in Exercise 2, that all the observations have a common unknown variance. Use the results of Exercise 6 to construct a confidence interval for  $\mu_1 - \mu_2$  with confidence coefficient 0.90.

**8.** In Example 9.6.5, determine the power of a level 0.01 test if  $|\mu_1 - \mu_2| = \sigma$ .

**9.** Suppose that we wish to test the hypotheses (9.6.9). We shall use the statistic  $U$  defined in Eq. (9.6.3) and reject  $H_0$  if  $|U|$  is large. Prove that the  $p$ -value when  $U = u$  is observed is  $2[1 - T_{m+n-2}(|u|)]$ .

**10.** Lyle et al. (1987) ran an experiment to study the effect of a calcium supplement on the blood pressure of African American males. A group of 10 men received a calcium supplement, and another group of 11 men received a placebo. The experiment lasted 12 weeks. Both

**Table 9.2** Blood pressure data for Exercise 10

Calcium	7	-4	18	17	-3	-5	1	10	11	-2
Placebo	-1	12	-1	-3	3	-5	5	2	-11	-1

before and after the 12-week period, each man had his systolic blood pressure measured while at rest. The changes (after minus before) are given in Table 9.2. Test the null hypothesis that the mean change in blood pressure for the calcium supplement group is lower than the mean change in blood pressure for the placebo group. Use level  $\alpha_0 = 0.1$ .

**11.** Frisby and Clatworthy (1975) studied the times that it takes subjects to fuse random-dot stereograms. Random-dot stereograms are pairs of images that appear at first to be random dots. After a subject looks at the pair of images from the proper distance and her eyes cross just the right amount, a recognizable object appears from the fusion of the two images. The experimenters were concerned with the extent to which prior information about the recognizable object affected the time it took to fuse the images.

One group of 43 subjects was not shown a picture of the object before being asked to fuse the images. Their average time was  $\bar{X}_{43} = 8.560$  and  $S_x^2 = 2745.7$ . The second group of 35 subjects was shown a picture of the object, and their sample statistics were  $\bar{Y}_{35} = 5.551$  and  $S_y^2 = 783.9$ . The null hypothesis is that the mean time of the

first group is no larger than the mean time of the second group, while the alternative hypothesis is that the first group takes longer.

- a. Test the hypotheses at the level of significance  $\alpha_0 = 0.01$ , assuming that the variances are equal for the two groups.
  - b. Test the hypotheses at the level of significance  $\alpha_0 = 0.01$ , using Welch's approximate test.
- 12.** Find the mean  $a$  and variance  $b$  of the random variable  $W$  in Eq. (9.6.15). Now, let  $a$  and  $b$  be the mean and variance, respectively, of the gamma distribution with parameters  $\alpha$  and  $\beta$ . Prove that  $2\alpha$  equals the expression in (9.6.16).
- 13.** Let  $U$  be as defined in Eq. (9.6.3), and suppose that it is desired to test the hypotheses in Eq. (9.6.9). Prove that each likelihood ratio test has the following form: reject  $H_0$  if  $|U| \geq c$ , where  $c$  is a constant. Hint: First prove that  $\Delta(x, y) = (1 + v^2)^{-(m+n)/2}$ , where  $v$  was defined in Eq. (9.6.12).

## 9.7 The *F* Distributions

*In this section, we introduce the family of *F* distributions. This family is useful in two different hypothesis-testing situations. The first situation is when we wish to test hypotheses about the variances of two different normal distributions. These tests, which we shall derive in this section, are based on a statistic that has an *F* distribution. The second situation will arise in Chapter 11 when we test hypotheses concerning the means of more than two normal distributions.*

### Definition of the *F* Distribution

#### Example 9.7.1

Rain from Seeded Clouds. In Example 9.6.1, we were interested in comparing the distributions of log-rainfalls from seeded and unseeded clouds. In Example 9.6.2, we used the two-sample *t* test to compare the means of these distributions under the assumption that the variances of the two distributions were the same. It would be good to have a procedure for testing whether or not such an assumption is warranted.

In this section, we shall introduce a family of distributions, called the *F* distributions, that arises in many important problems of testing hypotheses in which two or more normal distributions are to be compared on the basis of random samples from

each of the distributions. In particular, it arises naturally when we wish to compare the variances of two normal distributions.

**Definition 9.7.1** The  $F$  distributions. Let  $Y$  and  $W$  be independent random variables such that  $Y$  has the  $\chi^2$  distribution with  $m$  degrees of freedom and  $W$  has the  $\chi^2$  distribution with  $n$  degrees of freedom, where  $m$  and  $n$  are given positive integers. Define a new random variable  $X$  as follows:

$$X = \frac{Y/m}{W/n} = \frac{nY}{mW}. \quad (9.7.1)$$

Then the distribution of  $X$  is called the  $F$  distribution with  $m$  and  $n$  degrees of freedom.

Theorem 9.7.1 gives the general p.d.f. of an  $F$  distribution. Its proof relies on the methods of Sec. 3.9 and will be postponed until the end of this section.

**Theorem 9.7.1** Probability Density Function. Let  $X$  have the  $F$  distribution with  $m$  and  $n$  degrees of freedom. Then its p.d.f.  $f(x)$  is as follows, for  $x > 0$ :

$$f(x) = \frac{\Gamma\left[\frac{1}{2}(m+n)\right] m^{m/2} n^{n/2}}{\Gamma\left(\frac{1}{2}m\right) \Gamma\left(\frac{1}{2}n\right)} \cdot \frac{x^{(m/2)-1}}{(mx+n)^{(m+n)/2}}, \quad (9.7.2)$$

and  $f(x) = 0$  for  $x \leq 0$ .

### Properties of the $F$ Distributions

When we speak of the  $F$  distribution with  $m$  and  $n$  degrees of freedom, the order in which the numbers  $m$  and  $n$  are given is important, as can be seen from the definition of  $X$  in Eq. (9.7.1). When  $m \neq n$ , the  $F$  distribution with  $m$  and  $n$  degrees of freedom and the  $F$  distribution with  $n$  and  $m$  degrees of freedom are two different distributions. Theorem 9.7.2 gives a result relating the two distributions just mentioned along with a relationship between  $F$  distributions and  $t$  distributions.

**Theorem 9.7.2** If  $X$  has the  $F$  distribution with  $m$  and  $n$  degrees of freedom, then its reciprocal  $1/X$  has the  $F$  distribution with  $n$  and  $m$  degrees of freedom. If  $Y$  has the  $t$  distribution with  $n$  degrees of freedom, then  $Y^2$  has the  $F$  distribution with 1 and  $n$  degrees of freedom.

**Proof** The first statement follows from the representation of  $X$  as the ratio of two random variables, in Definition 9.7.1. The second statement follows from the representation of a  $t$  random variable in the form of Eq. (8.4.1). ■

Two short tables of quantiles for  $F$  distributions are given at the end of this book. In these tables, we give only the 0.95 quantile and the 0.975 quantile for different possible pairs of values of  $m$  and  $n$ . In other words, if  $G$  denotes the c.d.f. of the  $F$  distribution with  $m$  and  $n$  degrees of freedom, then the tables give the values of  $x_1$  and  $x_2$  such that  $G(x_1) = 0.95$  and  $G(x_2) = 0.975$ . By applying Theorem 9.7.2, it is possible to use the tables to obtain the 0.05 and 0.025 quantiles of an  $F$  distribution. Most statistical software will compute the c.d.f. and quantiles for general  $F$  distributions.

**Example 9.7.2** Determining the 0.05 Quantile of an  $F$  Distribution. Suppose that a random variable  $X$  has the  $F$  distribution with 6 and 12 degrees of freedom. We shall determine the 0.05 quantile of  $X$ , that is, the value of  $x$  such that  $\Pr(X < x) = 0.05$ .

If we let  $Y = 1/X$ , then  $Y$  will have the  $F$  distribution with 12 and 6 degrees of freedom. It can be found from the table given at the end of this book that  $\Pr(Y \leq 4.00) = 0.95$ ; hence,  $\Pr(Y > 4.00) = 0.05$ . Since  $Y > 4.00$  if and only if  $X < 0.25$ , it follows that  $\Pr(X < 0.25) = 0.05$ . Because  $F$  distributions are continuous,  $\Pr(X \leq 0.25) = 0.05$ , and 0.25 is the 0.05 quantile of  $X$ .  $\blacktriangleleft$

## Comparing the Variances of Two Normal Distributions

Suppose that the random variables  $X_1, \dots, X_m$  form a random sample of  $m$  observations from a normal distribution for which both the mean  $\mu_1$  and the variance  $\sigma_1^2$  are unknown, and suppose also that the random variables  $Y_1, \dots, Y_n$  form an independent random sample of  $n$  observations from another normal distribution for which both the mean  $\mu_2$  and the variance  $\sigma_2^2$  are unknown. Suppose finally that the following hypotheses are to be tested at a specified level of significance  $\alpha_0$  ( $0 < \alpha_0 < 1$ ):

$$\begin{aligned} H_0: \quad & \sigma_1^2 \leq \sigma_2^2, \\ H_1: \quad & \sigma_1^2 > \sigma_2^2. \end{aligned} \tag{9.7.3}$$

For each test procedure  $\delta$ , we shall let  $\pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2 | \delta)$  denote the power function of  $\delta$ . Later in this section, we shall derive the likelihood ratio test. For now, define  $S_X^2$  and  $S_Y^2$  to be the sums of squares defined in Eq. (9.6.2). Then  $S_X^2/(m - 1)$  and  $S_Y^2/(n - 1)$  are estimators of  $\sigma_1^2$  and  $\sigma_2^2$ , respectively. It makes intuitive sense that we should reject  $H_0$  if the ratio of these two estimators is large. That is, define

$$V = \frac{S_X^2/(m - 1)}{S_Y^2/(n - 1)}, \tag{9.7.4}$$

and reject  $H_0$  if  $V \geq c$ , where  $c$  is chosen to make the test have a desired level of significance.

**Definition 9.7.2**  $F$  test. The test procedure defined above is called an  $F$  test.

## Properties of $F$ Tests

**Theorem 9.7.3** Distribution of  $V$ . Let  $V$  be the statistic in Eq. (9.7.4). The distribution of  $(\sigma_2^2/\sigma_1^2)V$  is the  $F$  distribution with  $m - 1$  and  $n - 1$  degrees of freedom. In particular, if  $\sigma_1^2 = \sigma_2^2$ , then the distribution of  $V$  itself is the  $F$  distribution with  $m - 1$  and  $n - 1$  degrees of freedom.

**Proof** We know from Theorem 8.3.1 that the random variable  $S_X^2/\sigma_1^2$  has the  $\chi^2$  distribution with  $m - 1$  degrees of freedom, and the random variable  $S_Y^2/\sigma_2^2$  has the  $\chi^2$  distribution with  $n - 1$  degrees of freedom. Furthermore, these two random variables are independent, since they are calculated from two independent samples. Therefore, the following random variable  $V^*$  has the  $F$  distribution with  $m - 1$  and  $n - 1$  degrees of freedom:

$$V^* = \frac{S_X^2/[(m - 1)\sigma_1^2]}{S_Y^2/[(n - 1)\sigma_2^2]}. \tag{9.7.5}$$

It can be seen from Eqs. (9.7.4) and (9.7.5) that  $V^* = (\sigma_2^2/\sigma_1^2)V$ . This proves the first claim in the theorem. If  $\sigma_1^2 = \sigma_2^2$ , then  $V = V^*$ , which proves the second claim.  $\blacksquare$

If  $\sigma_1^2 = \sigma_2^2$ , it is possible to use a table of the  $F$  distribution to choose a constant  $c$  such that  $\Pr(V \geq c) = \alpha_0$ , regardless of the common value of  $\sigma_1^2$  and  $\sigma_2^2$ , and regardless of the values of  $\mu_1$  and  $\mu_2$ . In fact,  $c$  will be the  $1 - \alpha_0$  quantile of the corresponding  $F$  distribution. We prove next that the test that rejects  $H_0$  in (9.7.3) if  $V \geq c$  has level  $\alpha_0$ .

**Theorem  
9.7.4**

**Level, Power Function, and  $P$ -Values.** Let  $V$  be the statistic defined in Eq. (9.7.4). Let  $c$  be the  $1 - \alpha_0$  quantile of the  $F$  distribution with  $m - 1$  and  $n - 1$  degrees of freedom, and let  $G_{m-1,n-1}$  be the c.d.f. of that  $F$  distribution. Let  $\delta$  be test that rejects  $H_0$  in (9.7.3) when  $V \geq c$ . The power function  $\pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2 | \delta)$  satisfies the following properties:

- i.  $\pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2 | \delta) = 1 - G_{m-1,n-1}\left(\frac{\sigma_2^2}{\sigma_1^2}c\right)$ ,
- ii.  $\pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2 | \delta) = \alpha_0$  when  $\sigma_1^2 = \sigma_2^2$ ,
- iii.  $\pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2 | \delta) < \alpha_0$  when  $\sigma_1^2 < \sigma_2^2$ ,
- iv.  $\pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2 | \delta) > \alpha_0$  when  $\sigma_1^2 > \sigma_2^2$ ,
- v.  $\pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2 | \delta) \rightarrow 0$  as  $\sigma_1^2/\sigma_2^2 \rightarrow 0$ ,
- vi.  $\pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2 | \delta) \rightarrow 1$  as  $\sigma_1^2/\sigma_2^2 \rightarrow \infty$ .

The test  $\delta$  has level  $\alpha_0$  and is unbiased. The  $p$ -value when  $V = v$  is observed equals  $1 - G_{m-1,n-1}(v)$ .

**Proof** The power function is the probability of rejecting  $H_0$ , i.e., the probability that  $V \geq c$ . Let  $V^*$  be as defined in Eq. (9.7.5) so that  $V^*$  has the  $F$  distribution with  $m - 1$  and  $n - 1$  degrees of freedom. Then

$$\begin{aligned}\pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2 | \delta) &= \Pr(V \geq c) = \Pr\left(\frac{\sigma_1^2}{\sigma_2^2}V^* \geq c\right) = \Pr\left(V^* \geq \frac{\sigma_2^2}{\sigma_1^2}c\right) \\ &= 1 - G_{m-1,n-1}\left(\frac{\sigma_2^2}{\sigma_1^2}c\right),\end{aligned}\tag{9.7.6}$$

which proves property (i). Property (ii) follows from Theorem 9.7.3. For property (iii), let  $\sigma_1^2 < \sigma_2^2$  in Eq. (9.7.6). Since  $(\sigma_2^2/\sigma_1^2)c > c$ , the expression on the far right of (9.7.6) is less than  $1 - G_{m-1,n-1}(c) = \alpha_0$ . Similarly, if  $\sigma_1^2 > \sigma_2^2$ , the expression on the far right of (9.7.6) is greater than  $1 - G_{m-1,n-1}(c) = \alpha_0$ , proving property (iv). Properties (v) and (vi) follow from property (i) and elementary properties of c.d.f.'s, namely, Property 3.3.2. The fact that  $\delta$  has level  $\alpha_0$  follows from properties (ii) and (iii). The fact that  $\delta$  is unbiased follows from properties (ii) and (iv). Finally, the  $p$ -value is the smallest  $\alpha_0$  such that we would reject  $H_0$  at level  $\alpha_0$  if  $V = v$  were observed. We reject  $H_0$  at level  $\alpha_0$  if and only if  $v \geq G_{m-1,n-1}^{-1}(1 - \alpha_0)$ , which is equivalent to  $\alpha_0 \geq 1 - G_{m-1,n-1}(v)$ . Hence,  $1 - G_{m-1,n-1}(v)$  is the smallest  $\alpha_0$  such that we would reject  $H_0$ . ■

**Example  
9.7.3**

**Performing an  $F$  Test.** Suppose that six observations  $X_1, \dots, X_6$  are selected at random from a normal distribution for which both the mean  $\mu_1$  and the variance  $\sigma_1^2$  are unknown, and it is found that  $S_X^2 = 30$ . Suppose also that 21 observations,  $Y_1, \dots, Y_{21}$ , are selected at random from another normal distribution for which both the mean  $\mu_2$  and the variance  $\sigma_2^2$  are unknown, and that it is found that  $S_Y^2 = 40$ . We shall carry out an  $F$  test of the hypotheses (9.7.3).

In this example,  $m = 6$  and  $n = 21$ . Therefore, when  $H_0$  is true, the statistic  $V$  defined by Eq. (9.7.4) will have the  $F$  distribution with 5 and 20 degrees of freedom. It follows from Eq. (9.7.4) that the value of  $V$  for the given samples is

$$V = \frac{30/5}{40/20} = 3.$$

It is found from the tables given at the end of this book that the 0.95 quantile of the  $F$  distribution with 5 and 20 degrees of freedom is 2.71, and the 0.975 quantile of that distribution is 3.29. Hence, the tail area corresponding to the value  $V = 3$  is less than 0.05 and greater than 0.025. The hypothesis  $H_0$  that  $\sigma_1^2 \leq \sigma_2^2$  would therefore be rejected at the level of significance  $\alpha_0 = 0.05$ , and  $H_0$  would not be rejected at the level of significance  $\alpha_0 = 0.025$ . (Using a computer program to evaluate the c.d.f. of an  $F$  distribution provides the  $p$ -value equal to 0.035.) Finally, suppose that it is important to reject  $H_0$  if  $\sigma_1^2$  is three times as large as  $\sigma_2^2$ . We would then want the power function to be high when  $\sigma_1^2 = 3\sigma_2^2$ . We use a computer program to compute

$$1 - F_{5,20} \left( 2.71 \times \frac{1}{3} \right) = 0.498.$$

Even if  $\sigma_1^2$  is three times as large as  $\sigma_2^2$ , the level 0.05 test only has about a 50 percent chance of rejecting  $H_0$ .  $\blacktriangleleft$

## Two-Sided Alternative

Suppose that we wish to test the hypotheses

$$\begin{aligned} H_0: \quad & \sigma_1^2 = \sigma_2^2, \\ H_1: \quad & \sigma_1^2 \neq \sigma_2^2. \end{aligned} \tag{9.7.7}$$

It would make sense to reject  $H_0$  if either  $V \leq c_1$  or  $V \geq c_2$ , where  $V$  is defined in Eq. (9.7.4) and  $c_1$  and  $c_2$  are constants such that  $\Pr(V \leq c_1) + \Pr(V \geq c_2) = \alpha_0$  when  $\sigma_1^2 = \sigma_2^2$ . The most convenient choice of  $c_1$  and  $c_2$  is the one that makes  $\Pr(V \leq c_1) = \Pr(V \geq c_2) = \alpha_0/2$ . That is, choose  $c_1$  and  $c_2$  to be the  $\alpha_0/2$  and  $1 - \alpha_0/2$  quantiles of the appropriate  $F$  distribution.

---

### Example 9.7.4

**Rain from Seeded Clouds.** In Example 9.6.2, we compared the means of log-rainfalls from seeded and unseeded clouds under the assumption that the two variances were the same. We can now test the null hypothesis that the two variances are the same against the alternative hypothesis that the two variances are different at level of significance  $\alpha_0 = 0.05$ . Using the statistics given in Example 9.6.2, the value of  $V$  is  $63.96/67.39 = 0.9491$ , since  $m = n$ . We need to compare this to the 0.025 and 0.975 quantiles of the  $F$  distribution with 25 and 25 degrees of freedom. Since our table of  $F$  distribution quantiles does not have rows or columns for 25 degrees of freedom, we can either interpolate between 20 and 30 degrees of freedom or use a computer program to compute these quantiles. The quantiles are 0.4484 and 2.2303. Since  $V$  is between these two numbers, we would not reject the null hypothesis at level  $\alpha_0 = 0.05$ .  $\blacktriangleleft$

When  $m \neq n$ , the two-sided  $F$  test constructed above is not unbiased. (See Exercise 19.) Also, if  $m \neq n$ , it is not possible to write the two-sided  $F$  test described above in the form “reject the null hypothesis if  $T \geq c$ ” using the same statistic  $T$  for each significance level  $\alpha_0$ . Nevertheless, we can still compute the smallest  $\alpha_0$  such

that the two-sided  $F$  test with level of significance  $\alpha_0$  would reject  $H_0$ . The proof of the following result is left to Exercise 15 in this section.

**Theorem  
9.7.5**

**P-Value of Equal-Tailed Two-Sided  $F$  Test.** Let  $V$  be as defined in (9.7.4). Suppose that we wish to test the hypotheses (9.7.7). Let  $\delta_{\alpha_0}$  be the equal-tailed two-sided  $F$  test that rejects  $H_0$  when  $V \leq c_1$  or  $V \geq c_2$ , where  $c_1$  and  $c_2$  are, respectively, the  $\alpha_0/2$  and  $1 - \alpha_0/2$  quantiles of the appropriate  $F$  distribution. Then the smallest  $\alpha_0$  such that  $\delta_{\alpha_0}$  rejects  $H_0$  when  $V = v$  is observed is

$$2 \min\{1 - G_{m-1, n-1}(v), G_{m-1, n-1}(v)\}. \quad (9.7.8)$$

## ◆ The F Test as a Likelihood Ratio Test

Next, we shall show that the  $F$  test for hypotheses (9.7.3) is a likelihood ratio test. After the values  $x_1, \dots, x_m$  and  $y_1, \dots, y_n$  in the two samples have been observed, the likelihood function  $g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma_1^2, \sigma_2^2)$  is

$$g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma_1^2, \sigma_2^2) = f_m(\mathbf{x} | \mu_1, \sigma_1^2) f_n(\mathbf{y} | \mu_2, \sigma_2^2).$$

Here, both  $f_m(\mathbf{x} | \mu_1, \sigma_1^2)$  and  $f_n(\mathbf{y} | \mu_2, \sigma_2^2)$  have the general form given in Eq. (9.5.9). For the hypotheses in (9.7.3),  $\Omega_0$  contains all parameters  $\theta = (\mu_1, \mu_2, \sigma_1^2, \sigma_2^2)$  with  $\sigma_1^2 \leq \sigma_2^2$ , and  $\Omega_1$  contains all  $\theta$  with  $\sigma_1^2 > \sigma_2^2$ . The likelihood ratio statistic is

$$\Lambda(\mathbf{x}, \mathbf{y}) = \frac{\sup_{\{(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2) : \sigma_1^2 \leq \sigma_2^2\}} g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma_1^2, \sigma_2^2)}{\sup_{(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2)} g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma_1^2, \sigma_2^2)}. \quad (9.7.9)$$

The likelihood ratio test then specifies that  $H_0$  should be rejected if  $\Lambda(\mathbf{x}, \mathbf{y}) \leq k$ , where  $k$  is typically chosen to make the test have a desired level  $\alpha_0$ .

To facilitate the maximizations in (9.7.9), let

$$s_x^2 = \sum_{i=1}^m (x_i - \bar{x}_m)^2, \text{ and } s_y^2 = \sum_{i=1}^n (y_i - \bar{y}_n)^2.$$

Then we can write

$$\begin{aligned} g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma_1^2, \sigma_2^2) \\ = \frac{1}{(2\pi)^{(m+n)/2} \sigma_1^m \sigma_2^n} \exp\left(-\frac{1}{2\sigma_1^2} \left[n(\bar{x}_m - \mu_1)^2 + s_x^2\right] - \frac{1}{2\sigma_2^2} \left[n(\bar{y}_n - \mu_2)^2 + s_y^2\right]\right). \end{aligned}$$

For both the numerator and denominator of (9.7.9), we need  $\mu_1 = \bar{x}_m$  and  $\mu_2 = \bar{y}_n$  in order to maximize the likelihood. If  $s_x^2/m \leq s_y^2/n$ , then the numerator is maximized at  $\sigma_1^2 = s_x^2/m$  and  $\sigma_2^2 = s_y^2/n$ . These values also maximize the denominator. Hence,  $\Lambda(\mathbf{x}, \mathbf{y}) = 1$  if  $s_x^2/m \leq s_y^2/n$ . For the other case (the numerator when  $s_x^2/m > s_y^2/n$ ), it is straightforward to show that  $\sigma_1^2 = \sigma_2^2$  is required in order to achieve the maximum. In these cases, the maximum occurs when

$$\sigma_1^2 = \sigma_2^2 = \frac{s_x^2 + s_y^2}{m + n}.$$

Substituting all of these values into (9.7.9) yields

$$\Lambda(\mathbf{x}, \mathbf{y}) = \begin{cases} 1 & \text{if } s_x^2/m \leq s_y^2/n, \\ dw^{m/2}(1-w)^{n/2} & \text{if } s_x^2/m > s_y^2/n, \end{cases}$$

where

$$w = \frac{s_x^2}{s_x^2 + s_y^2}, \quad \text{and} \quad d = \frac{(m+n)^{(m+n)/2}}{m^{m/2} n^{n/2}}.$$

Note that  $s_x^2/m \leq s_y^2/n$  if and only if  $w \leq m/(m+n)$ . Next, use the fact that the function  $h(w) = w^{m/2}(1-w)^{n/2}$  is decreasing for  $m/(m+n) < w < 1$ . Finally, note that  $h(m/[m+n]) = 1/d$ . For  $k < 1$ , it follows that  $\Lambda(\mathbf{x}, \mathbf{y}) \leq k$  if and only if  $w \geq k'$  for some other constant  $k'$ . This, in turn, is equivalent to  $s_x^2/s_y^2 \geq k''$ . Since  $s_x^2/s_y^2$  is a positive constant times the observed value of  $V$ , the likelihood ratio test rejects  $H_0$  when  $V$  is large. This is the same as the  $F$  test.

One can easily adapt the above argument for the case in which the inequalities are reversed in the hypotheses. When the hypotheses are (9.7.7), that is, the alternative is two-sided, one can show (see Exercise 16) that the size  $\alpha_0$  likelihood ratio test will reject  $H_0$  if either  $V \leq c_1$  or  $V \geq c_2$ . Unfortunately, it is usually tedious to compute the necessary values  $c_1$  and  $c_2$ . For this reason, people often abandon the strict likelihood ratio criterion in this case and simply let  $c_1$  and  $c_2$  be the  $\alpha_0/2$  and  $1 - \alpha_0/2$  quantiles of the appropriate  $F$  distribution.

## ◆ Derivation of the p.d.f. of an $F$ distribution

Since the random variables  $Y$  and  $W$  in Definition 9.7.1 are independent, their joint p.d.f.  $g(y, w)$  is the product of their individual p.d.f.'s. Furthermore, since both  $Y$  and  $W$  have  $\chi^2$  distributions, it follows from the p.d.f. of the  $\chi^2$  distribution, as given in Eq. 8.2.1, that  $g(y, w)$  has the following form, for  $y > 0$  and  $w > 0$ :

$$g(y, w) = cy^{(m/2)-1}w^{(n/2)-1}e^{-(y+w)/2}, \quad (9.7.10)$$

where

$$c = \frac{1}{2^{(m+n)/2}\Gamma\left(\frac{1}{2}m\right)\Gamma\left(\frac{1}{2}n\right)}. \quad (9.7.11)$$

We shall now change variables from  $Y$  and  $W$  to  $X$  and  $W$ , where  $X$  is defined by Eq. (9.7.1). The joint p.d.f.  $h(x, w)$  of  $X$  and  $W$  is obtained by first replacing  $y$  in Eq. (9.7.10) with its expression in terms of  $x$  and  $w$  and then multiplying the result by  $|\partial y/\partial x|$ . It follows from Eq. (9.7.1) that  $y = (m/n)xw$  and  $\partial y/\partial x = (m/n)w$ . Hence, the joint p.d.f.  $h(x, w)$  has the following form, for  $x > 0$  and  $w > 0$ :

$$h(x, w) = c \left(\frac{m}{n}\right)^{m/2} x^{(m/2)-1} w^{[(m+n)/2]-1} \exp\left[-\frac{1}{2}\left(\frac{m}{n}x + 1\right)w\right]. \quad (9.7.12)$$

Here, the constant  $c$  is again given by Eq. (9.7.11).

The marginal p.d.f.  $f(x)$  of  $X$  can be obtained for each value of  $x > 0$  from the relation

$$f(x) = \int_0^\infty h(x, w) dw. \quad (9.7.13)$$

It follows from Theorem 5.7.3 that

$$\int_0^\infty w^{[(m+n)/2]-1} \exp\left[-\frac{1}{2}\left(\frac{m}{n}x + 1\right)w\right] dw = \frac{\Gamma\left[\frac{1}{2}(m+n)\right]}{\left[\frac{1}{2}\left(\frac{m}{n}x + 1\right)\right]^{(m+n)/2}}. \quad (9.7.14)$$

From Eqs. (9.7.11) to (9.7.14), we can conclude that the p.d.f  $f(x)$  has the form given in Eq. (9.7.2). 

## Summary

If  $Y$  and  $W$  are independent with  $Y$  having the  $\chi^2$  distribution with  $m$  degrees of freedom and  $W$  having the  $\chi^2$  distribution with  $n$  degrees of freedom, then  $(Y/m)/(W/n)$  has the  $F$  distribution with  $m$  and  $n$  degrees of freedom. Suppose that we observe two independent random samples from two normal distributions with possibly different variances. The ratio  $V$  of the usual unbiased estimators of the two variances will have an  $F$  distribution when the two variances are equal. Tests of hypotheses about the two variances can be constructed by comparing  $V$  to various quantiles of  $F$  distributions.

## Exercises

1. Consider again the situation described in Exercise 11 of Sec. 9.6. Test the null hypothesis that the variance of the fusion time for subjects who saw a picture of the object is no smaller than the variance for subjects who did see a picture. The alternative hypothesis is that the variance for subjects who saw a picture is smaller than the variance for subjects who did not see a picture. Use a level of significance of 0.05.
2. Suppose that a random variable  $X$  has the  $F$  distribution with three and eight degrees of freedom. Determine the value of  $c$  such that  $\Pr(X > c) = 0.975$ .
3. Suppose that a random variable  $X$  has the  $F$  distribution with one and eight degrees of freedom. Use the table of the  $t$  distribution to determine the value of  $c$  such that  $\Pr(X > c) = 0.3$ .
4. Suppose that a random variable  $X$  has the  $F$  distribution with  $m$  and  $n$  degrees of freedom ( $n > 2$ ). Show that  $E(X) = n/(n - 2)$ . Hint: Find the value of  $E(1/Z)$ , where  $Z$  has the  $\chi^2$  distribution with  $n$  degrees of freedom.
5. What is the value of the median of the  $F$  distribution with  $m$  and  $n$  degrees of freedom when  $m = n$ ?
6. Suppose that a random variable  $X$  has the  $F$  distribution with  $m$  and  $n$  degrees of freedom. Show that the random variable  $mX/(mX + n)$  has the beta distribution with parameters  $\alpha = m/2$  and  $\beta = n/2$ .
7. Consider two different normal distributions for which both the means  $\mu_1$  and  $\mu_2$  and the variances  $\sigma_1^2$  and  $\sigma_2^2$  are unknown, and suppose that it is desired to test the following hypotheses:

$$\begin{aligned} H_0: \quad & \sigma_1^2 \leq \sigma_2^2, \\ H_1: \quad & \sigma_1^2 > \sigma_2^2. \end{aligned}$$

Suppose further that a random sample consisting of 16 observations for the first normal distribution yields the values  $\sum_{i=1}^{16} X_i = 84$  and  $\sum_{i=1}^{16} X_i^2 = 563$ , and an independent random sample consisting of 10 observations from the second normal distribution yields the values  $\sum_{i=1}^{10} Y_i = 18$  and  $\sum_{i=1}^{10} Y_i^2 = 72$ .

- a. What are the M.L.E.'s of  $\sigma_1^2$  and  $\sigma_2^2$ ?
- b. If an  $F$  test is carried out at the level of significance 0.05, is the hypothesis  $H_0$  rejected or not?
8. Consider again the conditions of Exercise 7, but suppose now that it is desired to test the following hypotheses:

$$\begin{aligned} H_0: \quad & \sigma_1^2 \leq 3\sigma_2^2, \\ H_1: \quad & \sigma_1^2 > 3\sigma_2^2. \end{aligned}$$

Describe how to carry out an  $F$  test of these hypotheses.

9. Consider again the conditions of Exercise 7, but suppose now that it is desired to test the following hypotheses:

$$\begin{aligned} H_0: \quad & \sigma_1^2 = \sigma_2^2, \\ H_1: \quad & \sigma_1^2 \neq \sigma_2^2. \end{aligned}$$

Suppose also that the statistic  $V$  is defined by Eq. (9.7.4), and it is desired to reject  $H_0$  if either  $V \leq c_1$  or  $V \geq c_2$ , where the constants  $c_1$  and  $c_2$  are chosen so that when  $H_0$  is true,  $\Pr(V \leq c_1) = \Pr(V \geq c_2) = 0.025$ . Determine the values of  $c_1$  and  $c_2$  when  $m = 16$  and  $n = 10$ , as in Exercise 7.

10. Suppose that a random sample consisting of 16 observations is available from the normal distribution for which both the mean  $\mu_1$  and the variance  $\sigma_1^2$  are unknown, and an independent random sample consisting of 10 observations is available from the normal distribution for which both the mean  $\mu_2$  and the variance  $\sigma_2^2$  are also unknown.

For each constant  $r > 0$ , construct a test of the following hypotheses at the level of significance 0.05:

$$H_0: \frac{\sigma_1^2}{\sigma_2^2} = r, \quad H_1: \frac{\sigma_1^2}{\sigma_2^2} \neq r.$$

**11.** Consider again the conditions of Exercise 10. Use the results of that exercise to construct a confidence interval for  $\sigma_1^2/\sigma_2^2$  with confidence coefficient 0.95.

**12.** Suppose that a random variable  $Y$  has the  $\chi^2$  distribution with  $m_0$  degrees of freedom, and let  $c$  be a constant such that  $\Pr(Y > c) = 0.05$ . Explain why, in the table of 0.95 quantile of the  $F$  distribution, the entry for  $m = m_0$  and  $n = \infty$  will be equal to  $c/m_0$ .

**13.** The final column in the table of the 0.95 quantile of the  $F$  distribution contains values for which  $m = \infty$ . Explain how to derive the entries in this column from a table of the  $\chi^2$  distribution.

**14.** Consider again the conditions of Exercise 7. Find the power function of the  $F$  test when  $\sigma_1^2 = 2\sigma_2^2$ .

**15.** Prove Theorem 9.7.5. Also, compute the  $p$ -value for Example 9.7.4 using the formula in Eq. (9.7.8).

**16.** Let  $V$  be as defined in Eq. (9.7.4). We wish to determine the size  $\alpha_0$  likelihood ratio test of the hypotheses (9.7.7). Prove that the likelihood ratio test will reject  $H_0$  if

either  $V \leq c_1$  or  $V \geq c_2$ , where  $\Pr(V \leq c_1) + \Pr(V \geq c_2) = \alpha_0$  when  $\sigma_1^2 = \sigma_2^2$ .

**17.** Prove that the test found in Exercise 9 is *not* a likelihood ratio test.

**18.** Let  $\delta$  be the two-sided  $F$  test that rejects  $H_0$  in (9.7.3) when either  $V \leq c_1$  or  $V \geq c_2$  with  $c_1 < c_2$ . Prove that the power function of  $\delta$  is

$$\begin{aligned} \pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2 | \delta) \\ = G_{m-1, n-1} \left( \frac{\sigma_2^2}{\sigma_1^2} c_1 \right) + 1 - G_{m-1, n-1} \left( \frac{\sigma_2^2}{\sigma_1^2} c_2 \right). \end{aligned}$$

**19.** Suppose that  $X_1, \dots, X_{11}$  form a random sample from the normal distribution with unknown mean  $\mu_1$  and unknown variance  $\sigma_1^2$ . Suppose also that  $Y_1, \dots, Y_{21}$  form an independent random sample from the normal distribution with unknown mean  $\mu_2$  and unknown variance  $\sigma_2^2$ . Suppose that we wish to test the hypotheses in Eq. (9.7.7). Let  $\delta$  be the equal-tailed two-sided  $F$  test with level of significance  $\alpha_0 = 0.5$ .

- a. Compute the power function of  $\delta$  when  $\sigma_1^2 = 1.01\sigma_2^2$ .
- b. Compute the power function of  $\delta$  when  $\sigma_1^2 = \sigma_2^2/1.01$ .
- c. Show that  $\delta$  is not an unbiased test. (You will probably need computer software that computes the function  $G_{m-1, n-1}$ . And try to minimize the amount of rounding you do.)

## ★ 9.8 Bayes Test Procedures

*Here we summarize how one tests hypotheses from the Bayesian perspective. The general idea is to choose the action (reject  $H_0$  or not) that leads to the smaller posterior expected loss. We assume that the loss of making an incorrect decision is larger than the loss of making a correct decision. Many of the Bayes test procedures have the same forms as the tests we have already seen, but their interpretations are different.*

### Simple Null and Alternative Hypotheses

#### Example 9.8.1

**Service Times in a Queue.** In Example 9.2.1, a manager was trying to decide which of two joint distributions better describes customer service times. She was comparing the two joint p.d.f.'s  $f_1$  and  $f_0$  in Eqs. (9.2.1) and (9.2.2), respectively. Suppose that there are costs involved in making a bad choice. For example, if she chooses a joint distribution that models the service times as shorter than they really tend to be, there may be a cost due to customers becoming frustrated and taking their business elsewhere. On the other hand, if she chooses a joint distribution that models the service times as longer than they really tend to be, there may be a cost due to hiring additional unnecessary servers. How should the manager weigh these costs together with available evidence about how long she believes service times tend to be in order to choose between the two joint distributions? ◀

Consider a general problem in which the parameter space consists of two values  $\Omega = \{\theta_0, \theta_1\}$ . If  $\theta = \theta_i$  (for  $i = 0, 1$ ), let  $X_1, \dots, X_n$  form a random sample from a distribution for which the p.d.f. or the p.f. is  $f_i(\mathbf{x})$ . Suppose that it is desired to test the following simple hypotheses:

$$\begin{aligned} H_0: \quad & \theta = \theta_0, \\ H_1: \quad & \theta = \theta_1. \end{aligned} \quad (9.8.1)$$

We shall let  $d_0$  denote the decision not to reject the hypothesis  $H_0$  and let  $d_1$  denote the decision to reject  $H_0$ . Also, we shall assume that the losses resulting from choosing an incorrect decision are as follows: If decision  $d_1$  is chosen when  $H_0$  is actually the true hypothesis (type I error), then the loss is  $w_0$  units; if decision  $d_0$  is chosen when  $H_1$  is actually the true hypothesis (type II error), then the loss is  $w_1$  units. If the decision  $d_0$  is chosen when  $H_0$  is the true hypothesis or if the decision  $d_1$  is chosen when  $H_1$  is the true hypothesis, then the correct decision has been made and the loss is 0. Thus, for  $i = 0, 1$  and  $j = 0, 1$ , the loss  $L(\theta_i, d_j)$  that occurs when  $\theta_i$  is the true value of  $\theta$  and the decision  $d_j$  is chosen is given by the following table:

	$d_0$	$d_1$	
$\theta_0$	0	$w_0$	
$\theta_1$	$w_1$	0	

(9.8.2)

Next, suppose that the prior probability that  $H_0$  is true is  $\xi_0$ , and the prior probability that  $H_1$  is true is  $\xi_1 = 1 - \xi_0$ . Then the expected loss  $r(\delta)$  of each test procedure  $\delta$  will be

$$r(\delta) = \xi_0 E(\text{Loss} | \theta = \theta_0) + \xi_1 E(\text{Loss} | \theta = \theta_1). \quad (9.8.3)$$

If  $\alpha(\delta)$  and  $\beta(\delta)$  again denote the probabilities of the two types of errors for the procedure  $\delta$ , and if the table of losses just given is used, it follows that

$$\begin{aligned} E(\text{Loss} | \theta = \theta_0) &= w_0 \Pr(\text{Choosing } d_1 | \theta = \theta_0) = w_0 \alpha(\delta), \\ E(\text{Loss} | \theta = \theta_1) &= w_1 \Pr(\text{Choosing } d_0 | \theta = \theta_1) = w_1 \beta(\delta). \end{aligned} \quad (9.8.4)$$

Hence,

$$r(\delta) = \xi_0 w_0 \alpha(\delta) + \xi_1 w_1 \beta(\delta). \quad (9.8.5)$$

A procedure  $\delta$  for which this expected loss  $r(\delta)$  is minimized is called a *Bayes test procedure*.

Since  $r(\delta)$  is simply a linear combination of the form  $a\alpha(\delta) + b\beta(\delta)$  with  $a = \xi_0 w_0$  and  $b = \xi_1 w_1$ , a Bayes test procedure can immediately be determined from Theorem 9.2.1. Thus, a Bayes procedure will not reject  $H_0$  whenever  $\xi_0 w_0 f_0(\mathbf{x}) > \xi_1 w_1 f_1(\mathbf{x})$  and will reject  $H_0$  whenever  $\xi_0 w_0 f_0(\mathbf{x}) < \xi_1 w_1 f_1(\mathbf{x})$ . We can either reject  $H_0$  or not if  $\xi_0 w_0 f_0(\mathbf{x}) = \xi_1 w_1 f_1(\mathbf{x})$ . For simplicity, in the remainder of this section, we shall assume that  $H_0$  is rejected whenever  $\xi_0 w_0 f_0(\mathbf{x}) = \xi_1 w_1 f_1(\mathbf{x})$ .

**Note: Bayes Test Depends Only on the Ratio of Costs.** Notice that choosing  $\delta$  to minimize  $r(\delta)$  in Eq. (9.8.5) is not affected if we multiply  $w_0$  and  $w_1$  by the same positive constant, such as  $1/w_0$ . That is, the Bayes test  $\delta$  is also the test that minimizes

$$r^*(\delta) = \xi_0 \alpha(\delta) + \xi_1 \frac{w_1}{w_0} \beta(\delta).$$

So, a decision maker does not need to choose both of the two costs of error, but rather just the ratio of the two costs. One can think of choosing the ratio of costs as a replacement for specifying a level of significance when selecting a test procedure.

**Example  
9.8.2**

**Service Times in a Queue.** Suppose that the manager believes that each of the two models for service times is equally likely before observing any data so that  $\xi_0 = \xi_1 = 1/2$ . The model with joint p.d.f.  $f_1$  predicts both extremely large service times and extremely small service times to be more likely than does the model with joint p.d.f.  $f_0$ . Suppose that the cost of modeling extremely large service times as being less likely than they really are is the same as the cost of modeling extremely large service times to be more likely than they really are. The ratio of the cost of type II error  $w_1$  to the cost of type I error  $w_0$  is then  $w_1/w_0 = 1$ . The Bayes test is then to choose  $d_1$  (reject  $H_0$ ) if  $f_0(\mathbf{x}) < f_1(\mathbf{x})$ . This is equivalent to  $f_1(\mathbf{x})/f_0(\mathbf{x}) > 1$ .  $\blacktriangleleft$

### Tests Based on the Posterior Distribution

From the Bayesian viewpoint, it is more natural to base a test on the posterior distribution of  $\theta$  rather than on the prior distribution and the probabilities of error as we did in the preceding discussion. Fortunately, the same test procedure arises regardless of how one derives it. For example, Exercise 5 in this section asks you to prove that the test derived by minimizing a linear combination of error probabilities is the same as what one would obtain by minimizing the posterior expected value of the loss. The same is true in general when the losses are bounded, but the proof is more difficult. For the remainder of this section, we shall take the more natural approach of trying to minimize the posterior expected value of the loss directly.

Return again to the general situation in which the null hypothesis is  $H_0 : \theta \in \Omega_0$  and the alternative hypothesis is  $H_1 : \theta \in \Omega_1$ , where  $\Omega_0 \cup \Omega_1$  is the entire parameter space. As we did above, we shall let  $d_0$  denote the decision not to reject the null hypothesis  $H_0$  and let  $d_1$  denote the decision to reject  $H_0$ . As before, we shall assume that we incur a loss of  $w_0$  by making decision  $d_1$  when  $H_0$  is actually true, and a loss of  $w_1$  is incurred if we make decision  $d_0$  when  $H_1$  is true. (More realistic loss functions are available, but this simple type of loss will suffice for an introduction.) The loss function  $L(\theta, d_i)$  can be summarized in the following table:

	$d_0$	$d_1$	
If $H_0$ is true	0	$w_0$	
If $H_1$ is true	$w_1$	0	

(9.8.6)

We shall now take the approach outlined in Exercise 5. Suppose that  $\xi(\theta|\mathbf{x})$  is the posterior p.d.f. for  $\theta$ . Then the posterior expected loss  $r(d_i|\mathbf{x})$  for choosing decision  $d_i$  ( $i = 0, 1$ ) is

$$r(d_i|\mathbf{x}) = \int L(\theta, d_i) \xi(\theta|\mathbf{x}) d\theta.$$

We can write a simpler formula for this posterior expected loss for each of  $i = 0, 1$ :

$$\begin{aligned} r(d_0|\mathbf{x}) &= \int_{\Omega_1} w_1 \xi(\theta|\mathbf{x}) d\theta = w_1 [1 - \Pr(H_0 \text{ true}|\mathbf{x})], \\ r(d_1|\mathbf{x}) &= \int_{\Omega_0} w_0 \xi(\theta|\mathbf{x}) d\theta = w_0 \Pr(H_0 \text{ true}|\mathbf{x}). \end{aligned}$$

The Bayes test procedure is to choose the decision that has the smaller posterior expected loss, that is, choose  $d_0$  if  $r(d_0|\mathbf{x}) < r(d_1|\mathbf{x})$ , choose  $d_1$  if  $r(d_0|\mathbf{x}) \geq r(d_1|\mathbf{x})$ . Using the expressions above, it is easy to see that the inequality  $r(d_0|\mathbf{x}) \geq r(d_1|\mathbf{x})$

(when to reject  $H_0$ ) can be rewritten as

$$\Pr(H_0 \text{ true} | \mathbf{x}) \leq \frac{w_1}{w_0 + w_1}, \quad (9.8.7)$$

just as in part (c) of Exercise 5.

The test procedure that rejects  $H_0$  when (9.8.7) holds is the Bayes test in all situations in which the loss function is given by the table in (9.8.6). This result holds whether or not the distributions have monotone likelihood ratio, and it even applies when the alternative is two-sided or when the parameter is discrete rather than continuous. Furthermore, the Bayes test produces the same result if one were to switch the names of  $H_0$  and  $H_1$ , as well as the losses  $w_0$  and  $w_1$  and the names of the decisions  $d_0$  and  $d_1$ . (See Exercise 11 in this section.)

Despite the generality of (9.8.7), it is instructive to examine what the procedure looks like in special cases that we have already encountered.

## One-Sided Hypotheses

Suppose that the family of distributions has a monotone likelihood ratio and that the hypotheses are

$$\begin{aligned} H_0: \quad & \theta \leq \theta_0, \\ H_1: \quad & \theta > \theta_0. \end{aligned} \quad (9.8.8)$$

We shall prove next that the Bayes procedure that rejects  $H_0$  when (9.8.7) holds is a one-sided test as in Theorem 9.3.1.

**Theorem 9.8.1** Suppose that  $f_n(\mathbf{x}|\theta)$  has a monotone likelihood ratio in the statistic  $T = r(\mathbf{X})$ . Let the hypotheses be as in Eq. (9.8.8), and assume that the loss function is of the form

	$d_0$	$d_1$
$\theta \leq \theta_0$	0	$w_0$
$\theta > \theta_0$	$w_1$	0

where  $w_0, w_1 > 0$  are constants. Then a test procedure that minimizes the posterior expected loss is to reject  $H_0$  when  $T \geq c$  for some constant  $c$  (possibly infinite).

**Proof** According to Bayes' theorem for parameters and samples, (7.2.7), the posterior p.d.f.  $\xi(\theta|\mathbf{x})$  can be expressed as

$$\xi(\theta|\mathbf{x}) = \frac{f_n(\mathbf{x}|\theta)\xi(\theta)}{\int_{\Omega} f_n(\mathbf{x}|\psi)\xi(\psi) d\psi}.$$

The ratio of the posterior expected loss from making decision  $d_0$  to the posterior expected loss from making decision  $d_1$  after observing  $\mathbf{X} = \mathbf{x}$  is

$$\ell(\mathbf{x}) = \frac{\int_{\theta_0}^{\infty} w_1 \xi(\theta|\mathbf{x}) d\theta}{\int_{-\infty}^{\theta_0} w_0 \xi(\psi|\mathbf{x}) d\psi} = \frac{w_1 \int_{\theta_0}^{\infty} f_n(\mathbf{x}|\theta)\xi(\theta) d\theta}{w_0 \int_{-\infty}^{\theta_0} f_n(\mathbf{x}|\psi)\xi(\psi) d\psi}. \quad (9.8.9)$$

What we need to prove is that  $\ell(\mathbf{x}) \geq 1$  is equivalent to  $T \geq c$ . It suffices to show that  $\ell(\mathbf{x})$  is a nondecreasing function in  $T = r(\mathbf{x})$ . Let  $\mathbf{x}_1$  and  $\mathbf{x}_2$  be two possible observations with the property that  $r(\mathbf{x}_1) \leq r(\mathbf{x}_2)$ . We want to prove that  $\ell(\mathbf{x}_1) \leq \ell(\mathbf{x}_2)$ .

We can write

$$\ell(\mathbf{x}_1) - \ell(\mathbf{x}_2) = \frac{w_1 \int_{\theta_0}^{\infty} f_n(\mathbf{x}_1|\theta) \xi(\theta) d\theta}{w_0 \int_{-\infty}^{\theta_0} f_n(\mathbf{x}_1|\psi) \xi(\psi) d\psi} - \frac{w_1 \int_{\theta_0}^{\infty} f_n(\mathbf{x}_2|\theta) \xi(\theta) d\theta}{w_0 \int_{-\infty}^{\theta_0} f_n(\mathbf{x}_2|\psi) \xi(\psi) d\psi}. \quad (9.8.10)$$

We can put the two fractions on the right side of Eq. (9.8.10) over the common denominator  $w_0^2 \int_{-\infty}^{\theta_0} f_n(\mathbf{x}_2|\psi) \xi(\psi) d\psi \int_{-\infty}^{\theta_0} f_n(\mathbf{x}_1|\psi) \xi(\psi) d\psi$ . The numerator of the resulting fraction is  $w_0 w_1$  times

$$\begin{aligned} & \int_{\theta_0}^{\infty} f_n(\mathbf{x}_1|\theta) \xi(\theta) d\theta \int_{-\infty}^{\theta_0} f_n(\mathbf{x}_2|\psi) \xi(\psi) d\psi \\ & - \int_{\theta_0}^{\infty} f_n(\mathbf{x}_2|\theta) \xi(\theta) d\theta \int_{-\infty}^{\theta_0} f_n(\mathbf{x}_1|\psi) \xi(\psi) d\psi. \end{aligned} \quad (9.8.11)$$

We only need to show that (9.8.11) is at most 0. The difference in (9.8.11) can be written as the double integral

$$\int_{\theta_0}^{\infty} \int_{-\infty}^{\theta_0} \xi(\theta) \xi(\psi) [f_n(\mathbf{x}_1|\theta) f_n(\mathbf{x}_2|\psi) - f_n(\mathbf{x}_2|\theta) f_n(\mathbf{x}_1|\psi)] d\psi d\theta. \quad (9.8.12)$$

Notice that for all  $\theta$  and  $\psi$  in this double integral,  $\theta \geq \theta_0 \geq \psi$ . Since  $r(\mathbf{x}_1) \leq r(\mathbf{x}_2)$ , monotone likelihood ratio implies that

$$\frac{f_n(\mathbf{x}_1|\theta)}{f_n(\mathbf{x}_1|\psi)} - \frac{f_n(\mathbf{x}_2|\theta)}{f_n(\mathbf{x}_2|\psi)} \leq 0.$$

If one multiplies both sides of this last expression by the product of the two denominators, the result is

$$f_n(\mathbf{x}_1|\theta) f_n(\mathbf{x}_2|\psi) - f_n(\mathbf{x}_2|\theta) f_n(\mathbf{x}_1|\psi) \leq 0. \quad (9.8.13)$$

Notice that the left side of Eq. (9.8.13) appears inside the square brackets in the integrand of (9.8.12). Since this is nonpositive, it implies that (9.8.12) is at most 0, and so (9.8.11) is at most 0. ■

### Example 9.8.3

**Calorie Counts on Food Labels.** In Example 7.3.10 on page 400, we were interested in the percentage differences between the observed and advertised calorie counts for nationally prepared foods. We modeled the differences  $X_1, \dots, X_{20}$  as normal random variables with mean  $\theta$  and variance 100. The prior for  $\theta$  was a normal distribution with mean 0 and variance 60. The family of normal distributions has a monotone likelihood ratio in the statistic  $\bar{X}_{20} = \frac{1}{20} \sum_{i=1}^{20} X_i$ . The posterior distribution of  $\theta$  is the normal distribution with mean

$$\mu_1 = \frac{100 \times 0 + 20 \times 60 \times \bar{X}_{20}}{100 + 20 \times 60} = 0.923 \bar{X}_{20}$$

and variance  $v_1^2 = 4.62$ . Suppose that we wish to test the null hypothesis  $H_0: \theta \leq 0$  versus the alternative  $H_1: \theta > 0$ . The posterior probability that  $H_0$  is true is

$$\Pr(\theta \leq 0 | \bar{X}_{20}) = \Phi\left(\frac{0 - \mu_1}{v_1}\right) = \Phi(-0.429 \bar{X}_{20}).$$

The Bayes test will reject  $H_0$  if this probability is at most  $w_1/(w_0 + w_1)$ . Since  $\Phi$  is a strictly increasing function,  $\Phi(-0.429 \bar{X}_{20}) \leq w_1/(w_0 + w_1)$  if and only if  $\bar{X}_{20} \geq -\Phi^{-1}(w_1/(w_0 + w_1))/0.492$ . This is in the form of a one-sided test. ■

## Two-Sided Alternatives

On page 571, we argued that the hypotheses

$$\begin{aligned} H_0: \quad & \theta = \theta_0, \\ H_1: \quad & \theta \neq \theta_0 \end{aligned} \tag{9.8.14}$$

might be a useful surrogate for the null hypothesis that  $\theta$  is close to  $\theta_0$  against the alternative that it is not close. If the prior distribution of  $\theta$  is continuous, then the posterior distribution will usually be continuous as well. In such cases, the posterior probability that  $H_0$  is true will be 0, and  $H_0$  would be rejected without having to refer to the data. If one believed that  $\theta = \theta_0$  with positive probability, one should use a prior distribution that is not continuous, but we shall not take that approach here. (See a more advanced text, such as Schervish, 1995, section 4.2, for treatment of that approach.) Instead, we can calculate the posterior probability that  $\theta$  is close to  $\theta_0$ . If this probability is too small, we can reject the null hypothesis that  $\theta$  is close to  $\theta_0$ . To be specific, let  $d > 0$ , and consider the hypotheses

$$\begin{aligned} H_0: \quad & |\theta - \theta_0| \leq d, \\ H_1: \quad & |\theta - \theta_0| > d. \end{aligned} \tag{9.8.15}$$

Many experimenters might choose to test the hypotheses in (9.8.14) rather than those in (9.8.15) because they are not ready to specify a particular value of  $d$ . In such cases, one could calculate the posterior probability of  $|\theta - \theta_0| \leq d$  for all  $d$  and draw a little plot.

### Example 9.8.4

**Calorie Counts on Food Labels.** Suppose that we wish to test the hypotheses (9.8.15) with  $\theta_0 = 0$  in the situation described in Example 9.8.3. In Example 7.3.10, we found that the posterior distribution of  $\theta$  was the normal distribution with mean 0.1154 and variance 4.62. We can easily calculate

$$\Pr(|\theta - 0| \leq d | \mathbf{x}) = \Pr(-d \leq \theta \leq d | \mathbf{x}) = \Phi\left(\frac{d - 0.1154}{4.62^{1/2}}\right) - \Phi\left(\frac{-d - 0.1154}{4.62^{1/2}}\right),$$

for every value of  $d$  that we want. Figure 9.16 shows a plot of the posterior probability that  $|\theta|$  is at most  $d$  for all values of  $d$  between 0 and 5. In particular, we see that  $\Pr(|\theta| \leq 5 | \mathbf{x})$  is very close to 1. If 5 percent is considered a small discrepancy, then we can be pretty sure that  $|\theta|$  is small. On the other hand,  $\Pr(|\theta| \geq 1 | \mathbf{x})$  is greater than 0.6. If 1 percent is considered large, then there is a substantial chance that  $|\theta|$  is large. ◀

**Figure 9.16** Plot of  $\Pr(|\theta| \leq d | \mathbf{x})$  against  $d$  for Example 9.8.4. The dotted lines indicate that the median of the posterior distribution of  $|\theta|$  is 1.455.

**Note: What Counts as a Meaningful Difference?** The method illustrated in Example 9.8.4 raises a useful point. In order to complete the test procedure, we need to decide what counts as a meaningful difference between  $\theta$  and  $\theta_0$ . Otherwise, we cannot say whether or not the probability is large that a meaningful difference exists. Forcing experimenters to think about what counts as a meaningful difference is a good idea. Testing the hypotheses (9.8.14) at a fixed level, such as 0.05, does not require anyone to think about what counts as a meaningful difference. Indeed, if an experimenter did bother to decide what counted as a meaningful difference, it is not clear how to make use of that information in choosing a significance level at which to test the hypotheses in (9.8.14).

### Testing the Mean of a Normal Distribution with Unknown Variance

In Sec. 8.6, we considered the case in which a random sample is drawn from a normal distribution with unknown mean and variance. We introduced a family of conjugate prior distributions and found that the posterior distribution of a linear function of the mean  $\mu$  is a  $t$  distribution. If we wish to test the null hypothesis that  $\mu$  lies in an interval using (9.8.7) as the condition for rejecting the null hypothesis, then we only need a table or computer program to calculate the c.d.f. of an arbitrary  $t$  distribution. Most statistical software packages allow calculation of the c.d.f. and the quantile function of an arbitrary  $t$  distribution, and hence we can perform Bayes tests of null hypotheses of the form  $\mu \leq \mu_0$ ,  $\mu \geq \mu_0$ , or  $d_1 \leq \mu \leq d_2$ .

**Example  
9.8.5**

**Pesticide Residue on Celery.** Sharpe and Van Middelem (1955) describe an experiment in which  $n = 77$  samples of parathion residue were measured on celery after the vegetable had been taken from fields sprayed with parathion. Figure 9.17 shows a histogram of the observations. (Each concentration  $Z$  in parts per million was transformed to  $X = 100(Z - 0.7)$  for ease of recording.) Suppose that we model the  $X$  values as normal with mean  $\mu$  and variance  $\sigma^2$ . We will use an improper prior for  $\mu$  and  $\sigma^2$ . The sample average is  $\bar{x}_n = 50.23$ , and

$$s_n^2 = \sum_{i=1}^{77} (x_i - \bar{x}_{77})^2 = 34106.$$

As we saw in Eq. (8.6.21), this means that the posterior distribution of

$$\frac{n^{1/2}(\mu - \bar{x}_n)}{(s_n^2/(n-1))^{1/2}} = \frac{77^{1/2}(\mu - 50.23)}{(34106/76)^{1/2}} = 0.4142\mu - 20.81$$

**Figure 9.17** Histogram of parathion measurements on 77 celery samples.

is the  $t$  distribution with 76 degrees of freedom. Suppose that we are interested in testing the null hypothesis  $H_0 : \mu \geq 55$  against the alternative  $H_1 : \mu < 55$ . Suppose that our losses are described by (9.8.6). Then we should reject  $H_0$  if its posterior probability is at most  $\alpha_0 = w_1/(w_0 + w_1)$ . If we let  $T_{n-1}$  stand for the c.d.f. of the  $t$  distribution with  $n - 1$  degrees of freedom, we can write this probability as

$$\begin{aligned}\Pr(\mu \geq 55 | \mathbf{x}) &= \Pr\left(\frac{n^{1/2}(\mu - \bar{x}_n)}{(s_n^2/(n-1))^{1/2}} \geq \frac{n^{1/2}(55 - \bar{x}_n)}{(s_n^2/(n-1))^{1/2}} \mid \mathbf{x}\right) \\ &= 1 - T_{n-1}\left(\frac{n^{1/2}(55 - \bar{x}_n)}{(s_n^2/(n-1))^{1/2}}\right).\end{aligned}\quad (9.8.16)$$

Simple manipulation shows that this last probability is at most  $\alpha_0$  if and only if  $U \leq -T_{n-1}^{-1}(1 - \alpha_0)$ , where  $U$  is the random variable in Eq. (9.5.2) that was used to define the  $t$  test. Indeed, the level  $\alpha_0$   $t$  test of  $H_0$  versus  $H_1$  is precisely to reject  $H_0$  if  $U \leq -T_{n-1}^{-1}(1 - \alpha_0)$ . For the data in this example, the probability in Eq. (9.8.16) is  $1 - T_{76}(1.974) = 0.026$ .  $\blacktriangleleft$

**Note: Look at Your Data.** The histogram in Fig. 9.17 has a strange feature. Can you specify what it is? If you take a course in data analysis, you will probably learn some methods for dealing with data having features like this.

**Note: Bayes Tests for One-Sided Nulls with Improper Priors Are  $t$  Tests.** In Example 9.8.5, we saw that the Bayes test for one-sided hypotheses was the level  $\alpha_0$   $t$  test for the same hypotheses where  $\alpha_0 = w_1/(w_0 + w_1)$ . This holds in general for normal data with improper priors. It also follows that the  $p$ -values in these cases must be the same as the posterior probabilities that the null hypotheses are true. (See Exercise 7 in this section.)

## Comparing the Means of Two Normal Distributions

Next, consider the case in which we shall observe two independent normal random samples with common variance  $\sigma^2$ :  $X_1, \dots, X_m$  with mean  $\mu_1$  and  $Y_1, \dots, Y_n$  with mean  $\mu_2$ . In order to use the Bayesian approach, we need the posterior distribution of  $\mu_1 - \mu_2$ . We could introduce a family of conjugate prior distributions for the three parameters  $\mu_1, \mu_2$ , and  $\tau = 1/\sigma^2$ , and then proceed as we did in Sec. 8.6. For simplicity, we shall only handle the case of improper priors in this section, although there are proper conjugate priors that will lead to more general results. The usual improper prior for each parameter  $\mu_1$  and  $\mu_2$  is the constant function 1, and the usual improper prior for  $\tau$  is  $1/\tau$  for  $\tau > 0$ . If we combine these as if the parameters were independent, the improper prior p.d.f. would be  $\xi(\mu_1, \mu_2, \tau) = 1/\tau$  for  $\tau > 0$ . We can now find the posterior joint distribution of the parameters.

**Theorem  
9.8.2**

Suppose that  $X_1, \dots, X_m$  form a random sample from a normal distribution with mean  $\mu_1$  and precision  $\tau$  while  $Y_1, \dots, Y_n$  form a random sample from a normal distribution with mean  $\mu_2$  and precision  $\tau$ . Suppose that the parameters have the improper prior with “p.d.f.”  $\xi(\mu_1, \mu_2, \tau) = 1/\tau$  for  $\tau > 0$ . The posterior distribution of

$$(m+n-2)^{1/2} \frac{\mu_1 - \mu_2 - (\bar{x}_m - \bar{y}_n)}{\left(\frac{1}{m} + \frac{1}{n}\right)^{1/2} (s_x^2 + s_y^2)^{1/2}} \quad (9.8.17)$$

is the  $t$  distribution with  $m + n - 2$  degrees of freedom, where  $s_x^2$  and  $s_y^2$  are the observed values of  $S_X^2$  and  $S_Y^2$ , respectively. ■

The proof of Theorem 9.8.2 is left as Exercise 8 because it is very similar to results proven in Sec. 8.6.

For testing the hypotheses

$$H_0: \mu_1 - \mu_2 \leq 0,$$

$$H_1: \mu_1 - \mu_2 > 0,$$

we need the posterior probability that  $\mu_1 - \mu_2 \leq 0$ , which is easily obtained from the posterior distribution. Using the same idea as in Eq. (9.8.16), we can write  $\Pr(\mu_1 - \mu_2 \leq 0 | \mathbf{x}, \mathbf{y})$  as the probability that the random variable in (9.8.17) is at most  $-u$ , where  $u$  is the observed value of the random variable  $U$  in Eq. (9.6.3). It follows that

$$\Pr(\mu_1 - \mu_2 \leq 0 | \mathbf{x}, \mathbf{y}) = T_{m+n-2}(-u),$$

where  $T_{m+n-2}$  is the c.d.f. of the  $t$  distribution with  $m + n - 2$  degrees of freedom. Hence, the posterior probability that  $H_0$  is true is less than  $w_1/(w_0 + w_1)$  if and only if

$$T_{m+n-2}(-u) < \frac{w_1}{w_0 + w_1}.$$

This, in turn is true if and only if

$$-u < T_{m+n-2}^{-1}\left(\frac{w_1}{w_0 + w_1}\right).$$

This is true if and only if

$$u > T_{m+n-2}^{-1}\left(1 - \frac{w_1}{w_0 + w_1}\right). \quad (9.8.18)$$

If  $\alpha_0 = w_1/(w_0 + w_1)$ , then the Bayes test procedure that rejects  $H_0$  when Eq. (9.8.18) occurs is the same as the level  $\alpha_0$  two-sample  $t$  test derived in Sec. 9.6. Put another way, the one-sided level  $\alpha_0$  two-sample  $t$  test rejects the null hypothesis  $H_0$  if and only if the posterior probability that  $H_0$  is true (based on the improper prior) is at most  $\alpha_0$ . It follows from Exercise 7 that the posterior probability of the null hypothesis being true must equal the  $p$ -value in this case. ◀

---

**Example  
9.8.6**

**Roman Pottery in Britain.** In Example 9.6.3, we observed 14 samples of Roman pottery from Llanederyn in Great Britain and another five samples from Ashley Rails, and we were interested in whether the mean aluminum oxide percentage in Llanederyn  $\mu_1$  was larger than that in Ashley Rails  $\mu_2$ . We tested  $H_0: \mu_1 \geq \mu_2$  against  $H_1: \mu_1 < \mu_2$  and found that the  $p$ -value was  $4 \times 10^{-6}$ . If we had used an improper prior for the parameters, then  $\Pr(\mu_1 \geq \mu_2 | \mathbf{x}) = 4 \times 10^{-6}$ . ◀

**Two-Sided Alternatives with Unknown Variance** To test the hypothesis that the mean  $\mu$  of a normal distribution is close to  $\mu_0$ , we could specify a specific value  $d$  and test

$$H_0: |\mu - \mu_0| \leq d,$$

$$H_1: |\mu - \mu_0| > d.$$

If we do not feel comfortable selecting a single value of  $d$  to represent “close,” we could compute  $\Pr(|\mu - \mu_0| \leq d | \mathbf{x})$  for all  $d$  and draw a plot as we did in Example 9.8.4.

**Figure 9.18** Plot of  $\Pr(|\mu_1 - \mu_2| \leq d|\mathbf{x})$  against  $d$ . The dotted lines indicate that the median of the posterior distribution of  $|\mu_1 - \mu_2|$  is 4.76.

The case of testing that two means are close together can be dealt with in the same way.

**Example  
9.8.7**

**Roman Pottery in Britain.** In Example 9.8.6, we tested one-sided hypotheses about the difference in aluminum oxide contents in samples of pottery from two sites in Great Britain. Unless we are specifically looking for a difference in a particular direction, it might make more sense to test hypotheses of the form

$$\begin{aligned} H_0: \quad & |\mu_1 - \mu_2| \leq d, \\ H_1: \quad & |\mu_1 - \mu_2| > d, \end{aligned} \tag{9.8.19}$$

where  $d$  is some critical difference that is worth detecting. As we did in Example 9.8.4, we can draw a plot that allows us to test all hypotheses of the form (9.8.19) simultaneously. We just plot  $\Pr(|\mu_1 - \mu_2| \leq d|\mathbf{x})$  against  $d$ . The posterior distribution of  $\mu_1 - \mu_2$  was found in Eq. (9.8.17), using the improper prior. In this case, the following random variable has the  $t$  distribution with 17 degrees of freedom:

$$\begin{aligned} & (m + n - 2)^{1/2} \frac{\mu_1 - \mu_2 - (\bar{x}_m - \bar{y}_n)}{\left(\frac{1}{m} + \frac{1}{n}\right)^{1/2} (s_x^2 + s_y^2)^{1/2}} \\ &= 17^{1/2} \frac{\mu_1 - \mu_2 - (12.56 - 17.32)}{\left(\frac{1}{14} + \frac{1}{5}\right)^{1/2} (24.65 + 11.01)^{1/2}} = 1.33(\mu_1 - \mu_2 + 4.76), \end{aligned}$$

where the data summaries come from Example 9.6.3. It follows that

$$\begin{aligned} & \Pr(|\mu_1 - \mu_2| \leq d|\mathbf{x}) \\ &= \Pr(1.33(-d + 4.76) \leq 1.33(\mu_1 - \mu_2 + 4.76) \leq 1.33(d + 4.76)|\mathbf{x}) \\ &= T_{17}(1.33(d + 4.76)) - T_{17}(1.33(-d + 4.76)), \end{aligned}$$

where  $T_{17}$  is the c.d.f. of the  $t$  distribution with 17 degrees of freedom. Figure 9.18 is the plot of this posterior probability against  $d$ .  $\blacktriangleleft$

### Comparing the Variances of Two Normal Distributions

In order to test hypotheses concerning the variances of two normal distributions, we can make use of the posterior distribution of the ratio of the two variances. Suppose that  $X_1, \dots, X_m$  is a random sample from the normal distribution with mean  $\mu_1$  and variance  $\sigma_1^2$ , and  $Y_1, \dots, Y_n$  is a random sample from the normal distribution with mean  $\mu_2$  and variance  $\sigma_2^2$ . If we model the  $X$  data and associated parameters

as independent of the  $Y$  data and associated parameters, then we can perform two separate analyses just like the one in Sec. 8.6. In particular, we let  $\tau_i = 1/\sigma_i^2$  for  $i = 1, 2$ , and the joint posterior distribution will have  $(\mu_1, \tau_1)$  independent of  $(\mu_2, \tau_2)$  and each pair will have a normal-gamma distribution just as in Sec. 8.6. For convenience, we shall only do the remaining calculations using improper priors. With improper priors, the posterior distribution of  $\tau_1$  is the gamma distribution with parameters  $(m - 1)/2$  and  $s_x^2/2$ , where  $s_x^2$  is defined in Theorem 9.8.2. We also showed in Sec. 8.6 (using Exercise 1 in Sec. 5.7) that  $\tau_1 s_x^2$  has the  $\chi^2$  distribution with  $m - 1$  degrees of freedom. Similarly,  $\tau_2 s_y^2$  has the  $\chi^2$  distribution with  $n - 1$  degrees of freedom. Since  $\tau_1 s_x^2/(m - 1)$  and  $\tau_2 s_y^2/(n - 1)$  are independent, their ratio has the  $F$  distribution with  $m - 1$  and  $n - 1$  degrees of freedom. That is, the posterior distribution of

$$\frac{\tau_1 s_x^2/(m - 1)}{\tau_2 s_y^2/(n - 1)} = \frac{s_x^2/[(m - 1)\sigma_1^2]}{s_y^2/[(n - 1)\sigma_2^2]} \quad (9.8.20)$$

is the  $F$  distribution with  $m - 1$  and  $n - 1$  degrees of freedom. Notice that the expression on the right side of Eq. (9.8.20) is the same as the random variable  $V^*$  in Eq. (9.7.5). This is another case in which the sampling distribution of a random variable is the same as its posterior distribution. It will then follow that level  $\alpha_0$  tests of one-sided hypotheses about  $\sigma_1^2/\sigma_2^2$  based on the sampling distribution of  $V^*$  will be the same as Bayes tests of the form (9.8.7) so long as  $\alpha_0 = w_1/(w_0 + w_1)$ . The reader can prove this in Exercise 9.

## Summary

From a Bayesian perspective, one chooses a test procedure by minimizing the posterior expected loss. When the loss has the simple form of (9.8.6), then the Bayes test procedure is to reject  $H_0$  when its posterior probability is at most  $w_1/(w_0 + w_1)$ . In many one-sided cases, with improper priors, this procedure turns out to be the same as the most commonly used level  $\alpha_0 = w_1/(w_0 + w_1)$  test. In two-sided cases, as an alternative to testing  $H_0 : \theta = \theta_0$  against  $H_1 : \theta \neq \theta_0$ , one can draw a plot of  $\Pr(|\theta - \theta_0| \leq d | \mathbf{x})$  against  $d$ . One then needs to decide which values of  $d$  count as meaningful differences.

---

## Exercises

- 1.** Suppose that a certain industrial process can be either in control or out of control, and that at any specified time the prior probability that it will be in control is 0.9, and the prior probability that it will be out of control is 0.1. A single observation  $X$  of the output of the process is to be taken, and it must be decided immediately whether the process is in control or out of control. If the process is in control, then  $X$  will have the normal distribution with mean 50 and variance 1. If the process is out of control, then  $X$  will have the normal distribution with mean 52 and variance 1.

If it is decided that the process is out of control when in fact it is in control, then the loss from unnecessarily stopping the process will be \$1000. If it is decided that the process is in control when in fact it is out of control, then

the loss from continuing the process will be \$18,000. If a correct decision is made, then the loss will be 0. It is desired to find a test procedure for which the expected loss will be a minimum. For what values of  $X$  should it be decided that the process is out of control?

- 2.** A single observation  $X$  is to be taken from a continuous distribution for which the p.d.f. is either  $f_0$  or  $f_1$ , where

$$f_0(x) = \begin{cases} 1 & \text{for } 0 < x < 1, \\ 0 & \text{otherwise,} \end{cases}$$

and

$$f_1(x) = \begin{cases} 4x^3 & \text{for } 0 < x < 1, \\ 0 & \text{otherwise.} \end{cases}$$

On the basis of the observation  $X$ , it must be decided whether  $f_0$  or  $f_1$  is the correct p.d.f. Suppose that the prior probability that  $f_0$  is correct is  $2/3$  and the prior probability that  $f_1$  is correct is  $1/3$ . Suppose also that the loss from choosing the correct decision is  $0$ , the loss from deciding that  $f_1$  is correct when in fact  $f_0$  is correct is  $1$  unit, and the loss from deciding that  $f_0$  is correct when in fact  $f_1$  is correct is  $4$  units. If the expected loss is to be minimized, for what values of  $X$  should it be decided that  $f_0$  is correct?

**3.** Suppose that a failure in a certain electronic system can occur because of either a minor or a major defect. Suppose also that 80 percent of the failures are caused by minor defects, and 20 percent of the failures are caused by major defects. When a failure occurs,  $n$  independent soundings  $X_1, \dots, X_n$  are made on the system. If the failure was caused by a minor defect, these soundings form a random sample from the Poisson distribution with mean 3. If the failure was caused by a major defect, these soundings form a random sample from a Poisson distribution for which the mean is 7. The cost of deciding that the failure was caused by a major defect when it was actually caused by a minor defect is \$400. The cost of deciding that the failure was caused by a minor defect when it was actually caused by a major defect is \$2500. The cost of choosing a correct decision is  $0$ . For a given set of observed values of  $X_1, \dots, X_n$ , which decision minimizes the expected cost?

**4.** Suppose that the proportion  $p$  of defective items in a large manufactured lot is unknown, and it is desired to test the following simple hypotheses:

$$\begin{aligned} H_0: \quad p &= 0.3, \\ H_1: \quad p &= 0.4. \end{aligned}$$

Suppose that the prior probability that  $p = 0.3$  is  $1/4$ , and the prior probability that  $p = 0.4$  is  $3/4$ ; also suppose that the loss from choosing an incorrect decision is  $1$  unit, and the loss from choosing a correct decision is  $0$ . Suppose that a random sample of  $n$  items is selected from the lot. Show that the Bayes test procedure is to reject  $H_0$  if and only if the proportion of defective items in the sample is greater than

$$\frac{\log\left(\frac{7}{6}\right) + \frac{1}{n}\log\left(\frac{1}{3}\right)}{\log\left(\frac{14}{9}\right)}.$$

**5.** Suppose that we wish to test the hypotheses (9.8.1). Let the loss function have the form of (9.8.2).

- a. Prove that the posterior probability of  $\theta = \theta_0$  is  $\xi_0 f_0(\mathbf{x}) / [\xi_0 f_0(\mathbf{x}) + \xi_1 f_1(\mathbf{x})]$ .
- b. Prove that a test that minimizes  $r(\delta)$  also minimizes the posterior expected value of the loss given  $\mathbf{X} = \mathbf{x}$  for all  $\mathbf{x}$ .
- c. Prove that the following test is one of the tests described in part (b): “reject  $H_0$  if  $\Pr(H_0 \text{ true} | \mathbf{x}) \leq w_1 / (w_0 + w_1)$ .”

**6.** Prove that the conclusion of Theorem 9.8.1 still holds when the loss function is given by

	$d_0$	$d_1$
$\theta \leq \theta_0$	$0$	$w_0(\theta)$
$\theta > \theta_0$	$w_1(\theta)$	$0$

for arbitrary positive functions  $w_0(\theta)$  and  $w_1(\theta)$ . Hint: Replicate the proof of Theorem 9.8.1, but replace the constants  $w_0$  and  $w_1$  by the functions above and keep them inside of the integrals instead of factoring them out.

**7.** Suppose that we have a situation in which the Bayes test that rejects  $H_0$  when  $\Pr(H_0 \text{ true} | \mathbf{x}) \leq \alpha_0$  is the same as the level  $\alpha_0$  test of  $H_0$  for all  $\alpha_0$ . (Example 9.8.5 has this property, but so do many other situations.) Prove that the  $p$ -value equals the posterior probability that  $H_0$  is true.

**8.** In this exercise you will prove Theorem 9.8.2.

- a. Prove that the joint p.d.f. of the data given the parameters  $\mu_1$ ,  $\mu_2$ , and  $\tau$  can be written as a constant times

$$\begin{aligned} \tau^{(m+n)/2} \exp\left(-0.5m\tau(\mu_1 - \bar{x}_m)^2\right. \\ \left.- 0.5n\tau(\mu_2 - \bar{y}_n)^2 - 0.5(s_x^2 + s_y^2)\tau\right). \end{aligned}$$

- b. Multiply the prior p.d.f. times the p.d.f. in part (a). Bayes' theorem for random variables says that the result is proportional (as a function of the parameters) to the posterior p.d.f.

- i. Show that the posterior p.d.f., as a function of  $\mu_1$  for fixed  $\mu_2$  and  $\tau$ , is the p.d.f. of the normal distribution with mean  $\bar{x}_m$  and variance  $(m\tau)^{-1}$ .
- ii. Show that the posterior p.d.f., as a function of  $\mu_2$  for fixed  $\mu_1$  and  $\tau$ , is the p.d.f. of the normal distribution with mean  $\bar{y}_n$  and variance  $(n\tau)^{-1}$ .
- iii. Show that, conditional on  $\tau$ ,  $\mu_1$  and  $\mu_2$  are independent with the two normal distributions found above.
- iv. Show that the marginal posterior distribution of  $\tau$  is the gamma distribution with parameters  $(m+n-2)/2$  and  $(s_x^2 + s_y^2)/2$ .

- c. Show that the conditional distribution of

$$Z = \tau^{1/2} \frac{\mu_1 - \mu_2 - (\bar{x}_m - \bar{y}_n)}{\left(\frac{1}{m} + \frac{1}{n}\right)^{1/2}}$$

given  $\tau$  is a standard normal distribution and hence  $Z$  is independent of  $\tau$ .

- d.** Show that the distribution of  $W = (s_x^2 + s_y^2)\tau$  is the gamma distribution with parameters  $(m+n-2)/2$  and  $1/2$ , which is the same as the  $\chi^2$  distribution with  $m+n-2$  degrees of freedom.
- e.** Prove that  $Z/(W/(m+n-2))^{1/2}$  has the  $t$  distribution with  $m+n-2$  degrees of freedom and that it equals the expression in Eq. (9.8.17).

- 9.** Suppose that  $X_1, \dots, X_m$  form a random sample from the normal distribution with mean  $\mu_1$  and variance  $\sigma_1^2$ , and  $Y_1, \dots, Y_n$  form a random sample from the normal distribution with mean  $\mu_2$  and variance  $\sigma_2^2$ . Suppose that we use the usual improper prior and that we wish to test the hypotheses

$$\begin{aligned} H_0: \quad & \sigma_1^2 \leq \sigma_2^2, \\ H_1: \quad & \sigma_1^2 > \sigma_2^2. \end{aligned}$$

- a.** Prove that the level  $\alpha_0$   $F$  test is the same as the test in (9.8.7) when  $\alpha_0 = w_1/(w_0 + w_1)$ .
- b.** Prove that the  $p$ -value for the  $F$  test is the posterior probability that  $H_0$  is true.
- 10.** Consider again the situation in Example 9.6.2. Let  $\mu_1$  be the mean of log-rainfall from seeded clouds, and let  $\mu_2$  be the mean of log-rainfall from unseeded clouds. Use the improper prior for the parameters.
- a.** Find the posterior distribution of  $\mu_1 - \mu_2$ .
- b.** Draw a graph of the posterior probability that  $|\mu_1 - \mu_2| \leq d$  as a function of  $d$ .

- 11.** Let  $\theta$  be a general parameter taking values in a parameter space  $\Omega$ . Let  $\Omega' \cup \Omega'' = \Omega$  be a partition of  $\Omega$  into two disjoint sets  $\Omega'$  and  $\Omega''$ . We want to choose between two decisions:  $d'$  says that  $\theta \in \Omega'$ , and  $d''$  says that  $\theta \in \Omega''$ . We have the following loss function:

	$d'$	$d''$
If $\theta \in \Omega'$	0	$w'$
If $\theta \in \Omega''$	$w''$	0

We have two choices for expressing this decision problem as a hypothesis-testing problem. One choice would be to define  $H_0 : \theta \in \Omega'$  and  $H_1 : \theta \in \Omega''$ . The other choice would be to define  $H_0 : \theta \in \Omega''$  and  $H_1 : \theta \in \Omega'$ . In this problem, we show that the Bayes test makes the same decision regardless of which hypothesis we call the null and which we call the alternative.

- a.** For each choice, say how we would define each of the following in order to make this problem fit the hypothesis-testing framework described in this section:  $w_0, w_1, d_0, d_1, \Omega_0$ , and  $\Omega_1$ .
- b.** Now suppose that we can observe data  $\mathbf{X} = \mathbf{x}$  and compute the posterior distribution of  $\theta, \xi(\theta|\mathbf{x})$ . Show that, for each of the two setups constructed in the previous part, the Bayes test chooses the same decision  $d'$  or  $d''$ . That is, observing  $\mathbf{x}$  leads to choosing  $d'$  in the first setup if and only if observing  $\mathbf{x}$  leads to choosing  $d'$  in the second setup. Similarly, observing  $\mathbf{x}$  leads to choosing  $d''$  in the first setup if and only if observing  $\mathbf{x}$  leads to choosing  $d''$  in the second setup.

## ★ 9.9 Foundational Issues

*We discuss the relationship between significance level and sample size. We also distinguish between results that are significant in the statistical sense and those that are significant in a practical sense.*

### The Relationship between Level of Significance and Sample Size

In many statistical applications, it has become standard practice for an experimenter to specify a level of significance  $\alpha_0$ , and then to find a test procedure with a large power function on the alternative hypothesis among all procedures whose size  $\alpha(\delta) \leq \alpha_0$ . Alternatively, the experimenter will compute a  $p$ -value and report whether or not it was less than  $\alpha_0$ . For the case of testing simple null and alternative hypotheses, the Neyman-Pearson lemma explicitly describes how to construct such a procedure. Furthermore, it has become traditional in many applications to choose the level of significance  $\alpha_0$  to be 0.10, 0.05, or 0.01. The selected level depends on how serious the consequences of an error of type I are judged to be. The value of  $\alpha_0$  most commonly used is 0.05. If the consequences of an error of type I are judged to be relatively mild in a particular problem, the experimenter may choose  $\alpha_0$  to be 0.10. On the other

hand, if these consequences are judged to be especially serious, the experimenter may choose  $\alpha_0$  to be 0.01.

Because these values of  $\alpha_0$  have become established in statistical practice, the choice of  $\alpha_0 = 0.01$  is sometimes made by an experimenter who wishes to use a cautious test procedure, or one that will not reject  $H_0$  unless the sample data provide strong evidence that  $H_0$  is not true. We shall now show, however, that when the sample size  $n$  is large, the choice of  $\alpha_0 = 0.01$  can actually lead to a test procedure that will reject  $H_0$  for certain samples that, in fact, provide stronger evidence for  $H_0$  than they do for  $H_1$ .

To illustrate this property, suppose, as in Example 9.2.5, that a random sample is taken from the normal distribution with unknown mean  $\theta$  and known variance 1, and that the hypotheses to be tested are

$$\begin{aligned} H_0: \quad & \theta = 0, \\ H_1: \quad & \theta = 1. \end{aligned}$$

It follows from the discussion in Example 9.2.5 that, among all test procedures for which  $\alpha(\delta) \leq 0.01$ , the probability of type II error  $\beta(\delta)$  will be a minimum for the procedure  $\delta^*$  that rejects  $H_0$  when  $\bar{X}_n \geq k'$ , where  $k'$  is chosen so that  $\Pr(\bar{X}_n \geq k' | \theta = 0) = 0.01$ . When  $\theta = 0$ , the random variable  $\bar{X}_n$  has the normal distribution with mean 0 and variance  $1/n$ . Therefore, it can be found from a table of the standard normal distribution that  $k' = 2.326n^{-1/2}$ .

Furthermore, it follows from Eq. (9.2.12) that this test procedure  $\delta^*$  is equivalent to rejecting  $H_0$  when  $f_1(\mathbf{x})/f_0(\mathbf{x}) \geq k$ , where  $k = \exp(2.326n^{1/2} - 0.5n)$ . The probability of an error of type I will be  $\alpha(\delta^*) = 0.01$ . Also, by an argument similar to the one leading to Eq. (9.2.15), the probability of an error of type II will be  $\beta(\delta^*) = \Phi(2.326 - n^{1/2})$ , where  $\Phi$  denotes the c.d.f. of the standard normal distribution. For  $n = 1, 25$ , and  $100$ , the values of  $\beta(\delta^*)$  and  $k$  are as follows:

$n$	$\alpha(\delta^*)$	$\beta(\delta^*)$	$k$
1	0.01	0.91	6.21
25	0.01	0.0038	0.42
100	0.01	$8 \times 10^{-15}$	$2.5 \times 10^{-12}$

It can be seen from this tabulation that when  $n = 1$ , the null hypothesis  $H_0$  will be rejected only if the likelihood ratio  $f_1(\mathbf{x})/f_0(\mathbf{x})$  exceeds the value  $k = 6.21$ . In other words,  $H_0$  will not be rejected unless the observed values  $x_1, \dots, x_n$  in the sample are at least 6.21 times as likely under  $H_1$  as they are under  $H_0$ . In this case, the procedure  $\delta^*$  therefore satisfies the experimenter's desire to use a test that is cautious about rejecting  $H_0$ .

If  $n = 100$ , however, the procedure  $\delta^*$  will reject  $H_0$  whenever the likelihood ratio exceeds the value  $k = 2.5 \times 10^{-12}$ . Therefore,  $H_0$  will be rejected for certain observed values  $x_1, \dots, x_n$  that are actually millions of times more likely under  $H_0$  as they are under  $H_1$ . The reason for this result is that the value of  $\beta(\delta^*)$  that can be achieved when  $n = 100$ , which is  $8 \times 10^{-15}$ , is extremely small relative to the specified value  $\alpha_0 = 0.01$ . Hence, the procedure  $\delta^*$  actually turns out to be much more cautious about an error of type II than it is about an error of type I. We can see from this discussion that a value of  $\alpha_0$  that is an appropriate choice for a small value of  $n$  might be unnecessarily large for a large value of  $n$ . Hence, it would be sensible to let the level of significance  $\alpha_0$  decrease as the sample size increases.

Suppose now that the experimenter regards an error of type I to be much more serious than an error of type II, and she therefore desires to use a test procedure for which the value of the linear combination  $100\alpha(\delta) + \beta(\delta)$  will be a minimum. Then it follows from Theorem 9.2.1 that she should reject  $H_0$  if and only if the likelihood ratio exceeds the value  $k = 100$ , regardless of the sample size  $n$ . In other words, the procedure that minimizes the value of  $100\alpha(\delta) + \beta(\delta)$  will not reject  $H_0$  unless the observed values  $x_1, \dots, x_n$  are at least 100 times as likely under  $H_1$  as they are under  $H_0$ .

From this discussion, it seems more reasonable for the experimenter to take the values of both  $\alpha(\delta)$  and  $\beta(\delta)$  into account when choosing a test procedure, rather than to fix a value of  $\alpha(\delta)$  and minimize  $\beta(\delta)$ . For example, one could minimize the value of a linear combination of the form  $a\alpha(\delta) + b\beta(\delta)$ . In Sec. 9.8, we saw how the Bayesian point of view also leads to the conclusion that one should try to minimize a linear combination of this form. Lehmann (1958) suggested choosing a number  $k$  and requiring that  $\beta(\delta) = k\alpha(\delta)$ . Both the Bayesian method and Lehmann's method have the advantage of forcing the probabilities of both type I and type II errors to decrease as one obtains more data. Similar problems with fixing the significance level of a test arise when hypotheses are composite, as we illustrate later in this section.

## Statistically Significant Results

When the observed data lead to rejecting a null hypothesis  $H_0$  at level  $\alpha_0$ , it is often said that one has obtained a result that is *statistically significant* at level  $\alpha_0$ . When this occurs, it does not mean that the experimenter should behave as if  $H_0$  is false. Similarly, if the data do not lead to rejecting  $H_0$ , the result is not statistically significant at level  $\alpha_0$ , but the experimenter should not necessarily become convinced that  $H_0$  is true. Indeed, qualifying "significant" with the term "statistically" is a warning that a statistically significant result might be different than a practically significant result. Consider, once again, Example 9.5.10 on page 582, in which the hypotheses to be tested are

$$\begin{aligned} H_0: \quad & \mu = 5.2, \\ H_1: \quad & \mu \neq 5.2. \end{aligned}$$

It is extremely important for the experimenter to distinguish a statistically significant result from any claim that the parameter  $\mu$  is significantly different from the hypothesized value 5.2. Even if the data suggest that  $\mu$  is not equal to 5.2, this does not necessarily provide any evidence that the actual value of  $\mu$  is *significantly* different from 5.2. For a given set of data, the tail area corresponding to the observed value of the test statistic  $U$  might be very small, and yet the data might suggest that the actual value of  $\mu$  is so close to 5.2 that, for practical purposes, the experimenter would not regard  $\mu$  as being significantly different from 5.2.

The situation just described can arise when the statistic  $U$  is based on a very large random sample. Suppose, for instance, that in Example 9.5.10 the lengths of 20,000 fibers in a random sample are measured, rather than the lengths of only 15 fibers. For a given level of significance, say,  $\alpha_0 = 0.05$ , let  $\pi(\mu, \sigma^2 | \delta)$  denote the power function of the  $t$  test based on these 20,000 observations. Then  $\pi(5.2, \sigma^2 | \delta) = 0.05$  for every value of  $\sigma^2 > 0$ . However, because of the very large number of observations on which the test is based, the power  $\pi(\mu, \sigma^2 | \delta)$  will be very close to 1 for each value of  $\mu$  that differs only slightly from 5.2 and for a moderate value of  $\sigma^2$ . In other words, even if the value of  $\mu$  differs only slightly from 5.2, the probability is close to 1 that one

would obtain a statistically significant result. For example, with  $n = 20,000$ , the power of the level 0.05 test when  $|\mu - 5.2| = 0.03\sigma$  is 0.99.

As explained in Sec. 9.4, it is inconceivable that the mean length  $\mu$  of all the fibers in the entire population will be exactly 5.2. However,  $\mu$  may be very close to 5.2, and when it is, the experimenter will not want to reject the null hypothesis  $H_0$ . Nevertheless, it is very likely that the  $t$  test based on the sample of 20,000 fibers will lead to a statistically significant result. Therefore, when an experimenter analyzes a powerful test based on a very large sample, he must exercise caution in interpreting the actual significance of a “statistically significant” result. He knows in advance that there is a high probability of rejecting  $H_0$  even when the true value of  $\mu$  differs only slightly from the value 5.2 specified under  $H_0$ .

One way to handle this situation, as discussed earlier in this section, is to recognize that a level of significance much smaller than the traditional value of 0.05 or 0.01 is appropriate for a problem with a large sample size. Another way is to replace the single value of  $\mu$  in the null hypothesis by an interval, as we did on pages 571 and 610. A third way is to regard the statistical problem as one of estimation rather than one of testing hypotheses.

When a large random sample is available, the sample mean and the sample variance will be excellent estimators of the parameters  $\mu$  and  $\sigma^2$ . Before the experimenter chooses any decision involving the unknown values of  $\mu$  and  $\sigma^2$ , she should calculate and consider the values of these estimators as well as the value of the statistic  $U$ .

## Summary

When we reject a null hypothesis, we say that we have obtained a statistically significant result. The power function of a level  $\alpha_0$  test becomes very large, even for parameter values close to the null hypothesis, as the size of the sample increases. For the case of simple hypotheses, the probability of type II error can become very small while the probability of type I error stays as large as  $\alpha_0$ . One way to avoid this is to let the level of significance decrease as the sample size increases. If one rejects a null hypothesis at a particular level of significance  $\alpha_0$ , one must be careful to check whether the data actually suggest any deviation of practical importance from the null hypothesis.

## Exercises

---

1. Suppose that a single observation  $X$  is taken from the normal distribution with unknown mean  $\mu$  and known variance is 1. Suppose that it is known that the value of  $\mu$  must be  $-5, 0$ , or  $5$ , and it is desired to test the following hypotheses at the level of significance 0.05:

$$\begin{aligned} H_0: \mu &= 0, \\ H_1: \mu &= -5 \text{ or } \mu = 5. \end{aligned}$$

Suppose also that the test procedure to be used specifies rejecting  $H_0$  when  $|X| > c$ , where the constant  $c$  is chosen so that  $\Pr(|X| > c | \mu = 0) = 0.05$ .

- a. Find the value of  $c$ , and show that if  $X = 2$ , then  $H_0$  will be rejected.

- b. Show that if  $X = 2$ , then the value of the likelihood function at  $\mu = 0$  is 12.2 times as large as its value at  $\mu = 5$  and is  $5.9 \times 10^9$  times as large as its value at  $\mu = -5$ .

2. Suppose that a random sample of 10,000 observations is taken from the normal distribution with unknown mean  $\mu$  and known variance is 1, and it is desired to test the following hypotheses at the level of significance 0.05:

$$\begin{aligned} H_0: \mu &= 0, \\ H_1: \mu &\neq 0. \end{aligned}$$

Suppose also that the test procedure specifies rejecting  $H_0$  when  $|\bar{X}_n| \geq c$ , where the constant  $c$  is chosen so that  $\Pr(|\bar{X}_n| \geq c | \mu = 0) = 0.05$ . Find the probability that the

test will reject  $H_0$  if **(a)** the actual value of  $\mu$  is 0.01, and **(b)** the actual value of  $\mu$  is 0.02.

- 3.** Consider again the conditions of Exercise 2, but suppose now that it is desired to test the following hypotheses:

$$\begin{aligned} H_0: \quad \mu &\leq 0, \\ H_1: \quad \mu &> 0. \end{aligned}$$

Suppose also that in the random sample of 10,000 observations, the sample mean  $\bar{X}_n$  is 0.03. At what level of significance is this result just significant?

- 4.** Suppose that  $X_1, \dots, X_n$  comprise a random sample from the normal distribution with unknown mean  $\theta$  and known variance 1. Suppose that it is desired to test the same hypotheses as in Exercise 3. This time, however, the test procedure  $\delta$  will be chosen so as to minimize  $19\pi(0|\delta) + 1 - \pi(0.5|\delta)$ .

- a.** Find the value  $c_n$  so that the test procedure  $\delta$  rejects  $H_0$  if  $\bar{X}_n \geq c_n$  for each value  $n = 1, n = 100$ , and  $n = 10,000$ .

- b.** For each value of  $n$  in part (a), find the size of the test procedure  $\delta$ .

- 5.** Suppose that  $X_1, \dots, X_n$  comprise a random sample from the normal distribution with unknown mean  $\theta$  and variance 1. Suppose that it is desired to test the same hypotheses as in Exercise 3. This time, however, the test procedure  $\delta$  will be chosen so that  $19\pi(0|\delta) = 1 - \pi(0.5|\delta)$ .

- a.** Find the value  $c_n$  so that the test procedure  $\delta$  rejects  $H_0$  if  $\bar{X}_n \geq c_n$  for each value  $n = 1, n = 100$ , and  $n = 10,000$ .
- b.** For each value of  $n$  in part (a), find the size of the test procedure  $\delta$ .

## 9.10 Supplementary Exercises

- 1.** I will flip a coin three times and let  $X$  stand for the number of times that the coin comes up heads. Let  $\theta$  stand for the probability that the coin comes up heads on a single flip, and assume that the flips are independent given  $\theta$ . I wish to test the null hypothesis  $H_0: \theta = 1/2$  against the alternative hypothesis  $H_1: \theta = 3/4$ . Find the test  $\delta$  that minimizes  $\alpha(\delta) + \beta(\delta)$ , the sum of the type I and type II error probabilities, and find the two error probabilities for the test.

- 2.** Suppose that a sequence of Bernoulli trials is to be carried out with an unknown probability  $\theta$  of success on each trial, and the following hypotheses are to be tested:

$$\begin{aligned} H_0: \quad \theta &= 0.1, \\ H_1: \quad \theta &= 0.2. \end{aligned}$$

Let  $X$  denote the number of trials required to obtain a success, and suppose that  $H_0$  is to be rejected if  $X \leq 5$ . Determine the probabilities of errors of type I and type II.

- 3.** Consider again the conditions of Exercise 2. Suppose that the losses from errors of type I and type II are equal, and the prior probabilities that  $H_0$  and  $H_1$  are true are equal. Determine the Bayes test procedure based on the observation  $X$ .

- 4.** Suppose that a single observation  $X$  is to be drawn from the following p.d.f.:

$$f(x|\theta) = \begin{cases} 2(1-\theta)x + \theta & \text{for } 0 \leq x \leq 1, \\ 0 & \text{otherwise,} \end{cases}$$

where the value of  $\theta$  is unknown ( $0 \leq \theta \leq 2$ ). Suppose also that the following hypotheses are to be tested:

$$\begin{aligned} H_0: \quad \theta &= 2, \\ H_1: \quad \theta &= 0. \end{aligned}$$

Determine the test procedure  $\delta$  for which  $\alpha(\delta) + 2\beta(\delta)$  is a minimum, and calculate this minimum value.

- 5.** Consider again the conditions of Exercise 4, and suppose that  $\alpha(\delta)$  is required to be a given value  $\alpha_0$  ( $0 < \alpha_0 < 1$ ). Determine the test procedure  $\delta$  for which  $\beta(\delta)$  will be a minimum, and calculate this minimum value.

- 6.** Consider again the conditions of Exercise 4, but suppose now that the following hypotheses are to be tested:

$$\begin{aligned} H_0: \quad \theta &\geq 1, \\ H_1: \quad \theta &< 1. \end{aligned}$$

- a.** Determine the power function of the test  $\delta$  that specifies rejecting  $H_0$  if  $X \geq 0.9$ .
- b.** What is the size of the test  $\delta$ ?

- 7.** Consider again the conditions of Exercise 4. Show that the p.d.f.  $f(x|\theta)$  has a monotone likelihood ratio in the statistic  $r(X) = -X$ , and determine a UMP test of the following hypotheses at the level of significance  $\alpha_0 = 0.05$ :

$$\begin{aligned} H_0: \quad \theta &\leq \frac{1}{2}, \\ H_1: \quad \theta &> \frac{1}{2}. \end{aligned}$$

- 8.** Suppose that a box contains a large number of chips of three different colors, red, brown, and blue, and it is desired to test the null hypothesis  $H_0$  that chips of the three colors are present in equal proportions against the alternative hypothesis  $H_1$  that they are not present in equal proportions. Suppose that three chips are to be drawn at

random from the box, and  $H_0$  is to be rejected if and only if at least two of the chips have the same color.

- a. Determine the size of the test.
  - b. Determine the power of the test if 1/7 of the chips are red, 2/7 are brown, and 4/7 are blue.
9. Suppose that a single observation  $X$  is to be drawn from an unknown distribution  $P$ , and that the following simple hypotheses are to be tested:

$H_0$ :  $P$  is the uniform distribution on the interval  $[0, 1]$ ,

$H_1$ :  $P$  is the standard normal distribution.

Determine the most powerful test of size 0.01, and calculate the power of the test when  $H_1$  is true.

10. Suppose that the 12 observations  $X_1, \dots, X_{12}$  form a random sample from the normal distribution with unknown mean  $\mu$  and unknown variance  $\sigma^2$ . Describe how to carry out a  $t$  test of the following hypotheses at the level of significance  $\alpha_0 = 0.005$ :

$$\begin{aligned} H_0: \quad & \mu \geq 3, \\ H_1: \quad & \mu < 3. \end{aligned}$$

11. Suppose that  $X_1, \dots, X_n$  form a random sample from the normal distribution with unknown mean  $\theta$  and known variance 1, and it is desired to test the following hypotheses:

$$\begin{aligned} H_0: \quad & \theta \leq 0, \\ H_1: \quad & \theta > 0. \end{aligned}$$

Suppose also that it is decided to use a UMP test for which the power is 0.95 when  $\theta = 1$ . Determine the size of this test if  $n = 16$ .

12. Suppose that eight observations  $X_1, \dots, X_8$  are drawn at random from a distribution with the following p.d.f.:

$$f(x|\theta) = \begin{cases} \theta x^{\theta-1} & \text{for } 0 < x < 1, \\ 0 & \text{otherwise.} \end{cases}$$

Suppose also that the value of  $\theta$  is unknown ( $\theta > 0$ ), and it is desired to test the following hypotheses:

$$\begin{aligned} H_0: \quad & \theta \leq 1, \\ H_1: \quad & \theta > 1. \end{aligned}$$

Show that the UMP test at the level of significance  $\alpha_0 = 0.05$  specifies rejecting  $H_0$  if  $\sum_{i=1}^8 \log X_i \geq -3.981$ .

13. Suppose that  $X_1, \dots, X_n$  form a random sample from the  $\chi^2$  distribution with unknown degrees of freedom  $\theta$  ( $\theta = 1, 2, \dots$ ), and it is desired to test the following hypotheses at a given level of significance  $\alpha_0$  ( $0 < \alpha_0 < 1$ ):

$$\begin{aligned} H_0: \quad & \theta \leq 8, \\ H_1: \quad & \theta \geq 9. \end{aligned}$$

Show that there exists a UMP test, and the test specifies rejecting  $H_0$  if  $\sum_{i=1}^n \log X_i \geq k$  for some appropriate constant  $k$ .

14. Suppose that  $X_1, \dots, X_{10}$  form a random sample from a normal distribution for which both the mean and the variance are unknown. Construct a statistic that does not depend on any unknown parameters and has the  $F$  distribution with three and five degrees of freedom.

15. Suppose that  $X_1, \dots, X_m$  form a random sample from the normal distribution with unknown mean  $\mu_1$  and unknown variance  $\sigma_1^2$ , and that  $Y_1, \dots, Y_n$  form an independent random sample from the normal distribution with unknown mean  $\mu_2$  and unknown variance  $\sigma_2^2$ . Suppose also that it is desired to test the following hypotheses with the usual  $F$  test at the level of significance  $\alpha_0 = 0.05$ :

$$\begin{aligned} H_0: \quad & \sigma_1^2 \leq \sigma_2^2, \\ H_1: \quad & \sigma_1^2 > \sigma_2^2. \end{aligned}$$

Assuming that  $m = 16$  and  $n = 21$ , show that the power of the test when  $\sigma_1^2 = 2\sigma_2^2$  is given by  $\Pr(V^* \geq 1.1)$ , where  $V^*$  is a random variable having the  $F$  distribution with 15 and 20 degrees of freedom.

16. Suppose that the nine observations  $X_1, \dots, X_9$  form a random sample from the normal distribution with unknown mean  $\mu_1$  and unknown variance  $\sigma^2$ , and the nine observations  $Y_1, \dots, Y_9$  form an independent random sample from the normal distribution with unknown mean  $\mu_2$  and the same unknown variance  $\sigma^2$ . Let  $S_X^2$  and  $S_Y^2$  be as defined in Eq. (9.6.2) (with  $m = n = 9$ ), and let

$$T = \max \left\{ \frac{S_X^2}{S_Y^2}, \frac{S_Y^2}{S_X^2} \right\}.$$

Determine the value of the constant  $c$  such that  $\Pr(T > c) = 0.05$ .

17. An unethical experimenter desires to test the following hypotheses:

$$\begin{aligned} H_0: \quad & \theta = \theta_0, \\ H_1: \quad & \theta \neq \theta_0. \end{aligned}$$

She draws a random sample  $X_1, \dots, X_n$  from a distribution with the p.d.f.  $f(x|\theta)$ , and carries out a test of size  $\alpha$ . If this test does not reject  $H_0$ , she discards the sample, draws a new independent random sample of  $n$  observations, and repeats the test based on the new sample. She continues drawing new independent samples in this way until she obtains a sample for which  $H_0$  is rejected.

- a. What is the overall size of this testing procedure?
- b. If  $H_0$  is true, what is the expected number of samples that the experimenter will have to draw until she rejects  $H_0$ ?

18. Suppose that  $X_1, \dots, X_n$  form a random sample from the normal distribution with unknown mean  $\mu$  and unknown precision  $\tau$ , and the following hypotheses are to

be tested:

$$\begin{aligned} H_0: \quad & \mu \leq 3, \\ H_1: \quad & \mu > 3. \end{aligned}$$

Suppose that the prior joint distribution of  $\mu$  and  $\tau$  is the normal-gamma distribution, as described in Theorem 8.6.1, with  $\mu_0 = 3$ ,  $\lambda_0 = 1$ ,  $\alpha_0 = 1$ , and  $\beta_0 = 1$ . Suppose finally that  $n = 17$ , and it is found from the observed values in the sample that  $\bar{X}_n = 3.2$  and  $\sum_{i=1}^n (X_i - \bar{X}_n)^2 = 17$ . Determine both the prior probability and the posterior probability that  $H_0$  is true.

**19.** Consider a problem of testing hypotheses in which the following hypotheses about an arbitrary parameter  $\theta$  are to be tested:

$$\begin{aligned} H_0: \quad & \theta \in \Omega_0, \\ H_1: \quad & \theta \in \Omega_1. \end{aligned}$$

Suppose that  $\delta$  is a test procedure of size  $\alpha$  ( $0 < \alpha < 1$ ) based on some vector of observations  $X$ , and let  $\pi(\theta|\delta)$  denote the power function of  $\delta$ . Show that if  $\delta$  is unbiased, then  $\pi(\theta|\delta) \geq \alpha$  at every point  $\theta \in \Omega_1$ .

**20.** Consider again the conditions of Exercise 19. Suppose now that we have a two-dimensional vector  $\theta = (\theta_1, \theta_2)$ , where  $\theta_1$  and  $\theta_2$  are real-valued parameters. Suppose also that  $A$  is a particular circle in the  $\theta_1\theta_2$ -plane, and that the hypotheses to be tested are as follows:

$$\begin{aligned} H_0: \quad & \theta \in A, \\ H_1: \quad & \theta \notin A. \end{aligned}$$

Show that if the test procedure  $\delta$  is unbiased and of size  $\alpha$ , and if its power function  $\pi(\theta|\delta)$  is a continuous function of  $\theta$ , then it must be true that  $\pi(\theta|\delta) = \alpha$  at each point  $\theta$  on the boundary of the circle  $A$ .

**21.** Consider again the conditions of Exercise 19. Suppose now that  $\theta$  is a real-valued parameter, and the following hypotheses are to be tested:

$$\begin{aligned} H_0: \quad & \theta = \theta_0, \\ H_1: \quad & \theta \neq \theta_0. \end{aligned}$$

Assume that  $\theta_0$  is an interior point of the parameter space  $\Omega$ . Show that if the test procedure  $\delta$  is unbiased and if its power function  $\pi(\theta|\delta)$  is a differentiable function of  $\theta$ , then  $\pi'(\theta_0|\delta) = 0$ , where  $\pi'(\theta_0|\delta)$  denotes the derivative of  $\pi(\theta|\delta)$  evaluated at the point  $\theta = \theta_0$ .

**22.** Suppose that the differential brightness  $\theta$  of a certain star has an unknown value, and it is desired to test the following simple hypotheses:

$$\begin{aligned} H_0: \quad & \theta = 0, \\ H_1: \quad & \theta = 10. \end{aligned}$$

The statistician knows that when he goes to the observatory at midnight to measure  $\theta$ , there is probability 1/2 that the meteorological conditions will be good, and he will be

able to obtain a measurement  $X$  having the normal distribution with mean  $\theta$  and variance 1. He also knows that there is probability 1/2 that the meteorological conditions will be poor, and he will obtain a measurement  $Y$  having the normal distribution with mean  $\theta$  and variance 100. The statistician also learns whether the meteorological conditions were good or poor.

- a. Construct the most powerful test that has conditional size  $\alpha = 0.05$ , given good meteorological conditions, and one that has conditional size  $\alpha = 0.05$ , given poor meteorological conditions.
  - b. Construct the most powerful test that has conditional size  $\alpha = 2.0 \times 10^{-7}$ , given good meteorological conditions, and one that has conditional size  $\alpha = 0.0999998$ , given poor meteorological conditions. (You will need a computer program to do this.)
  - c. Show that the overall size of both the test found in part (a) and the test found in part (b) is 0.05, and determine the power of each of these two tests.
- 23.** Consider again the situation described in Exercise 22. This time, assume that there is a loss function of the form (9.8.6). Also, assume that the prior probability of  $\theta = 0$  is  $\xi_0$  and the prior probability of  $\theta = 10$  is  $\xi_1$ .
- a. Find the formula for the Bayes test for general loss function of the form (9.8.6).
  - b. Prove that the test in part (a) of Exercise 22 is not a special case of the Bayes test found in part (a) of the present exercise.
  - c. Prove that the test in part (b) of Exercise 22 is (up to rounding error) a special case of the Bayes test found in part (a) of the present exercise.

**24.** Let  $X_1, \dots, X_n$  be i.i.d. with the Poisson distribution having mean  $\theta$ . Let  $Y = \sum_{i=1}^n X_i$ .

- a. Suppose that we wish to test the hypotheses  $H_0: \theta \geq 1$  versus  $H_1: \theta < 1$ . Show that the test “reject  $H_0$  if  $Y = 0$ ” is uniformly most powerful level  $\alpha_0$  for some number  $\alpha_0$ . Also find  $\alpha_0$ .
- b. Find the power function of the test from part (a).

**25.** Consider a family of distributions with parameter  $\theta$  and monotone likelihood ratio in a statistic  $T$ . We learned how to find a uniformly most powerful level  $\alpha_0$  test  $\delta_c$  of the null hypothesis  $H_{0,c}: \theta \leq c$  versus  $H_{1,c}: \theta > c$  for every  $c$ . We also know that these tests are equivalent to a coefficient  $1 - \alpha_0$  confidence interval, where the confidence interval contains  $c$  if and only if  $\delta_c$  does not reject  $H_{0,c}$ . The confidence interval is called *uniformly most accurate coefficient*  $1 - \alpha_0$ . Based on the equivalence of the tests and the confidence interval, figure out what the definition of “uniformly most accurate coefficient  $1 - \alpha_0$ ” must be. Write the definition in terms of the conditional probability that the interval covers  $\theta_1$  given that  $\theta = \theta_2$  for various pairs of values  $\theta_1$  and  $\theta_2$ .

## 10.1 Tests of Goodness-of-Fit

*In some problems, we have one specific distribution in mind for the data we will observe. If that one distribution is not appropriate, we do not necessarily have a parametric family of alternative distributions in mind. In these cases, and others, we can still test the null hypothesis that the data come from the one specific distribution against the alternative hypothesis that the data do not come from that distribution.*

### Description of Nonparametric Problems

**Example**  
**10.1.1**

Failure Times of Ball Bearings. In Example 5.6.9, we observed the failure times of 23 ball bearings, and we modeled the logarithms of these failure times as normal random variables. Suppose that we are not so confident that the normal distribution is a good model for the logarithms of the failure times. Is there a way to test the null hypothesis that a normal distribution is a good model against the alternative that no normal distribution is a good model? Is there a way to estimate features of the distribution of failure times (such as the median, variance, etc.) if we are unwilling to model the data as normal random variables? ◀

In each of the problems of estimation and testing hypotheses that we considered in Chapters 7, 8, and 9, we have assumed that the observations that are available to the statistician come from distributions for which the exact form is known, even though the values of some parameters are unknown. For example, it might be assumed that the observations form a random sample from a Poisson distribution for which the mean is unknown, or it might be assumed that the observations come from two normal distributions for which the means and variances are unknown. In other words, we have assumed that the observations come from a certain *parametric family* of distributions, and a statistical inference must be made about the values of the parameters defining that family.

In many of the problems to be discussed in this chapter, we shall not assume that the available observations come from a particular parametric family of distributions. Rather, we shall study inferences that can be made about the distribution from which the observations come, without making special assumptions about the form of that distribution. As one example, we might simply assume that the observations form

a random sample from a continuous distribution, without specifying the form of this distribution any further, and we might then investigate the possibility that this distribution is a normal distribution. As a second example, we might be interested in making an inference about the value of the median of the distribution from which the sample was drawn, and we might assume only that this distribution is continuous. As a third example, we might be interested in investigating the possibility that two independent random samples actually come from the same distribution, and we might assume only that both distributions from which the samples are taken are continuous.

Problems in which the possible distributions of the observations are not restricted to a specific parametric family are called *nonparametric problems*, and the statistical methods that are applicable in such problems are called *nonparametric methods*.

### Categorical Data

**Example  
10.1.2**

**Blood Types.** In Example 5.9.3, we learned about a study of blood types among a sample of 6004 white Californians. Suppose that the actual counts of people with the four blood types are given in Table 10.1. We might be interested in whether or not these data are consistent with a theory that predicts a particular set of probabilities for the blood types. Table 10.2 gives theoretical probabilities for the four blood types. How can we go about testing the null hypothesis that the theoretical probabilities in Table 10.2 are the probabilities with which the data in Table 10.1 were sampled? ◀

In this section and the next four sections, we shall consider statistical problems based on data such that each observation can be classified as belonging to one of a finite number of possible categories or types. Observations of this type are called *categorical data*. Since there are only a finite number of possible categories in these problems, and since we are interested in making inferences about the probabilities of these categories, these problems actually involve just a finite number of parameters. However, as we shall see, methods based on categorical data can be usefully applied in both parametric and nonparametric problems.

## The $\chi^2$ Test

Suppose that a large population consists of items of  $k$  different types, and let  $p_i$  denote the probability that an item selected at random will be of type  $i$  ( $i = 1, \dots, k$ ). Example 10.1.2 is of this type with  $k = 4$ . Of course,  $p_i \geq 0$  for  $i = 1, \dots, k$  and  $\sum_{i=1}^k p_i = 1$ . Let  $p_1^0, \dots, p_k^0$  be specific numbers such that  $p_i^0 > 0$  for  $i = 1, \dots, k$  and  $\sum_{i=1}^k p_i^0 = 1$ , and suppose that the following hypotheses are to be tested:

$$\begin{aligned} H_0: \quad p_i &= p_i^0 \quad \text{for } i = 1, \dots, k, \\ H_1: \quad p_i &\neq p_i^0 \quad \text{for at least one value of } i. \end{aligned} \tag{10.1.1}$$

We shall assume that a random sample of size  $n$  is to be taken from the given population. That is,  $n$  independent observations are to be taken, and there is probability  $p_i$  that each observation will be of type  $i$  ( $i = 1, \dots, k$ ). On the basis of these  $n$  observations, the hypotheses (10.1.1) are to be tested.

For  $i = 1, \dots, k$ , we shall let  $N_i$  denote the number of observations in the random sample that are of type  $i$ . Thus,  $N_1, \dots, N_k$  are nonnegative integers such that  $\sum_{i=1}^k N_i = n$ . Indeed,  $(N_1, \dots, N_n)$  has the multinomial distribution (see Sec. 5.9) with parameters  $n$  and  $\mathbf{p} = (p_1, \dots, p_k)$ . When the null hypothesis  $H_0$  is true, the expected number of observations of type  $i$  is  $np_i^0$  ( $i = 1, \dots, k$ ). The difference between the actual number of observations  $N_i$  and the expected number  $np_i^0$  will tend to be smaller when  $H_0$  is true than when  $H_0$  is not true. It seems reasonable, therefore, to base a test of the hypotheses (10.1.1) on values of the differences  $N_i - np_i^0$  for  $i = 1, \dots, k$  and reject  $H_0$  when the magnitudes of these differences are relatively large.

In 1900, Karl Pearson proved the following result, whose proof will not be given here.

**Theorem 10.1.1**  $\chi^2$  Statistic. The following statistic

$$Q = \sum_{i=1}^k \frac{(N_i - np_i^0)^2}{np_i^0} \tag{10.1.2}$$

has the property that if  $H_0$  is true and the sample size  $n \rightarrow \infty$ , then  $Q$  converges in distribution to the  $\chi^2$  distribution with  $k - 1$  degrees of freedom. (See Definition 6.3.1.) ■

Theorem 10.1.1 says that if  $H_0$  is true and the sample size  $n$  is large, the distribution of  $Q$  will be approximately the  $\chi^2$  distribution with  $k - 1$  degrees of freedom. The discussion that we have presented indicates that  $H_0$  should be rejected when  $Q \geq c$ , where  $c$  is an appropriate constant. If it is desired to carry out the test at the level of significance  $\alpha_0$ , then  $c$  should be chosen to be the  $1 - \alpha_0$  quantile of the  $\chi^2$  distribution with  $k - 1$  degrees of freedom. This test is called the  $\chi^2$  test of goodness-of-fit.

**Note: General form of  $\chi^2$  test statistic.** The form of the statistic  $Q$  in (10.1.2) is common to all  $\chi^2$  tests including those that will be introduced later in this chapter. The form is a sum of terms, each of which is the square of the difference between an observed count and an expected count divided by the expected count:  $\sum(\text{observed} - \text{expected})^2/\text{expected}$ . The expected counts are computed under the assumption that the null hypothesis is true.

Whenever the value of each expected count,  $np_i^0$  ( $i = 1, \dots, k$ ), is not too small, the  $\chi^2$  distribution will be a good approximation to the actual distribution of  $Q$ .

Specifically, the approximation will be very good if  $np_i^0 \geq 5$  for  $i = 1, \dots, k$ , and the approximation should still be satisfactory if  $np_i^0 \geq 1.5$  for  $i = 1, \dots, k$ .

We shall now illustrate the use of the  $\chi^2$  test of goodness-of-fit by some examples.

**Example  
10.1.3**

**Blood Types.** In Example 10.1.2, we have specified a hypothetical vector of probabilities  $(p_1^0, \dots, p_4^0)$  for the four blood types in Table 10.2. We can use the data in Table 10.1 to test the null hypothesis  $H_0$  that the probabilities  $(p_1, \dots, p_4)$  of the four blood types equal  $(p_1^0, \dots, p_4^0)$ . The four expected counts under  $H_0$  are

$$\begin{aligned} np_1^0 &= 6004 \times \frac{1}{3} = 2001.3, & np_2^0 &= 6004 \times \frac{1}{8} = 750.5, \\ np_3^0 &= 6004 \times \frac{1}{24} = 250.2, & \text{and} & np_4^0 = 6004 \times \frac{1}{2} = 3002.0. \end{aligned}$$

The  $\chi^2$  test statistic is then

$$Q = \frac{(2162 - 2001.3)^2}{2001.3} + \frac{738 - 750.5}{750.5} + \frac{(228 - 250.2)^2}{250.2} + \frac{(2876 - 3002.0)^2}{3002.0} = 20.37.$$

To test  $H_0$  at level  $\alpha_0$ , we would compare  $Q$  to the  $1 - \alpha_0$  quantile of the  $\chi^2$  distribution with three degrees of freedom. Alternatively, we can compute the  $p$ -value, which would be the smallest  $\alpha_0$  at which we could reject  $H_0$ . In the case of the  $\chi^2$  goodness of fit test, the  $p$ -value equals  $1 - X_{k-1}^2(Q)$ , where  $X_{k-1}^2$  is the c.d.f. of the  $\chi^2$  distribution with  $k - 1$  degrees of freedom. In this example,  $k = 4$  and the  $p$ -value is  $1.42 \times 10^{-4}$ .  $\blacktriangleleft$

**Example  
10.1.4**

**Montana Outlook Poll.** The Bureau of Business and Economic Research at the University of Montana conducted a poll of opinions of Montana residents in May 1992. Among other things, respondents were asked whether their personal financial status was worse, the same, or better than one year ago. Table 10.3 displays some results. We might be interested in whether the respondents' answers are uniformly distributed over the three possible responses. That is, we can test the null hypothesis that the probabilities of the three responses are all equal to  $1/3$ . We calculate

$$Q = \frac{(58 - 189/3)^2}{189/3} + \frac{(64 - 189/3)^2}{189/3} + \frac{(67 - 189/3)^2}{189/3} = 0.6667.$$

Since 0.6667 is the 0.283 quantile of the  $\chi^2$  distribution with two degrees of freedom, we would only reject the null at levels greater than  $1 - 0.283 = 0.717$ .  $\blacktriangleleft$

**Example  
10.1.5**

**Testing Hypotheses about a Proportion.** Suppose that the proportion  $p$  of defective items in a large population of manufactured items is unknown and that the following

<b>Table 10.3</b> Responses to personal financial status question from Montana Outlook Poll			
Worse	Same	Better	Total
58	64	67	189

hypotheses are to be tested:

$$\begin{aligned} H_0: \quad p &= 0.1, \\ H_1: \quad p &\neq 0.1. \end{aligned} \tag{10.1.3}$$

Suppose also that in a random sample of 100 items, it is found that 16 are defective. We shall test the hypotheses (10.1.3) by carrying out a  $\chi^2$  test of goodness-of-fit.

Since there are only two types of items in this example, namely, defective items and nondefective items, we know that  $k = 2$ . Furthermore, if we let  $p_1$  denote the unknown proportion of defective items and let  $p_2$  denote the unknown proportion of nondefective items, then the hypotheses (10.1.3) can be rewritten in the following form:

$$\begin{aligned} H_0: \quad p_1 &= 0.1 \text{ and } p_2 = 0.9, \\ H_1: \quad \text{The hypothesis } H_0 &\text{ is not true.} \end{aligned} \tag{10.1.4}$$

For the sample size  $n = 100$ , the expected number of defective items if  $H_0$  is true is  $np_1^0 = 10$ , and the expected number of nondefective items is  $np_2^0 = 90$ . Let  $N_1$  denote the number of defective items in the sample, and let  $N_2$  denote the number of nondefective items in the sample. Then, when  $H_0$  is true, the distribution of the statistic  $Q$  defined by Eq. (10.1.2) will be approximately the  $\chi^2$  distribution with one degree of freedom.

In this example,  $N_1 = 16$  and  $N_2 = 84$ , and it is found that the value of  $Q$  is 4. It can now be determined, either from interpolation in a table of the  $\chi^2$  distribution with one degree of freedom or from statistical software, that the tail area ( $p$ -value) corresponding to the value  $Q = 4$  is approximately 0.0455. Hence, the null hypothesis  $H_0$  would be rejected at levels of significance greater than 0.0455, but not at smaller levels. For hypotheses about a single proportion, we developed tests in Sec. 9.1. (See Exercise 11 in Sec. 9.1, for example.) You can compare the test from Sec. 9.1 to the test in this example in Exercise 1 at the end of this section. ◀

## Testing Hypotheses about a Continuous Distribution

Consider a random variable  $X$  that takes values in the interval  $0 < X < 1$  but has an unknown p.d.f. over this interval. Suppose that a random sample of 100 observations is taken from this unknown distribution, and it is desired to test the null hypothesis that the distribution is the uniform distribution on the interval  $[0, 1]$  against the alternative hypothesis that the distribution is not uniform. This problem is a nonparametric problem, since the distribution of  $X$  might be any continuous distribution on the interval  $[0, 1]$ . However, as we shall now show, the  $\chi^2$  test of goodness-of-fit can be applied to this problem.

Suppose that we divide the interval  $[0, 1]$  into 20 subintervals of equal length, namely, the interval  $[0, 0.05]$ , the interval  $[0.05, 0.10]$ , and so on. If the actual distribution is a uniform distribution, then the probability that each observation will fall within the  $i$ th subinterval is  $1/20$ , for  $i = 1, \dots, 20$ . Since the sample size in this example is  $n = 100$ , it follows that the expected number of observations in each subinterval is 5. If  $N_i$  denotes the number of observations in the sample that actually fall within the  $i$ th subinterval, then the statistic  $Q$  defined by Eq. (10.1.2) can be rewritten simply as follows:

$$Q = \frac{1}{5} \sum_{i=1}^{20} (N_i - 5)^2. \tag{10.1.5}$$

If the null hypothesis is true, and the distribution from which the observations were taken is indeed a uniform distribution, then  $Q$  will have approximately the  $\chi^2$  distribution with 19 degrees of freedom.

The method that has been presented in this example obviously can be applied to every continuous distribution. To test whether a random sample of observations comes from a particular distribution, the following procedure can be adopted:

- i. Partition the entire real line, or any particular interval that has probability 1, into a finite number  $k$  of disjoint subintervals. Generally,  $k$  is chosen so that the expected number of observations in each subinterval is at least 5 if  $H_0$  is true.
- ii. Determine the probability  $p_i^0$  that the particular hypothesized distribution would assign to the  $i$ th subinterval, and calculate the expected number  $np_i^0$  of observations in the  $i$ th subinterval ( $i = 1, \dots, k$ ).
- iii. Count the number  $N_i$  of observations in the sample that fall within the  $i$ th subinterval ( $i = 1, \dots, k$ ).
- iv. Calculate the value of  $Q$  as defined by Eq. (10.1.2). If the hypothesized distribution is correct,  $Q$  will have approximately the  $\chi^2$  distribution with  $k - 1$  degrees of freedom.

**Example  
10.1.6**

**Failure Times of Ball Bearings.** Return to Example 10.1.1. Suppose that we wish to use the  $\chi^2$  test to test the null hypothesis that the logarithms of the lifetimes are an i.i.d. sample from the normal distribution with mean  $\log(50) = 3.912$  and variance 0.25. In order to have the expected count in each interval be at least 5, we can use at most  $k = 4$  intervals. We shall make these intervals each have probability 0.25 under the null hypothesis. That is, we shall divide the intervals at the 0.25, 0.5, and 0.75 quantiles of the hypothesized normal distribution. These quantiles are

$$\begin{aligned} 3.912 + 0.5\Phi^{-1}(0.25) &= 3.192 + 0.5 \times (-0.674) = 3.575, \\ 3.912 + 0.5\Phi^{-1}(0.5) &= 3.192 + 0.5 \times 0 = 3.912, \\ 3.912 + 0.5\Phi^{-1}(0.75) &= 3.192 + 0.5 \times 0.674 = 4.249, \end{aligned}$$

because the 0.25 and 0.75 quantiles of the standard normal distribution are  $\pm 0.674$ . The observed logarithms are

2.88	3.36	3.50	3.73	3.74	3.82	3.88	3.95
3.95	3.99	4.02	4.22	4.23	4.23	4.23	4.43
4.53	4.59	4.66	4.66	4.85	4.85	5.16	

The numbers of observations in each of the four intervals are then 3, 4, 8, and 8. We then calculate

$$\begin{aligned} Q &= \frac{(3 - 23 \times 0.25)^2}{23 \times 0.25} + \frac{(4 - 23 \times 0.25)^2}{23 \times 0.25} + \frac{(8 - 23 \times 0.25)^2}{23 \times 0.25} \\ &\quad + \frac{(8 - 23 \times 0.25)^2}{23 \times 0.25} = 3.609. \end{aligned}$$

Our table of the  $\chi^2$  distribution with three degrees of freedom indicates that 3.609 is between the 0.6 and 0.7 quantiles, so we would not reject the null hypothesis at levels less 0.3 and reject the null hypothesis at levels greater than 0.4. (Actually, the  $p$ -value is 0.307.) ◀

One arbitrary feature of the procedure just described is the way in which the subintervals are chosen. Two statisticians working on the same problem might very well choose the subintervals in two different ways. Generally speaking, it is a good policy to choose the subintervals so that the expected numbers of observations in the individual subintervals are approximately equal, and also to choose as many subintervals as possible without allowing the expected number of observations in any subinterval to become small. This is what we did in Example 10.1.6.

## Likelihood Ratio Tests for Proportions

In Examples 10.1.3 and 10.1.4, we used the  $\chi^2$  goodness-of-fit test to test hypotheses of the form (10.1.4). Although  $\chi^2$  tests are commonly used in such examples, we could actually use parametric tests in these examples. For example, the vector of responses in Table 10.3 can be thought of as the observed value of a multinomial random vector with parameters 189 and  $\mathbf{p} = (p_1, p_2, p_3)$ . (See Sec. 5.9.) The hypotheses in Eq. (10.1.4) are then of the form

$$H_0: \mathbf{p} = \mathbf{p}^{(0)} \text{ versus } H_1: \mathbf{p} \text{ is not true.}$$

As such, we can use the method of likelihood ratio tests for testing the hypotheses. Specifically, we shall apply Theorem 9.1.4. The likelihood function from a multinomial vector  $\mathbf{x} = (N_1, \dots, N_k)$  is

$$f(\mathbf{x}|\mathbf{p}) = \binom{n}{N_1, \dots, N_k} p_1^{N_1} \cdots p_k^{N_k}. \quad (10.1.6)$$

In order to apply Theorem 9.1.4, the parameter space must be an open set in  $k$ -dimensional space. This is not true for the multinomial distribution if we let  $\mathbf{p}$  be the parameter. The set of probability vectors lies in a  $(k - 1)$ -dimensional subset of  $k$ -dimensional space because the coordinates are constrained to add up to 1. However, we can just as effectively treat the vector  $\theta = (p_1, \dots, p_{k-1})$  as the parameter because  $p_k = 1 - p_1 - \cdots - p_{k-1}$  is a function of  $\theta$ . As long as we believe that all coordinates of  $\mathbf{p}$  are strictly between 0 and 1, the set of possible values of the  $(k - 1)$ -dimensional parameter  $\theta$  is open. The likelihood function (10.1.6) can then be rewritten as

$$g(\mathbf{x}|\theta) = \binom{n}{N_1, \dots, N_k} \theta_1^{N_1} \cdots \theta_{k-1}^{N_{k-1}} (1 - \theta_1 - \cdots - \theta_{k-1})^{N_k}. \quad (10.1.7)$$

If  $H_0$  is true, there is only one possible value for (10.1.7), namely,

$$\binom{n}{N_1, \dots, N_k} (p_1^{(0)})^{N_1} \cdots (p_k^{(0)})^{N_k},$$

which is then the numerator of the likelihood ratio statistic  $\Lambda(\mathbf{x})$  from Definition 9.1.11. The denominator of  $\Lambda(\mathbf{x})$  is found by maximizing (10.1.7). It is not difficult to show that the M.L.E.'s are  $\hat{\theta}_i = N_i/n$  for  $i = 1, \dots, k - 1$ . The large-sample likelihood ratio test statistic is then

$$-2 \log \Lambda(\mathbf{x}) = -2 \sum_{i=1}^k N_i \log \left( \frac{np_i^{(0)}}{N_i} \right).$$

The large-sample test rejects  $H_0$  at level of significance  $\alpha_0$  if this statistic is greater than the  $1 - \alpha_0$  quantile of the  $\chi^2$  distribution with  $k - 1$  degrees of freedom.

### Example 10.1.7

**Blood Types.** Using the data in Table 10.1, we can test the null hypothesis that the vector of probabilities equals the vector of numbers in Table 10.2. The values of  $np_i^{(0)}$

for  $i = 1, 2, 3, 4$  were already calculated in Example 10.1.3. The test statistic is

$$\begin{aligned} -2 & \left[ 2162 \log \left( \frac{2001.3}{2162} \right) + 738 \log \left( \frac{750.5}{738} \right) + 228 \log \left( \frac{250.2}{228} \right) + 2876 \log \left( \frac{3002.0}{2876} \right) \right] \\ & = 20.16. \end{aligned}$$

The  $p$ -value is the probability that a  $\chi^2$  random variable with three degrees of freedom is greater than 20.16, namely,  $1.57 \times 10^{-4}$ . This is nearly the same as the  $p$ -value from the  $\chi^2$  test in Example 10.1.3. 

## Discussion of the Test Procedure

The  $\chi^2$  test of goodness-of-fit is subject to the criticisms of tests of hypotheses that were presented in Sec. 9.9. In particular, the null hypothesis  $H_0$  in the  $\chi^2$  test specifies the distribution of the observations exactly, but it is not likely that the actual distribution of the observations will be exactly the same as that of a random sample from this specific distribution. Therefore, if the  $\chi^2$  test is based on a very large number of observations, we can be almost certain that the tail area corresponding to the observed value of  $Q$  will be very small. For this reason, a very small tail area should not be regarded as strong evidence against the hypothesis  $H_0$  without further analysis. Before a statistician concludes that the hypothesis  $H_0$  is unsatisfactory, he should be certain that there exist *reasonable* alternative distributions for which the observed values provide a much better fit. For example, the statistician might calculate the values of the statistic  $Q$  for a few reasonable alternative distributions in order to be certain that, for at least one of these distributions, the tail area corresponding to the calculated value of  $Q$  is substantially larger than it is for the distribution specified by  $H_0$ .

A particular feature of the  $\chi^2$  test of goodness-of-fit is that the procedure is designed to test the null hypothesis  $H_0$  that  $p_i = p_i^0$  for  $i = 1, \dots, k$  against the general alternative that  $H_0$  is not true. If it is desired to use a test procedure that is especially effective for detecting certain types of deviations of the actual values of  $p_1, \dots, p_k$  from the hypothesized values  $p_1^0, \dots, p_k^0$ , then the statistician should design special tests that have higher power for these types of alternatives and lower power for alternatives of lesser interest. This topic will not be discussed in this book.

Because the random variables  $N_1, \dots, N_k$  in Eq. (10.1.2) are discrete, the  $\chi^2$  approximation to the distribution of  $Q$  can sometimes be improved by introducing a correction for continuity of the type described in Sec. 6.4. However, we shall not use the correction in this book. 

## Summary

The  $\chi^2$  test of goodness-of-fit was introduced as a method for testing the null hypothesis that our data form an i.i.d. sample from a specific distribution against the alternative hypothesis that the data have some other distribution. The test is most natural when the specific distribution is discrete. Suppose that there are  $k$  possible values for each observation, and we observe  $N_i$  with value  $i$  for  $i = 1, \dots, k$ . Suppose that the null hypothesis says that the probability of the  $i$ th possible value is  $p_i^0$  for

$i = 1, \dots, k$ . Then we compute

$$Q = \sum_{i=1}^k \frac{(N_i - np_i^0)^2}{np_i^0},$$

where  $n = \sum_{i=1}^k N_i$  is the sample size. When the null hypothesis says that the data have a continuous distribution, then one must first create a corresponding discrete distribution. One does this by dividing the real line into finitely many (say,  $k$ ) intervals, calculating the probability of each interval  $p_1^0, \dots, p_k^0$ , and then pretending as if all we learned from the data were into which intervals each observation fell. This converts the original data into discrete data with  $k$  possible values. For example, the value of  $N_i$  used in the formula for  $Q$  is the number of observations that fell into the  $i$ th interval. All of the  $\chi^2$  test statistics in this text have the form  $\sum(\text{observed} - \text{expected})^2/\text{expected}$ , where “observed” stands for an observed count and “expected” stands for the expected value of the observed count under the assumption that the null hypothesis is true.

## Exercises

---

1. Consider the hypotheses being tested in Example 10.1.5. Use a test procedure of the form outlined in Exercise 11 of Sec. 9.1 and compare the result to the numerical result obtained in Example 10.1.5.

2. Show that if  $p_i^0 = 1/k$  for  $i = 1, \dots, k$ , then the statistic  $Q$  defined by Eq. (10.1.2) can be written in the form

$$Q = \left( \frac{k}{n} \sum_{i=1}^k N_i^2 \right) - n.$$

3. Investigate the “randomness” of your favorite pseudo-random number generator as follows. Simulate 200 pseudo-random numbers between 0 and 1 and divide the unit interval into  $k = 10$  intervals of length 0.1 each. Apply the  $\chi^2$  test of the hypothesis that each of the 10 intervals has the same probability of containing a pseudo-random number.

4. According to a simple genetic principle, if both the mother and the father of a child have genotype  $Aa$ , then there is probability  $1/4$  that the child will have genotype  $AA$ , probability  $1/2$  that she will have genotype  $Aa$ , and probability  $1/4$  that she will have genotype  $aa$ . In a random sample of 24 children having both parents with genotype  $Aa$ , it is found that 10 have genotype  $AA$ , 10 have genotype  $Aa$ , and four have genotype  $aa$ . Investigate whether the simple genetic principle is correct by carrying out a  $\chi^2$  test of goodness-of-fit.

5. Suppose that in a sequence of  $n$  Bernoulli trials, the probability  $p$  of success on each trial is unknown. Suppose also that  $p_0$  is a given number in the interval  $(0, 1)$ , and it is desired to test the following hypotheses:

$$H_0: p = p_0,$$

$$H_1: p \neq p_0.$$

Let  $\bar{X}_n$  denote the proportion of successes in the  $n$  trials, and suppose that the given hypotheses are to be tested by using a  $\chi^2$  test of goodness-of-fit.

- a. Show that the statistic  $Q$  defined by Eq. (10.1.2) can be written in the form

$$Q = \frac{n(\bar{X}_n - p_0)^2}{p_0(1 - p_0)}.$$

- b. Assuming that  $H_0$  is true, prove that as  $n \rightarrow \infty$ , the c.d.f. of  $Q$  converges to the c.d.f. of the  $\chi^2$  distribution with one degree of freedom. Hint: Show that  $Q = Z^2$ , where it is known from the central limit theorem that  $Z$  is a random variable whose c.d.f. converges to the c.d.f. of the standard normal distribution.

6. It is known that 30 percent of small steel rods produced by a standard process will break when subjected to a load of 3000 pounds. In a random sample of 50 similar rods produced by a new process, it was found that 21 of them broke when subjected to a load of 3000 pounds. Investigate the hypothesis that the breakage rate for the new process is the same as the rate for the old process by carrying out a  $\chi^2$  test of goodness-of-fit.

7. In a random sample of 1800 observed values from the interval  $(0, 1)$ , it was found that 391 values were between 0 and 0.2, 490 values were between 0.2 and 0.5, 580 values were between 0.5 and 0.8, and 339 values were between 0.8 and 1. Test the hypothesis that the random sample was drawn from the uniform distribution on the interval  $[0, 1]$  by carrying out a  $\chi^2$  test of goodness-of-fit at the level of significance 0.01.

- 8.** Suppose that the distribution of the heights of men who reside in a certain large city is the normal distribution for which the mean is 68 inches and the standard deviation is 1 inch. Suppose also that when the heights of 500 men who reside in a certain neighborhood of the city were measured, the distribution in Table 10.4 was obtained. Test the hypothesis that, with regard to height, these 500 men form a random sample from all the men who reside in the city.

**Table 10.4** Data for Exercise 8

Height	Number of men
Less than 66 in.	18
Between 66 and 67.5 in.	177
Between 67.5 and 68.5 in.	198
Between 68.5 and 70 in.	102
Greater than 70 in.	5

- 9.** The 50 values in Table 10.5 are intended to be a random sample from the standard normal distribution.

**Table 10.5** Data for Exercise 9

-1.28	-1.22	-0.45	-0.35	0.72
-0.32	-0.80	-1.66	1.39	0.38
-1.38	-1.26	0.49	-0.14	-0.85
2.33	-0.34	-1.96	-0.64	-1.32
-1.14	0.64	3.44	-1.67	0.85
0.41	-0.01	0.67	-1.13	-0.41
-0.49	0.36	-1.24	-0.04	-0.11
1.05	0.04	0.76	0.61	-2.04
0.35	2.82	-0.46	-0.63	-1.61
0.64	0.56	-0.11	0.13	-1.81

- a. Carry out a  $\chi^2$  test of goodness-of-fit by dividing the real line into five intervals, each of which has probability 0.2 under the standard normal distribution.
- b. Carry out a  $\chi^2$  test of goodness-of-fit by dividing the real line into 10 intervals, each of which has probability 0.1 under the standard normal distribution.

## 10.2 Goodness-of-Fit for Composite Hypotheses

We can extend the goodness-of-fit test to deal with the case in which the null hypothesis is that the distribution of our data belongs to a particular parametric family. The alternative hypothesis is that the data have a distribution that is not a member of that parametric family. There are two changes to the test procedure in going from the case of a simple null hypothesis to the case of a composite null hypothesis. First, in the test statistic  $Q$ , the probabilities  $p_i^0$  are replaced by estimated probabilities based on the parametric family. Second, the degrees of freedom are reduced by the number of parameters.

### Composite Null Hypotheses

**Example  
10.2.1**

**Failure Times of Ball Bearings.** In Example 10.1.6, we tested the null hypothesis that the logarithms of ball bearing lifetimes have the normal distribution with mean 3.912 and variance 0.25. Suppose that we are not even sure that a normal distribution is a good model for the log-lifetimes. Is there a way for us to test the composite null hypothesis that the distribution of log-lifetimes is a member of the normal family? 

We shall consider again a large population that consists of items of  $k$  different types and again let  $p_i$  denote the probability that an item selected at random will be of type  $i$  ( $i = 1, \dots, k$ ). We shall suppose now, however, that instead of testing the simple null hypothesis that the parameters  $p_1, \dots, p_k$  have specific values, we are interested in testing the composite null hypothesis that the values of  $p_1, \dots, p_k$  belong to some specified subset of possible values. In particular, we shall consider

problems in which the null hypothesis specifies that the parameters  $p_1, \dots, p_k$  can actually be represented as functions of a smaller number of parameters.

**Example  
10.2.2**

**Genetics.** Consider a gene (such as in Example 1.6.4 on page 23) that has two different alleles. Each individual in a given population must have one of three possible genotypes. If the alleles arrive independently from the two parents, and if every parent has the same probability  $\theta$  of passing the first allele to each offspring, then the probabilities  $p_1, p_2$ , and  $p_3$  of the three different genotypes can be represented in the following form:

$$p_1 = \theta^2, \quad p_2 = 2\theta(1 - \theta), \quad p_3 = (1 - \theta)^2. \quad (10.2.1)$$

Here, the value of the parameter  $\theta$  is unknown and can lie anywhere in the interval  $0 < \theta < 1$ . For each value of  $\theta$  in this interval, it can be seen that  $p_i > 0$  for  $i = 1, 2$ , or  $3$ , and  $p_1 + p_2 + p_3 = 1$ . In this problem, a random sample is taken from the population, and the statistician must use the observed numbers of individuals who have each of the three genotypes to determine whether it is reasonable to believe that there is *some* value of  $\theta$  in the interval  $0 < \theta < 1$  such that  $p_1, p_2$ , and  $p_3$  can be represented in the hypothesized form (10.2.1).

If a gene has three different alleles, each individual in the population must have one of six possible genotypes. Once again, if the alleles pass independently from the parents, and if each parent has probabilities  $\theta_1$  and  $\theta_2$  of passing the first and second alleles, respectively, to an offspring, then the probabilities  $p_1, \dots, p_6$  of the different genotypes can be represented in the following form, for *some* values of  $\theta_1$  and  $\theta_2$  such that  $\theta_1 > 0, \theta_2 > 0$ , and  $\theta_1 + \theta_2 < 1$ :

$$\begin{aligned} p_1 &= \theta_1^2, & p_2 &= \theta_2^2, & p_3 &= (1 - \theta_1 - \theta_2)^2, & p_4 &= 2\theta_1\theta_2, \\ p_5 &= 2\theta_1(1 - \theta_1 - \theta_2), & p_6 &= 2\theta_2(1 - \theta_1 - \theta_2). \end{aligned} \quad (10.2.2)$$

Again, for all values of  $\theta_1$  and  $\theta_2$  satisfying the stated conditions, it can be verified that  $p_i > 0$  for  $i = 1, \dots, 6$  and  $\sum_{i=1}^6 p_i = 1$ . On the basis of the observed numbers  $N_1, \dots, N_6$  of individuals having each genotype in a random sample, the statistician must decide whether or not to reject the null hypothesis that the probabilities  $p_1, \dots, p_6$  can be represented in the form (10.2.2) for some values of  $\theta_1$  and  $\theta_2$ . ◀

In formal terms, in a problem like those in Example 10.2.2, we are interested in testing the hypothesis that for  $i = 1, \dots, k$ , each probability  $p_i$  can be represented as a particular function  $\pi_i(\theta)$  of a vector of parameters  $\theta = (\theta_1, \dots, \theta_s)$ . It is assumed that  $s < k - 1$  and no component of the vector  $\theta$  can be expressed as a function of the other  $s - 1$  components. We shall let  $\Omega$  denote the  $s$ -dimensional parameter space of all possible values of  $\theta$ . Furthermore, we shall assume that the functions  $\pi_1(\theta), \dots, \pi_k(\theta)$  always form a feasible set of values of  $p_1, \dots, p_k$  in the sense that for every value of  $\theta \in \Omega$ ,  $\pi_i(\theta) > 0$  for  $i = 1, \dots, k$  and  $\sum_{i=1}^k \pi_i(\theta) = 1$ .

The hypotheses to be tested can be written in the following form:

$$\begin{aligned} H_0: \quad &\text{There exists a value of } \theta \in \Omega \text{ such that} \\ &p_i = \pi_i(\theta) \text{ for } i = 1, \dots, k, \\ H_1: \quad &\text{The hypothesis } H_0 \text{ is not true.} \end{aligned} \quad (10.2.3)$$

The assumption that  $s < k - 1$  guarantees that the hypothesis  $H_0$  actually restricts the values of  $p_1, \dots, p_k$  to a proper subset of the set of all possible values of these probabilities. In other words, as the vector  $\theta$  runs through all the values in the set  $\Omega$ ,

the vector  $[\pi_1(\theta), \dots, \pi_k(\theta)]$  runs through only a proper subset of the possible values of  $(p_1, \dots, p_k)$ .

### The $\chi^2$ Test for Composite Null Hypotheses

In order to carry out a  $\chi^2$  test of goodness-of-fit of the hypotheses (10.2.3), the statistic  $Q$  defined by Eq. (10.1.2) must be modified because the expected number  $np_i^0$  of observations of type  $i$  in a random sample of  $n$  observations is no longer completely specified by the null hypothesis  $H_0$ . The modification that is used is simply to replace  $np_i^0$  by the M.L.E. of this expected number under the assumption that  $H_0$  is true. In other words, if  $\hat{\theta}$  denotes the M.L.E. of the parameter vector  $\theta$  based on the observed numbers  $N_1, \dots, N_k$ , then the statistic  $Q$  is defined as follows:

$$Q = \sum_{i=1}^k \frac{[N_i - n\pi_i(\hat{\theta})]^2}{n\pi_i(\hat{\theta})}. \quad (10.2.4)$$

Again, it is reasonable to base a test of the hypotheses (10.2.3) on this statistic  $Q$  by rejecting  $H_0$  if  $Q \geq c$ , where  $c$  is an appropriate constant. In 1924, R. A. Fisher proved the following result, whose precise statement and proof are not given here. (See Schervish 1995, theorem 7.133.)

**Theorem  
10.2.1**

$\chi^2$  Test for Composite Null. Suppose that the null hypothesis  $H_0$  in (10.2.3) is true and certain regularity conditions are satisfied. Then as the sample size  $n \rightarrow \infty$ , the c.d.f. of  $Q$  in (10.2.4) converges to the c.d.f. of the  $\chi^2$  distribution with  $k - 1 - s$  degrees of freedom. ■

When the sample size  $n$  is large and the null hypothesis  $H_0$  is true, the distribution of  $Q$  will be approximately a  $\chi^2$  distribution. To determine the number of degrees of freedom, we must subtract  $s$  from the number  $k - 1$  used in Sec. 10.1 because we are now estimating the  $s$  parameters  $\theta_1, \dots, \theta_s$  when we compare the observed number  $N_i$  with the expected number  $n\pi_i(\hat{\theta})$  for  $i = 1, \dots, k$ . In order that this result will hold, it is necessary to satisfy the following regularity conditions: First, the M.L.E.  $\hat{\theta}$  of the vector  $\theta$  must occur at a point where the partial derivatives of the likelihood function with respect to each of the parameters  $\theta_1, \dots, \theta_s$  equal 0. Furthermore, these partial derivatives must satisfy certain conditions of the type alluded to in Sec. 8.8 when we discussed the asymptotic properties of M.L.E.'s.

**Example  
10.2.3**

Genetics. As examples of the use of the statistic  $Q$  defined by Eq. (10.2.4), consider the two types of genetics problems described in Example 10.2.2. In a problem of the first type,  $k = 3$ , and it is desired to test the null hypothesis  $H_0$  that the probabilities  $p_1, p_2$ , and  $p_3$  can be represented in the form (10.2.1) against the alternative  $H_1$  that  $H_0$  is not true. In this problem,  $s = 1$ . Therefore, when  $H_0$  is true, the distribution of the statistic  $Q$  defined by Eq. (10.2.4) will be approximately the  $\chi^2$  distribution with one degree of freedom.

In a problem of the second type,  $k = 6$ , and it is desired to test the null hypothesis  $H_0$  that the probabilities  $p_1, \dots, p_6$  can be represented in the form (10.2.2) against the alternative  $H_1$  that  $H_0$  is not true. In this problem,  $s = 2$ . Therefore, when  $H_0$  is true, the distribution of  $Q$  will be approximately the  $\chi^2$  distribution with three degrees of freedom. ■

### Determining the Maximum Likelihood Estimates

When the null hypothesis  $H_0$  in (10.2.3) is true, the likelihood function  $L(\theta)$  for the observed numbers  $N_1, \dots, N_k$  will be

$$L(\theta) = \binom{n}{N_1, \dots, N_k} [\pi_1(\theta)]^{N_1} \cdots [\pi_k(\theta)]^{N_k}. \quad (10.2.5)$$

Thus,

$$\log L(\theta) = \log \binom{n}{N_1, \dots, N_k} + \sum_{i=1}^k N_i \log \pi_i(\theta). \quad (10.2.6)$$

The M.L.E.  $\hat{\theta}$  will be the value of  $\theta$  for which  $\log L(\theta)$  is a maximum. The multinomial coefficient in (10.2.6) does not affect the maximization, and we shall ignore it for the remainder of this section.

**Example  
10.2.4**

Genetics. In the first parts of Examples 10.2.2 and 10.2.3,  $k = 3$  and  $H_0$  specifies that the probabilities  $p_1$ ,  $p_2$ , and  $p_3$  can be represented in the form (10.2.1). In this case,

$$\begin{aligned} \log L(\theta) &= N_1 \log(\theta^2) + N_2 \log[2\theta(1-\theta)] + N_3 \log[(1-\theta)^2] \\ &= (2N_1 + N_2) \log \theta + (2N_3 + N_2) \log(1-\theta) + N_2 \log 2. \end{aligned} \quad (10.2.7)$$

It can be found by differentiation that the value of  $\theta$  for which  $\log L(\theta)$  is a maximum is

$$\hat{\theta} = \frac{2N_1 + N_2}{2(N_1 + N_2 + N_3)} = \frac{2N_1 + N_2}{2n}. \quad (10.2.8)$$

The value of the statistic  $Q$  defined by Eq. (10.2.4) can now be calculated from the observed numbers  $N_1$ ,  $N_2$ , and  $N_3$ . As previously mentioned, when  $H_0$  is true and  $n$  is large, the distribution of  $Q$  will be approximately the  $\chi^2$  distribution with one degree of freedom. Hence, the tail area corresponding to the observed value of  $Q$  can be found from that  $\chi^2$  distribution. ◀

### Testing Whether a Distribution Is Normal

Consider now a problem in which a random sample  $X_1, \dots, X_n$  is taken from some continuous distribution for which the p.d.f. is unknown, and it is desired to test the null hypothesis  $H_0$  that this distribution is a normal distribution against the alternative hypothesis  $H_1$  that the distribution is not normal. To perform a  $\chi^2$  test of goodness-of-fit in this problem, divide the real line into  $k$  subintervals and count the number  $N_i$  of observations in the random sample that fall into the  $i$ th subinterval ( $i = 1, \dots, k$ ).

If  $H_0$  is true, and if  $\mu$  and  $\sigma^2$  denote the unknown mean and variance of the normal distribution, then the parameter vector  $\theta$  is the two-dimensional vector  $\theta = (\mu, \sigma^2)$ . The probability  $\pi_i(\theta)$ , or  $\pi_i(\mu, \sigma^2)$ , that an observation will fall within the  $i$ th subinterval, is the probability assigned to that subinterval by the normal distribution with mean  $\mu$  and variance  $\sigma^2$ . In other words, if the  $i$ th subinterval is the interval from  $a_i$  to  $b_i$ , then

$$\begin{aligned} \pi_i(\mu, \sigma^2) &= \int_{a_i}^{b_i} \frac{1}{(2\pi)^{1/2}\sigma} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] dx \\ &= \Phi\left(\frac{b_i - \mu}{\sigma}\right) - \Phi\left(\frac{a_i - \mu}{\sigma}\right), \end{aligned} \quad (10.2.9)$$

where  $\Phi(\cdot)$  is the standard normal c.d.f., and  $\Phi(-\infty) = 0$  and  $\Phi(\infty) = 1$ .

It is important to note that in order to calculate the value of the statistic  $Q$  defined by Eq. (10.2.4), the M.L.E.'s  $\hat{\mu}$  and  $\hat{\sigma}^2$  must be found by using the numbers  $N_1, \dots, N_k$  of observations in the different subintervals. The M.L.E.'s should *not* be found by using the observed values of  $X_1, \dots, X_n$  themselves. In other words,  $\hat{\mu}$  and  $\hat{\sigma}^2$  will be the values of  $\mu$  and  $\sigma^2$  that maximize the likelihood function

$$L(\mu, \sigma^2) = [\pi_1(\mu, \sigma^2)]^{N_1} \cdots [\pi_k(\mu, \sigma^2)]^{N_k}. \quad (10.2.10)$$

Because of the complicated nature of the function  $\pi_i(\mu, \sigma^2)$ , as given by Eq. (10.2.9), a lengthy numerical computation would usually be required to determine the values of  $\mu$  and  $\sigma^2$  that maximize  $L(\mu, \sigma^2)$ . On the other hand, we know that the M.L.E.'s of  $\mu$  and  $\sigma^2$  based on the  $n$  observed values  $X_1, \dots, X_n$  in the original sample are simply the sample mean  $\bar{X}_n$  and the sample variance  $S_n^2/n$ . Furthermore, if the estimators that maximize the likelihood function  $L(\mu, \sigma^2)$  are used to calculate the statistic  $Q$ , then we know that when  $H_0$  is true, the distribution of  $Q$  will be approximately the  $\chi^2$  distribution with  $k - 3$  degrees of freedom. On the other hand, if the M.L.E.'s  $\bar{X}_n$  and  $S_n^2/n$ , which are based on the observed values in the original sample, are used to calculate  $Q$ , then this  $\chi^2$  approximation to the distribution of  $Q$  will not be appropriate. Because of the simple nature of the estimators  $\bar{X}_n$  and  $S_n^2/n$ , we shall use these estimators to calculate  $Q$ , but we shall describe how their use modifies the distribution of  $Q$ .

In 1954, H. Chernoff and E. L. Lehmann established the following general result, which we shall not prove here.

**Theorem  
10.2.2**

Let  $X_1, \dots, X_n$  be a random sample from a distribution with a  $p$ -dimensional parameter  $\theta$ . Let  $\hat{\theta}_n$  denote the M.L.E. as defined in Definition 7.5.2. Partition the real line into  $k > p + 1$  disjoint intervals  $I_1, \dots, I_k$ . Let  $N_i$  be the number of observations that fall into  $I_i$  for  $i = 1, \dots, k$ . Let  $\pi_i(\theta) = \Pr(X_i \in I_i | \theta)$ . Let

$$Q' = \sum_{i=1}^k \frac{[N_i - n\pi_i(\hat{\theta}_n)]^2}{n\pi_i(\hat{\theta}_n)}. \quad (10.2.11)$$

Assume the regularity conditions needed for asymptotic normality of the M.L.E. Then, as  $n \rightarrow \infty$ , the c.d.f. of  $Q'$  converges to a c.d.f. that lies between the c.d.f. of the  $\chi^2$  distribution with  $k - p - 1$  degrees of freedom and the c.d.f. of the  $\chi^2$  distribution with  $k - 1$  degrees of freedom. ■

For the case of testing that the distribution is normal, suppose that we use the M.L.E.'s  $\bar{X}_n$  and  $S_n^2/n$  and calculate the statistic  $Q'$  in Eq. (10.2.11) instead of the statistic  $Q$  in Eq. (10.2.4). If the null hypothesis  $H_0$  is true, then as  $n \rightarrow \infty$ , the c.d.f. of  $Q'$  converges to a c.d.f. that lies between the c.d.f. of the  $\chi^2$  distribution with  $k - 3$  degrees of freedom and the c.d.f. of the  $\chi^2$  distribution with  $k - 1$  degrees of freedom. It follows that if the value of  $Q'$  is calculated in this simplified way, then the tail area corresponding to this value of  $Q'$  is actually larger than the tail area found from a table of the  $\chi^2$  distribution with  $k - 3$  degrees of freedom. In fact, the appropriate tail area lies somewhere between the tail area found from a table of the  $\chi^2$  distribution with  $k - 3$  degrees of freedom and the larger tail area found from a table of the  $\chi^2$  distribution with  $k - 1$  degrees of freedom. Thus, when the value of  $Q'$  is calculated in this simplified way, the corresponding tail area will be bounded by two values that can be obtained from a table of the  $\chi^2$  distribution.

**Example  
10.2.5**

**Failure Times of Ball Bearings.** Return to Example 10.2.1. We are now in a position to try to test the composite null hypothesis that the logarithms of ball bearing lifetimes have some normal distribution. We shall divide the real line into the same subintervals that we used in Example 10.1.6, namely,  $(-\infty, 3.575]$ ,  $(3.575, 3.912]$ ,  $(3.912, 4.249]$ , and  $(4.249, \infty)$ . The counts for the four intervals are still 3, 4, 8, and 8. We shall use Theorem 10.2.2, which allows us to use the M.L.E.'s based on the original data. This yields  $\hat{\mu} = 4.150$  and  $\hat{\sigma}^2 = 0.2722$ . The probabilities of the four intervals are

$$\begin{aligned}\pi_1(\hat{\mu}, \hat{\sigma}^2) &= \Phi\left(\frac{3.575 - 4.150}{(0.2722)^{1/2}}\right) = 0.1350, \\ \pi_2(\hat{\mu}, \hat{\sigma}^2) &= \Phi\left(\frac{3.912 - 4.150}{(0.2722)^{1/2}}\right) - \Phi\left(\frac{3.575 - 4.150}{(0.2722)^{1/2}}\right) = 0.1888, \\ \pi_3(\hat{\mu}, \hat{\sigma}^2) &= \Phi\left(\frac{4.249 - 4.150}{(0.2722)^{1/2}}\right) - \Phi\left(\frac{3.912 - 4.150}{(0.2722)^{1/2}}\right) = 0.2511, \\ \pi_4(\hat{\mu}, \hat{\sigma}^2) &= 1 - \Phi\left(\frac{4.249 - 4.150}{(0.2722)^{1/2}}\right) = 0.4251.\end{aligned}$$

This makes the value of  $Q'$  equal to

$$\begin{aligned}Q' &= \frac{(3 - 23 \times 0.1350)^2}{23 \times 0.1350} + \frac{(4 - 23 \times 0.1888)^2}{23 \times 0.1888} + \frac{(8 - 23 \times 0.2511)^2}{23 \times 0.2511} \\ &\quad + \frac{(8 - 23 \times 0.4251)^2}{23 \times 0.4251} = 1.211.\end{aligned}$$

The tail area corresponding to 1.211 needs to be computed for  $\chi^2$  distributions with  $k - 1 = 3$  and  $k - 3 = 1$  degrees of freedom. For one degree of freedom, the  $p$ -value is 0.2711, and for three degrees of freedom the  $p$ -value is 0.7504. So, our actual  $p$ -value lies in the interval  $[0.2711, 0.7504]$ . Although this interval is wide, it tells not to reject  $H_0$  at level  $\alpha_0$  if  $\alpha_0 < 0.2711$ .  $\blacktriangleleft$

**Note: Testing Composite Hypotheses about an Arbitrary Distribution.** Theorem 10.2.2 is very general and applies to both continuous and discrete distributions. Suppose, for example, that a random sample of  $n$  observations is taken from a discrete distribution for which the possible values are the nonnegative integers 0, 1, 2,  $\dots$ . Suppose also that it is desired to test the null hypothesis  $H_0$  that this distribution is a Poisson distribution against the alternative hypothesis  $H_1$  that the distribution is not Poisson. Finally, suppose that the nonnegative integers 0, 1, 2,  $\dots$  are divided into  $k$  classes such that each observation will lie in one of these classes.

It is known from Exercise 5 of Sec. 7.5 that if  $H_0$  is true, then the sample mean  $\bar{X}_n$  is the M.L.E. of the unknown mean  $\theta$  of the Poisson distribution based on the  $n$  observed values in the original sample. Therefore, if the estimator  $\hat{\theta} = \bar{X}_n$  is used to calculate the statistic  $Q'$  defined by Eq. (10.2.11) rather than the  $Q$  in Eq. (10.2.4), then the approximate distribution of  $Q'$  when  $H_0$  is true lies between the  $\chi^2$  distribution with  $k - 2$  degrees of freedom and the  $\chi^2$  distribution with  $k - 1$  degrees of freedom.

**Example  
10.2.6**

**Prussian Army Deaths.** In Example 7.3.14, we modeled the numbers of deaths by horsekick in Prussian army units as Poisson random variables. Suppose that we wish to test the null hypothesis that the numbers are a random sample from some Poisson

distribution versus the alternative hypothesis that they are not a Poisson random sample. The numbers of counts reported in Example 7.3.14 are repeated here:

Count	0	1	2	3	$\geq 4$
Number of Observations	144	91	32	11	2

The likelihood function, assuming that the data form a random sample from a Poisson distribution, is proportional (as a function of  $\theta$ ) to  $\exp(-280\theta)\theta^{196}$ . The M.L.E. is  $\hat{\theta}_n = 196/280 = 0.7$ . We can use the  $k = 5$  classes above to compute the statistic  $Q'$ . The five class probabilities are

Count	0	1	2	3	$\geq 4$
$\pi_i(\hat{\theta}_n)$	0.4966	0.3476	0.1217	0.0283	0.0058

Then

$$\begin{aligned} Q' &= \frac{(144 - 280 \times 0.4966)^2}{280 \times 0.4966} + \frac{(91 - 280 \times 0.3476)^2}{280 \times 0.3476} + \frac{(32 - 280 \times 0.1217)^2}{280 \times 0.1217} \\ &\quad + \frac{(11 - 280 \times 0.0283)^2}{280 \times 0.0283} + \frac{(2 - 280 \times 0.0058)^2}{280 \times 0.0058} = 1.979. \end{aligned}$$

The tail areas corresponding to the observed  $Q'$  and degrees of freedom four and three are, respectively, 0.7396 and 0.5768. We would not be able to reject  $H_0$  at level  $\alpha_0$  for  $\alpha_0 < 0.5768$ .  $\blacktriangleleft$

## Summary

If we want to test the composite hypothesis that our data have a distribution from a parametric family, we must estimate the parameter  $\theta$ . We do this by first dividing the real numbers into  $k$  disjoint intervals. Then we reduce the data to the counts  $N_1, \dots, N_k$  of how many observations fall into each of the  $k$  intervals. We then construct the likelihood function  $L(\theta) = \prod_{i=1}^k \pi_i(\theta)^{N_i}$ , where  $\pi_i(\theta)$  is the probability that one observation falls into the  $i$ th interval. We estimate  $\theta$  to be the value  $\hat{\theta}$  that maximizes  $L(\theta)$ . We then compute the test statistic  $Q = \sum_{i=1}^k [N_i - n\pi_i(\hat{\theta})]^2/[n\pi_i(\hat{\theta})]$ , which has the form  $\sum(\text{observed} - \text{expected})^2/\text{expected}$ . In order to test the null hypothesis at level  $\alpha_0$ , we compare  $Q$  to the  $1 - \alpha_0$  quantile of the  $\chi^2$  distribution with  $k - 1 - s$  degrees of freedom, where  $s$  is the dimension of  $\theta$ . Alternatively, we can find the usual M.L.E.  $\hat{\theta}$  based on the original observations. In this case, we need to compare  $Q$  to a number between the  $1 - \alpha_0$  quantile of the  $\chi^2$  distribution with  $k - 1 - s$  degrees of freedom and the  $1 - \alpha_0$  quantile of the  $\chi^2$  distribution with  $k - 1$  degrees of freedom.

## Exercises

---

**1.** The 41 numbers in Table 10.6 are average sulfur dioxide contents over the years 1969–71 (micrograms per cubic meter) measured in the air in 41 U.S. cities. The data appear on pp. 619–620 of Sokal and Rohlf (1981).

- a.** Test the null hypothesis that these data arise from a normal distribution.
- b.** Test the null hypothesis that these data arise from a lognormal distribution.

**Table 10.6** Sulfur dioxide in the air of 41 U.S. cities

10	13	12	17	56	36	29
14	10	24	110	28	17	8
30	9	47	35	29	14	56
14	11	46	11	23	65	26
69	61	94	10	18	9	10
28	31	26	29	31	16	

**2.** At the fifth hockey game of the season at a certain arena, 200 people were selected at random and asked how many of the previous four games they had attended. The results are given in Table 10.7. Test the hypothesis that these 200 observed values can be regarded as a random sample from a binomial distribution; that is, there exists a number  $\theta$  ( $0 < \theta < 1$ ) such that the probabilities are as follows:

$$\begin{aligned} p_0 &= (1 - \theta)^4, & p_1 &= 4\theta(1 - \theta)^3, & p_2 &= 6\theta^2(1 - \theta)^2, \\ p_3 &= 4\theta^3(1 - \theta), & p_4 &= \theta^4. \end{aligned}$$

**Table 10.7** Data for Exercise 2

Number of games previously attended	Number of people
0	33
1	67
2	66
3	15
4	19

**3.** Consider a genetics problem in which each individual in a certain population must have one of six genotypes, and it is desired to test the null hypothesis  $H_0$  that the probabilities of the six genotypes can be represented in the form specified in Eq. (10.2.2).

- a.** Suppose that in a random sample of  $n$  individuals, the observed numbers of individuals having the six

genotypes are  $N_1, \dots, N_6$ . Find the M.L.E.'s of  $\theta_1$  and  $\theta_2$  when the null hypothesis  $H_0$  is true.

- b.** Suppose that in a random sample of 150 individuals, the observed numbers are as follows:

$$\begin{aligned} N_1 &= 2, & N_2 &= 36, & N_3 &= 14, & N_4 &= 36, \\ N_5 &= 20, & N_6 &= 42. \end{aligned}$$

Determine the value of  $Q$  and the corresponding tail area.

**4.** Consider again the sample consisting of the heights of 500 men given in Exercise 8 of Sec. 10.1. Suppose that before these heights were grouped into the intervals given in that exercise, it was found that for the 500 observed heights in the original sample, the sample mean was  $\bar{X}_n = 67.6$  and the sample variance was  $S_n^2/n = 1.00$ . Test the hypothesis that these observed heights form a random sample from a normal distribution.

**5.** In a large city, 200 persons were selected at random, and each person was asked how many tickets he purchased that week in the state lottery. The results are given in Table 10.8. Suppose that among the seven persons who had purchased five or more tickets, three persons had purchased exactly five tickets, two persons had purchased six tickets, one person had purchased seven tickets, and one person had purchased 10 tickets. Test the hypothesis that these 200 observations form a random sample from a Poisson distribution.

**Table 10.8** Data for Exercise 5

Number of tickets previously purchased	Number of persons
0	52
1	60
2	55
3	18
4	8
5 or more	7

**6.** Rutherford and Geiger (1910) counted the numbers of alpha particles emitted by a certain mass of polonium during 2608 disjoint time periods, each of which lasted 7.5 seconds. The results are given in Table 10.9. Test the hypothesis that these 2608 observations form a random sample from a Poisson distribution.

**Table 10.9** Data for Exercise 6 from Rutherford and Geiger (1910)

Number of particles emitted	Number of time periods

## 10.3 Contingency Tables

When each observation in our sample is a bivariate discrete random vector (a pair of discrete random variables), then there is a simple way to test the hypothesis that the two random variables are independent. The test is another form of  $\chi^2$  test like the ones used earlier in this chapter.

### Independence in Contingency Tables

#### Example 10.3.1

**College Survey.** Suppose that 200 students are selected at random from the entire enrollment at a large university, and each student in the sample is classified both according to the curriculum in which he is enrolled and according to his preference for either of two candidates *A* and *B* in a forthcoming election. Suppose that the results are as presented in Table 10.12. We might be interested in whether the choices of

**Table 10.12** Classification of students by curriculum and candidate preference

Curriculum	Candidate preferred			Totals
	A	B	Undecided	
Engineering and science	24	23	12	59
Humanities and social sciences	24	14	10	48
Fine arts	17	8	13	38
Industrial and public administration	27	19	9	55
Totals	92	64	44	200

curriculum and candidate are independent of each other. To be more precise, suppose that a student is selected at random from the entire enrollment at the university. Independence means that for each  $i$  and  $j$ , the probability that such a randomly chosen student prefers candidate  $j$  and is in curriculum  $i$  equals the product of the probability that he prefers candidate  $j$  times the probability that he is enrolled in curriculum  $i$ .  $\blacktriangleleft$

Tables of data like Table 10.12 are very common and have a special name.

**Definition 10.3.1** **Contingency Tables.** A table in which each observation is classified in two or more ways is called a *contingency table*.

In Table 10.12, only two classifications are considered for each student, namely, the curriculum in which he is enrolled and the candidate he prefers. Such a table is called a *two-way contingency table*.

In general, we shall consider a two-way contingency table containing  $R$  rows and  $C$  columns. For  $i = 1, \dots, R$  and  $j = 1, \dots, C$ , we shall let  $p_{ij}$  denote the probability that an individual selected at random from a given population will be classified in the  $i$ th row and the  $j$ th column of the table. Furthermore, we shall let  $p_{i+}$  denote the marginal probability that the individual will be classified in the  $i$ th row of the table and  $p_{+j}$  denote the marginal probability that the individual will be classified in the  $j$ th column of the table. Thus,

$$p_{i+} = \sum_{j=1}^C p_{ij} \quad \text{and} \quad p_{+j} = \sum_{i=1}^R p_{ij}.$$

Furthermore, since the sum of the probabilities for all the cells of the table must be 1, we have

$$\sum_{i=1}^R \sum_{j=1}^C p_{ij} = \sum_{i=1}^R p_{i+} = \sum_{j=1}^C p_{+j} = 1.$$

Suppose now that a random sample of  $n$  individuals is taken from the given population. For  $i = 1, \dots, R$ , and  $j = 1, \dots, C$ , we shall let  $N_{ij}$  denote the number of individuals who are classified in the  $i$ th row and the  $j$ th column of the table. Furthermore, we shall let  $N_{i+}$  denote the total number of individuals classified in the  $i$ th row and  $N_{+j}$  denote the total number of individuals classified in the  $j$ th column.

Thus,

$$N_{i+} = \sum_{j=1}^C N_{ij} \quad \text{and} \quad N_{+j} = \sum_{i=1}^R N_{ij}. \quad (10.3.1)$$

Also,

$$\sum_{i=1}^R \sum_{j=1}^C N_{ij} = \sum_{i=1}^R N_{i+} = \sum_{j=1}^C N_{+j} = n. \quad (10.3.2)$$

On the basis of these observations, the following hypotheses are to be tested:

$$\begin{aligned} H_0: \quad p_{ij} &= p_{i+} p_{+j} \quad \text{for } i = 1, \dots, R \text{ and } j = 1, \dots, C, \\ H_1: \quad \text{The hypothesis } H_0 &\text{ is not true.} \end{aligned} \quad (10.3.3)$$

### The $\chi^2$ Test of Independence

The  $\chi^2$  tests described in Sec. 10.2 can be applied to the problem of testing the hypotheses (10.3.3). Each individual in the population from which the sample is taken must belong in one of the  $RC$  cells of the contingency table. Under the null hypothesis  $H_0$ , the unknown probabilities  $p_{ij}$  of these cells have been expressed as functions of the unknown parameters  $p_{i+}$  and  $p_{+j}$ . Since  $\sum_{i=1}^R p_{i+} = 1$  and  $\sum_{j=1}^C p_{+j} = 1$ , the actual number of unknown parameters to be estimated when  $H_0$  is true is  $s = (R - 1) + (C - 1)$ , or  $s = R + C - 2$ .

For  $i = 1, \dots, R$ , and  $j = 1, \dots, C$ , let  $\hat{E}_{ij}$  denote the M.L.E., when  $H_0$  is true, of the expected number of observations that will be classified in the  $i$ th row and the  $j$ th column of the table. In this problem, the statistic  $Q$  defined by Eq. (10.2.4) will have the following form:

$$Q = \sum_{i=1}^R \sum_{j=1}^C \frac{(N_{ij} - \hat{E}_{ij})^2}{\hat{E}_{ij}}. \quad (10.3.4)$$

Furthermore, since the contingency table contains  $RC$  cells, and since  $s = R + C - 2$  parameters are to be estimated when  $H_0$  is true, it follows that when  $H_0$  is true and  $n \rightarrow \infty$ , the c.d.f. of  $Q$  converges to the c.d.f. of the  $\chi^2$  distribution for which the number of degrees of freedom is  $RC - 1 - s = (R - 1)(C - 1)$ .

Next, we shall consider the form of the estimator  $\hat{E}_{ij}$ . The expected number of observations in the  $i$ th row and the  $j$ th column is simply  $np_{ij}$ . When  $H_0$  is true,  $p_{ij} = p_{i+} p_{+j}$ . Therefore, if  $\hat{p}_{i+}$  and  $\hat{p}_{+j}$  denote the M.L.E.'s of  $p_{i+}$  and  $p_{+j}$ , then it follows that  $\hat{E}_{ij} = n\hat{p}_{i+}\hat{p}_{+j}$ . Next, since  $p_{i+}$  is the probability that an observation will be classified in the  $i$ th row,  $\hat{p}_{i+}$  is simply the proportion of observations in the sample that are classified in the  $i$ th row; that is,  $\hat{p}_{i+} = N_{i+}/n$ . Similarly,  $\hat{p}_{+j} = N_{+j}/n$ , and it follows that

$$\hat{E}_{ij} = n \left( \frac{N_{i+}}{n} \right) \left( \frac{N_{+j}}{n} \right) = \frac{N_{i+} N_{+j}}{n}. \quad (10.3.5)$$

If we substitute this value of  $\hat{E}_{ij}$  into Eq. (10.3.4), we can calculate the value of  $Q$  from the observed values of  $N_{ij}$ . The null hypothesis  $H_0$  should be rejected if  $Q \geq c$ , where  $c$  is an appropriately chosen constant. When  $H_0$  is true, and the sample size  $n$  is large, the distribution of  $Q$  will be approximately the  $\chi^2$  distribution with  $(R - 1)(C - 1)$  degrees of freedom.

**Example  
10.3.2**

**College Survey.** Suppose that we wish to test the hypotheses (10.3.3) on the basis of the data in Table 10.12. By using the totals given in the table, we find that  $N_{1+} = 59$ ,  $N_{2+} = 48$ ,  $N_{3+} = 38$ , and  $N_{4+} = 55$ , and also  $N_{+1} = 92$ ,  $N_{+2} = 64$ , and  $N_{+3} = 44$ . Because  $n = 200$ , it follows from Eq. (10.3.5) that the  $4 \times 3$  table of values of  $\hat{E}_{ij}$  is as shown in Table 10.13.

The values of  $N_{ij}$  given in Table 10.12 can now be compared with the values of  $\hat{E}_{ij}$  in Table 10.13. The value of  $Q$  defined by Eq. (10.3.4) turns out to be 6.68. Since  $R = 4$  and  $C = 3$ , the corresponding tail area is to be found from a table of the  $\chi^2$  distribution with  $(R - 1)(C - 1) = 6$  degrees of freedom. Its value is larger than 0.3. Therefore, we would only reject  $H_0$  at level  $\alpha_0$  if  $\alpha_0 \geq 0.3$ .  $\blacktriangleleft$

**Example  
10.3.3**

**Montana Outlook Poll.** In Example 10.1.4, we examined the surveyed opinions of Montana residents on their personal financial status. Another question that survey participants were asked was an income range. Table 10.14 gives a cross-tabulation of the answers to both questions. We can use the  $\chi^2$  test to test the null hypothesis that income is independent of opinion on personal financial status. Table 10.15 gives the expected counts for each cell of Table 10.14 under the null hypothesis. We can now compute the test statistic  $Q = 5.210$  with  $(3 - 1) \times (3 - 1) = 4$  degrees of freedom. The  $p$ -value associated with this value of  $Q$  is 0.266, so we would only reject the null hypothesis at a level  $\alpha_0$  greater than 0.266.  $\blacktriangleleft$

**Table 10.14** Responses to two questions from Montana Outlook Poll

Income range	Personal financial status			Total
	Worse	Same	Better	
Under \$20,000	20	15	12	47
\$20,000–\$35,000	24	27	32	83
Over \$35,000	14	22	23	59
Total	58	64	67	189

**Table 10.15** Expected cell counts for Table 10.14 under the assumption of independence

Income range	Personal financial status			Total
	Worse	Same	Better	
Under \$20,000	14.42	15.92	16.66	47
\$20,000–\$35,000	25.47	28.11	29.42	83
Over \$35,000	18.11	19.98	20.92	59
Total	58	64	67	189

## Summary

We learned how to test the null hypothesis that two discrete random variables are independent based on a random sample of  $n$  pairs. First, form a contingency table of the counts for every pair of possible observed values. Then, estimate the two marginal distributions of the two random variables. Under the null hypothesis that the random variables are independent, the expected count for value  $i$  of the first variable and value  $j$  of the second variable is  $n$  times the product of the two estimated marginal probabilities. We then form the  $\chi^2$  statistic  $Q$  by summing  $(\text{observed} - \text{expected})^2/\text{expected}$  over all of the cells in the contingency table. The degrees of freedom is  $(R - 1)(C - 1)$ , where  $R$  is the number of rows in the table and  $C$  is the number of columns.

## Exercises

---

1. Chase and Dummer (1992) studied the attitudes of school-aged children in Michigan. The children were asked which of the following was most important to them: good grades, athletic ability, or popularity. Additional information about each child was also collected, and Table 10.16 shows the results for 478 children classified by sex and their response to the survey question. Test the null hypothesis that a child's answer to the survey question is independent of his or her sex.

**Table 10.16** Data for Exercise 1 from Chase and Dummer (1992)

	Good grades	Athletic ability	Popularity
Boys	117	60	50
Girls	130	30	91

2. Show that the statistic  $Q$  defined by Eq. (10.3.4) can be rewritten in the form

$$Q = \left( \sum_{i=1}^R \sum_{j=1}^C \frac{N_{ij}^2}{\hat{E}_{ij}} \right) - n.$$

3. Show that if  $C = 2$ , the statistic  $Q$  defined by Eq. (10.3.4) can be rewritten in the form

$$Q = \frac{n}{N_{+2}} \left( \sum_{i=1}^R \frac{N_{i1}^2}{\hat{E}_{i1}} - N_{+1} \right).$$

4. Suppose that an experiment is carried out to see if there is any relation between a man's age and whether he wears a moustache. Suppose that 100 men, 18 years of age or older, are selected at random, and each man is classified according to whether or not he is between 18 and 30 years of age and also according to whether or not he wears a moustache. The observed numbers are given in Table 10.17. Test the hypothesis that there is no relationship between a man's age and whether he wears a moustache.

**Table 10.17** Data for Exercise 4

	Wears a moustache	Does not wear a moustache
Between 18 and 30	12	28
Over 30	8	52

5. Suppose that 300 persons are selected at random from a large population, and each person in the sample is classified according to blood type,  $O$ ,  $A$ ,  $B$ , or  $AB$ , and also according to  $Rh$ , positive or negative. The observed numbers are given in Table 10.18. Test the hypothesis that the two classifications of blood types are independent.

**Table 10.18** Data for Exercise 5

	$O$	$A$	$B$	$AB$
$Rh$ positive	82	89	54	19
$Rh$ negative	13	27	7	9

6. Suppose that a store carries two different brands,  $A$  and  $B$ , of a certain type of breakfast cereal. Suppose that during a one-week period the store noted whether each package of this type of cereal that was purchased was brand  $A$  or brand  $B$  and also noted whether the purchaser was a man or a woman. (A purchase made by a child or by a man and a woman together was not counted.) Suppose that 44 packages were purchased, and that the results were as shown in Table 10.19. Test the hypothesis that the brand purchased and the sex of the purchaser are independent.

**Table 10.19** Data for Exercise 6

	Brand A	Brand B
Men	9	6
Women	13	16

7. Consider a two-way contingency table with three rows and three columns. Suppose that, for  $i = 1, 2, 3$  and  $j = 1, 2, 3$ , the probability  $p_{ij}$  that an individual selected at random from a given population will be classified in the  $i$ th row and the  $j$ th column of Table 10.20.

**Table 10.20** Data for Exercise 7

0.15	0.09	0.06
0.15	0.09	0.06
0.20	0.12	0.08

- a. Show that the rows and columns of this table are independent by verifying that the values  $p_{ij}$  satisfy

the null hypothesis  $H_0$  in Eq. (10.3.3).

- b. Generate a random sample of 300 observations from the given population using a uniform pseudo-random number generator. Select 300 pseudo-random numbers between 0 and 1 and proceed as follows: Since  $p_{11} = 0.15$ , classify a pseudo-random number  $x$  in the first cell if  $x < 0.15$ . Since  $p_{11} + p_{12} = 0.24$ , classify a pseudo-random number  $x$  in the second cell if  $0.15 \leq x < 0.24$ . Continue in this way for all nine cells. For example, since the sum of all probabilities except  $p_{33}$  is 0.92, a pseudo-random number  $x$  will be classified in the lower-right cell of the table if  $x \geq 0.92$ .
- c. Consider the  $3 \times 3$  table of observed values  $N_{ij}$  generated in part (b). Pretend that the probabilities  $p_{ij}$  were unknown, and test the hypotheses (10.3.3).
8. If all the students in a class carry out Exercise 7 independently of each other and use different pseudo-random numbers, then the different values of the statistic  $Q$  obtained by the different students should form a random sample from the  $\chi^2$  distribution with four degrees of freedom. If the values of  $Q$  for all the students in the class are available to you, test the hypothesis that these values form such a random sample.

9. Consider a three-way contingency table of size  $R \times C \times T$ . For  $i = 1, \dots, R$ ,  $j = 1, \dots, C$ , and  $k = 1, \dots, T$ , let  $p_{ijk}$  denote the probability that an individual selected at random from a given population will fall into the  $(i, j, k)$  cell of the table. Let

$$p_{i++} = \sum_{j=1}^C \sum_{k=1}^T p_{ijk}, \quad p_{+j+} = \sum_{i=1}^R \sum_{k=1}^T p_{ijk},$$

$$p_{++k} = \sum_{i=1}^R \sum_{j=1}^C p_{ijk}.$$

On the basis of a random sample of  $n$  observations from the given population, construct a test of the following hypotheses:

$$H_0: p_{ijk} = p_{i++}p_{+j+}p_{++k} \text{ for all values of } i, j, \text{ and } k,$$

$H_1$ : The hypothesis  $H_0$  is not true.

10. Consider again the conditions of Exercise 9. For  $i = 1, \dots, R$ , and  $j = 1, \dots, C$ , let

$$p_{ij+} = \sum_{k=1}^T p_{ijk}.$$

On the basis of a random sample of  $n$  observations from the given population, construct a test of the following hypotheses:

$$H_0: p_{ijk} = p_{ij+}p_{+jk}p_{++k} \text{ for all values of } i, j, \text{ and } k,$$

$H_1$ : The hypothesis  $H_0$  is not true.

## 10.4 Tests of Homogeneity

*Imagine that we select subjects from several different populations, and that we observe a discrete random variable for each subject. We might be interested in whether or not the distribution of that discrete random variable is the same in each population. There is a  $\chi^2$  test of this hypothesis that is very similar to the  $\chi^2$  test of independence.*

### Samples from Several Populations

**Example  
10.4.1**

**College Survey.** Consider again the problem described in Example 10.3.1. There we assumed that a random sample of 200 students was drawn from the entire enrollment at a large university and classified in a contingency table according to the curriculum in which he is enrolled and according to his preference for either of two political candidates *A* and *B*. The resulting table appears in Table 10.12.

Suppose, now, that instead of sampling 200 students at random, we had actually sampled separately from each of the four curricula. That is, suppose that we had sampled 59 students at random from those enrolled in engineering and science along with 48 students selected at random from those enrolled in humanities and social sciences and 38 from those enrolled in fine arts and 55 from those enrolled in industrial and public administration. After the students are sampled, those in each curriculum are then classified according to whether they prefer candidate *A* or *B*, or are undecided. Suppose that the responses within each curriculum are the same as those reported in Table 10.12.

We might still be interested in investigating whether there is a relationship between the curriculum in which a student is enrolled and the candidate he prefers. This time, we might word the question of interest as follows: Are the distributions of candidate preferences within the different curricula the same or do the students in different curricula have different distributions of preferences among the candidates? ▶

In Example 10.4.1, we are assuming that we have obtained a table of values identical to Table 10.12; we are assuming now that this table was obtained by taking four different random samples from the different populations of students defined by the four rows of the table. This is in contrast to Example 10.3.1, in which we assumed that all students were drawn from one population and then classified according to the values of two variables: preference and curriculum. In the present context, we are interested in testing the hypothesis that, in all four populations, the same proportion of students prefers candidate *A*, the same proportion prefers candidate *B*, and the same proportion is undecided.

In general, we shall consider a problem in which random samples are taken from *R* different populations, and each observation in each sample can be classified as one of *C* different types. Thus, the data obtained from the *R* samples can be represented in an  $R \times C$  table. For  $i = 1, \dots, R$ , and  $j = 1, \dots, C$ , we shall let  $p_{ij}$  denote the probability that an observation chosen at random from the *i*th population will be of type *j*. Thus,

$$\sum_{j=1}^C p_{ij} = 1 \quad \text{for } i = 1, \dots, R.$$

The hypotheses to be tested are as follows:

$$\begin{aligned} H_0: \quad p_{1j} = p_{2j} = \cdots = p_{Rj} & \quad \text{for } j = 1, \dots, C, \\ H_1: \quad \text{The hypothesis } H_0 & \text{ is not true.} \end{aligned} \tag{10.4.1}$$

The null hypothesis  $H_0$  in (10.4.1) states that all the distributions from which the  $R$  different samples are drawn are actually alike, that is, that the  $R$  distributions are identical. If the null hypothesis in (10.4.1) were true, then combining the  $R$  populations would produce one homogeneous population with regard to the distribution of the random variables we are studying. For this reason, a test of the hypotheses (10.4.1) is called a *test of homogeneity* of the  $R$  distributions.

For  $i = 1, \dots, R$ , we shall let  $N_{i+}$  denote the number of observations in the random sample from the  $i$ th population; for  $j = 1, \dots, C$ , we shall let  $N_{ij}$  denote the number of observations in this random sample that are of type  $j$ . Thus,

$$\sum_{j=1}^C N_{ij} = N_{i+} \quad \text{for } i = 1, \dots, R.$$

Furthermore, if we let  $n$  denote the total number of observations in all  $R$  samples and  $N_{+j}$  denote the total number of observations of type  $j$  in the  $R$  samples, then all the relations in Eqs. (10.3.1) and (10.3.2) will again be satisfied.

### The $\chi^2$ Test of Homogeneity

We shall now develop a test procedure for the hypotheses (10.4.1). Suppose for the moment that the probabilities  $p_{ij}$  are known, and consider the following statistic calculated from the observations in the  $i$ th random sample:

$$\sum_{j=1}^C \frac{(N_{ij} - N_{i+}p_{ij})^2}{N_{i+}p_{ij}}.$$

This statistic is just the standard  $\chi^2$  statistic, introduced in Eq. (10.1.2), for the random sample of  $N_{i+}$  observations from the  $i$ th population. Therefore, when the sample size  $N_{i+}$  is large, the distribution of this statistic will be approximately the  $\chi^2$  distribution with  $C - 1$  degrees of freedom.

If we now sum this statistic over the  $R$  different samples, we obtain the following statistic:

$$\sum_{i=1}^R \sum_{j=1}^C \frac{(N_{ij} - N_{i+}p_{ij})^2}{N_{i+}p_{ij}}. \tag{10.4.2}$$

Since the observations in the  $R$  samples are drawn independently, the distribution of the statistic (10.4.2) will be the distribution of the sum of  $R$  independent random variables, each of which has approximately the  $\chi^2$  distribution with  $C - 1$  degrees of freedom. Hence, the distribution of the statistic (10.4.2) will be approximately the  $\chi^2$  distribution with  $R(C - 1)$  degrees of freedom.

Since the probabilities  $p_{ij}$  are not actually known, their values must be estimated from the observed numbers in the  $R$  random samples. When the null hypothesis  $H_0$  is true, the  $R$  random samples are actually drawn from the same distribution. Therefore, the M.L.E. of the probability that an observation in each of these samples will be of type  $j$  is simply the proportion of all the observations in the  $R$  samples that are of type  $j$ . In other words, the M.L.E. of  $p_{ij}$  is the same for all values of  $i$  ( $i = 1, \dots, R$ ), and this estimator is  $\hat{p}_{ij} = N_{+j}/n$ . When this M.L.E. is substituted into (10.4.2), we

obtain the statistic

$$Q = \sum_{i=1}^R \sum_{j=1}^C \frac{(N_{ij} - \hat{E}_{ij})^2}{\hat{E}_{ij}}, \quad (10.4.3)$$

where

$$\hat{E}_{ij} = \frac{N_{i+} N_{+j}}{n}. \quad (10.4.4)$$

It can be seen that Eqs. (10.4.3) and (10.4.4) are precisely the same as Eqs. (10.3.4) and (10.3.5). Thus, the statistic  $Q$  to be used for the test of homogeneity in this section is precisely the same as the statistic  $Q$  to be used for the test of independence in Sec. 10.3. We shall now show that the number of degrees of freedom is also precisely the same for the test of homogeneity as for the test of independence.

Because the distributions of the  $R$  populations are alike when  $H_0$  is true, and because  $\sum_{j=1}^C p_{ij} = 1$  for this common distribution, we have estimated  $C - 1$  parameters in this problem. Therefore, the statistic  $Q$  will have approximately the  $\chi^2$  distribution with  $R(C - 1) - (C - 1) = (R - 1)(C - 1)$  degrees of freedom. This number is the same as that found in Sec. 10.3.

In summary, consider Table 10.12 again. The statistical analysis of this table will be the same for either of the following two procedures: The 200 observations are drawn as a single random sample from the entire enrollment of the university, and a test of independence is carried out; or the 200 observations are drawn as separate random samples from four different groups of students, and a test of homogeneity is carried out. In either case, in a problem of this type with  $R$  rows and  $C$  columns, we should calculate the statistic  $Q$  defined by Eqs. (10.4.3) and (10.4.4), and we should assume that its distribution when  $H_0$  is true will be approximately the  $\chi^2$  distribution with  $(R - 1)(C - 1)$  degrees of freedom.

**Note: Why the two  $\chi^2$  tests look so similar.** The reason that the same calculation is appropriate for both the  $\chi^2$  test of independence and the  $\chi^2$  test of homogeneity is the following: First, consider the situation of Sec. 10.3, in which one sample is drawn and the random variables corresponding to rows and columns are measured. Independence of the row and column variables is equivalent to the conditional distribution of the column variable given a value of the row variable being the same for every value of the row variable. Hence, the test of independence tests that the conditional distributions of the column variable are the same for each value of the row variable. Next, think of the row variable as defining subpopulations (for example, different curricula in Table 10.12). The conditional distributions of the column variable given each value of the row variable are the distributions of the column variable within each subpopulation. The test of homogeneity tests that the distributions within the subpopulations are the same if the samples had been drawn separately from each subpopulation rather than drawn at random from the entire population.

## Comparing Two or More Proportions

### Example 10.4.2

**Television Survey.** Suppose that independent samples are drawn from adults in several cities. Each sampled person is asked whether or not they watched a particular television program. Suppose that we want to test the null hypothesis  $H_0$  that the proportion of adults who watched a certain television program was the same in each of the cities. To be specific, suppose that there are  $R$  different cities ( $R \geq 2$ ). Suppose

<b>Table 10.21</b> Form of table for comparing two or more proportions			
City	Watched program	Did not watch	Sample size
1	$N_{11}$	$N_{12}$	$N_{1+}$
2	$N_{21}$	$N_{22}$	$N_{2+}$
$\vdots$			
$R$	$N_{R1}$	$N_{R2}$	$N_{R+}$

that for  $i = 1, \dots, R$ , a random sample of  $N_{i+}$  adults is selected from city  $i$ , the number in the sample who watched the program is  $N_{i1}$ , and the number who did not watch the program is  $N_{i2} = N_{i+} - N_{i1}$ . These data can be presented in an  $R \times 2$  table such as Table 10.21. The hypotheses to be tested will have the same form as the hypotheses (10.4.1). Hence, when the null hypothesis  $H_0$  is true, that is, when the proportion of adults who watched the program is the same in all  $R$  cities, the statistic  $Q$  defined by Eqs. (10.4.3) and (10.4.4) will have approximately the  $\chi^2$  distribution with  $R - 1$  degrees of freedom.  $\blacktriangleleft$

The reasoning in Example 10.4.2 extends to other problems in which we wish to compare a collection of proportions.

**Example  
10.4.3**

A Clinical Trial. The data in Table 2.1 (see Example 2.1.4 on page 57) are the numbers of subjects in four different treatment groups in a clinical trial together with the numbers who did or did not relapse after treatment. We might wish to test the null hypothesis that the probability of no relapse is the same in all four treatment groups. We can easily compute the statistic  $Q$  in Eq. (10.4.3) to be 10.80. This is the 0.987 quantile of the  $\chi^2$  distribution with three degrees of freedom. That is, the  $p$ -value is 0.013, and the null hypothesis of equal probabilities would be rejected at every level  $\alpha_0 \geq 0.013$ .  $\blacktriangleleft$

## Correlated $2 \times 2$ Tables

We shall now describe a type of problem in which the use of the  $\chi^2$  test of homogeneity would not be appropriate. Suppose that 100 persons were selected at random in a certain city, and that each person was asked whether she thought the service provided by the fire department in the city was satisfactory. Shortly after this survey was carried out, a large fire occurred in the city. Suppose that after this fire, the same 100 persons were again asked whether they thought that the service provided by the fire department was satisfactory. The results are presented in Table 10.22.

Table 10.22 has the same general appearance as other tables we have been considering in this section. However, it would not be appropriate to carry out a  $\chi^2$  test of homogeneity for this table, because the observations taken before the fire and the observations taken after the fire are not independent. Although the total number of observations in Table 10.22 is 200, only 100 independently chosen persons were questioned in the surveys. It is reasonable to believe that a particular person's

**Table 10.22** Correlated  $2 \times 2$  table

	Satisfactory	Unsatisfactory
Before the fire	80	20
After the fire	72	28

**Table 10.23**  $2 \times 2$  table for correlated responses

		After the fire	
		Satisfactory	Unsatisfactory
Before the fire	Satisfactory	70	10
	Unsatisfactory	2	18

opinion before the fire and her opinion after the fire are dependent. For this reason, Table 10.22 is called a correlated  $2 \times 2$  table.

The proper way to display the opinions of the 100 persons in the random sample is shown in Table 10.23. It is not possible to construct Table 10.23 from the data in Table 10.22 alone. The entries in Table 10.22 are simply the marginal totals of Table 10.23. However, in order to construct Table 10.23, it is necessary to go back to the original data and, for each person in the sample, to consider her opinion before the fire and her opinion after the fire.

Furthermore, it usually is not appropriate to carry out either a  $\chi^2$  test of independence or a  $\chi^2$  test of homogeneity for Table 10.23, because the hypotheses that are tested by either of these procedures usually are not those in which a researcher would be interested in this type of problem. In fact, in this problem a researcher would basically be interested in the answers to one or both of the following two questions: First, what proportion of the persons in the city changed their opinions about the fire department after the fire occurred? Second, among those persons in the city who did change their opinions after the fire, were the changes predominantly in one direction rather than the other?

Table 10.23 provides information pertaining to both these questions. According to Table 10.23, the number of persons in the sample who changed their opinions after the fire was  $10 + 2 = 12$ . Furthermore, among the 12 persons who did change their opinions, the opinions of 10 of them were changed from satisfactory to unsatisfactory and the opinions of two of them were changed from unsatisfactory to satisfactory. On the basis of these statistics, it is possible to make inferences about the corresponding proportions for the entire population of the city.

In this example, the M.L.E.  $\hat{\theta}$  of the proportion of the population who changed their opinions after the fire is 0.12. Also, among those who did change their opinions, the M.L.E.  $\hat{p}_{12}$  of the proportion who changed from satisfactory to unsatisfactory is  $5/6$ . Of course, if  $\hat{\theta}$  is very small in a particular problem, then there is little interest in the value of  $\hat{p}_{12}$ .

## Summary

When we sample discrete random variables from several populations, we might be interested in the null hypothesis that the distribution of the random variables is the same in all populations. We can perform a  $\chi^2$  test of this null hypothesis as follows: Create a new variable with values equal to the names of the different populations. Next, pretend as if each observation consists of the original discrete random variable together with the new “population name” variable. Finally, compute the  $\chi^2$  test statistic  $Q$  from Sec. 10.3 with the same degrees of freedom. For the type of data considered in this section, the “population name” for each observation is known before sampling begins, and hence it is not a random variable. Whether the population name is known ahead of time or is observed as part of the sampled data (as in Sec. 10.3), the mechanics of the  $\chi^2$  test are the same.

## Exercises

- 1.** The survey of Chase and Dummer (1992) discussed in Exercise 1 of Sec. 10.3 was actually collected by sampling from three subpopulations according to the locations of the schools: rural, suburban, and urban. Table 10.24 shows the responses to the survey question classified by school location. Test the null hypothesis that the distribution of responses is the same in all three types of school location.

**Table 10.24** Data for Exercise 1 from Chase and Dummer (1992)

	Good grades	Athletic ability	Popularity
Rural	57	42	50
Suburban	87	22	42
Urban	103	26	49

- 2.** An examination was given to 500 high school seniors in each of two large cities, and their grades were recorded as low, medium, or high. The results are given in Table 10.25. Test the hypothesis that the distributions of scores among seniors in the two cities are the same.

**Table 10.25** Data for Exercise 2

	Low	Medium	High
City A	103	145	252
City B	140	136	224

- 3.** Every Tuesday afternoon during the school year, a certain university brought in a visiting speaker to present a lecture on some topic of current interest. On the day after the fourth lecture of the year, random samples of 70 freshmen, 70 sophomores, 60 juniors, and 50 seniors were

selected from the student body at the university, and each of these students was asked how many of the four lectures she had attended. The results are given in Table 10.26. Test the hypothesis that freshmen, sophomores, juniors, and seniors at the university attended the lectures with equal frequency.

**Table 10.26** Data for Exercise 3

	Number of lectures attended				
	0	1	2	3	4
Freshmen	10	16	27	6	11
Sophomores	14	19	20	4	13
Juniors	15	15	17	4	9
Seniors	19	8	6	5	12

- 4.** Suppose that five persons shoot at a target. Suppose also that for  $i = 1, \dots, 5$ , person  $i$  shoots  $n_i$  times and hits the target  $y_i$  times, and that the values of  $n_i$  and  $y_i$  are as given in Table 10.27. Test the hypothesis that the five persons are equally good marksmen.

**Table 10.27** Data for Exercise 4

$i$	$n_i$	$y_i$

2	16	4
3	10	7
4	24	13
5	16	10

5. A manufacturing plant has preliminary contracts with three different suppliers of machines. Each supplier delivered 15 machines, which were used in the plant for four months in preliminary production. It turned out that one of the machines from supplier 1 was defective, seven of the machines from supplier 2 were defective, and seven of the machines from supplier 3 were defective. The plant statistician decided to test the null hypothesis  $H_0$  that the three suppliers provided the same quality. Therefore, he set up Table 10.28 and carried out a  $\chi^2$  test. By summing the values in the bottom row of Table 10.28, he found that the value of the  $\chi^2$  statistic was 24/5 with two degrees of freedom. He then found from a table of the  $\chi^2$  distribution that  $H_0$  should be accepted when the level of significance is 0.05. Criticize this procedure and provide a meaningful analysis of the observed data.

**Table 10.28** Data for Exercise 5

	Supplier		
	1	2	3
Number of defectives $N_i$	1	7	7
Expected number of defectives $E_i$ under $H_0$	5	5	5
$\frac{(N_i - E_i)^2}{E_i}$	16/5	4/5	4/5

6. Suppose that 100 students in a physical education class shoot at a target with a bow and arrow, and 27 students hit the target. These 100 students are then given a demonstration on the proper technique for shooting with the bow and arrow. After the demonstration, they again shoot at the target. This time 35 students hit the target. What additional information, if any, is needed in order to investigate the hypothesis that the demonstration was helpful?

7. As people entered a certain meeting,  $n$  persons were selected at random, and each was asked either to name one of two political candidates she favored in a forthcoming election or to say "undecided" if she had no real preference. During the meeting, the people heard a speech on behalf of one of the candidates. After the meeting, each of the same  $n$  persons was again asked to express her opinion. Describe a method for evaluating the effectiveness of the speaker.

## 10.5 Simpson's Paradox

*When tabulating discrete data, we need to be careful about aggregating groups. Suppose that a survey has two questions. If we construct a single table of responses to the two questions that includes both men and women, we might get a very different picture than if we construct separate tables for the responses of men and women.*

### An Example of the Paradox

**Example**  
**10.5.1**

**Comparing Treatments in an Aggregated Table.** Suppose that an experiment is carried out in order to compare a new treatment for a particular disease with the standard treatment for the disease. In the experiment, 80 subjects suffering from the disease are treated, 40 subjects receiving the new treatment and 40 receiving the standard treatment. After a certain period of time, it is observed how many of the subjects in each group have improved and how many have not. Suppose that the overall results for all 80 patients are as shown in Table 10.29.

According to this table, 20 of the 40 subjects who received the new treatment improved, and 24 of the 40 subjects who received the standard treatment improved. Thus, 50 percent of the subjects improved under the new treatment, whereas 60 percent improved under the standard treatment. On the basis of these results, the new treatment appears inferior to the standard treatment. ◀

**Table 10.29** Results of experiment comparing two treatments

All patients	Improved	Not improved	Percent improved
New treatment	20	20	50
Standard treatment	24	16	60

**Table 10.30** Table 10.29 disaggregated by sex

Men only	Improved	Not improved	Percent improved
New treatment	12	18	40
Standard treatment	3	7	30
<b>Women only</b>			
New treatment	8	2	80
Standard treatment	21	9	70

Many contingency tables, such as Table 10.29, summarize the results of a study in only one of several possible ways. The next example looks at the same data from a different point of view and draws a different conclusion.

**Example  
10.5.2**

**Comparing Treatments in an Disaggregated Table.** In order to investigate more carefully the efficacy of the new treatment in Example 10.5.1, we might compare it with the standard treatment just for the men in the sample and, separately, just for the women in the sample. The results in Table 10.29 can thus be partitioned into two tables, one pertaining just to men and the other just to women. This process of splitting the overall data into disjoint components pertaining to different subgroups of the population is called *disaggregation*.

Suppose that when the values in Table 10.29 are disaggregated by considering the men and the women separately, the results are as shown in Table 10.30. It can be verified that when the data in these separate tables are combined, or *aggregated*, we again obtain Table 10.29. However, Table 10.30 contains a big surprise because the new treatment appears to be superior to the standard treatment both for men and for women. Specifically, 40 percent of the men (12 out of 30) who received the new treatment improved, but only 30 percent of the men (3 out of 10) who received the standard treatment improved. Furthermore, 80 percent of the women (8 out of 10) who received the new treatment improved, but only 70 percent of the women (21 out of 30) who received the standard treatment improved. ◀

Tables 10.29 and 10.30 together yield somewhat anomalous results. According to Table 10.30, the new treatment is superior to the standard treatment both for men and for women, but according to Table 10.29, the new treatment is inferior to the

standard treatment when all the subjects are aggregated. This type of result is known as *Simpson's paradox*.

It should be emphasized that Simpson's paradox is *not* a phenomenon that occurs because we are working with small samples. The small numbers in Tables 10.29 and 10.30 were used merely for convenience in this explanation. Each of the entries in these tables could be multiplied by 1000 or by 1,000,000 without changing the results.

## The Paradox Explained

Of course, Simpson's paradox is not actually a paradox; it is merely a result that is surprising and puzzling to someone who has not seen or thought about it before. It can be seen from Table 10.30 that in the example we are considering, women have a higher rate of improvement from the disease than men have, regardless of which treatment they receive. Furthermore, most of the women in the sample received the standard treatment while most of the men received the new treatment. Specifically, among the 40 men in the sample, 30 received the new treatment, and only 10 received the standard treatment, whereas among the 40 women in the sample, these numbers are reversed.

The new treatment looks bad in the aggregated table because most of the people who weren't going to respond well to either treatment got the new treatment while most of the people who were going to respond well to either treatment got the standard treatment. Even though the numbers of men and women in the experiment were equal, a high proportion of the women and a low proportion of the men received the standard treatment. Since women have a much higher rate of improvement than men, it is found in the aggregated Table 10.29 that the standard treatment manifests a higher overall rate of improvement than does the new treatment.

Simpson's paradox demonstrates dramatically the dangers in making inferences from an aggregated table like Table 10.29. To make sure that Simpson's paradox cannot occur in an experiment like the one just described, the proportions of men and women among the subjects who receive the new treatment must be the same, or approximately the same, as the proportions of men and women among the subjects who receive the standard treatment. It is *not* necessary that there be equal numbers of men and women in the sample.

We can express Simpson's paradox in probability terms. Let  $A$  denote the event that a subject chosen for the experiment will be a man, and let  $A^c$  denote the event that the subject will be a woman. Also, let  $B$  denote the event that a subject will receive the new treatment, and let  $B^c$  denote the event that the subject will receive the standard treatment. Finally, let  $I$  denote the event that a subject will improve. Simpson's paradox then reflects the fact that it is possible for all three of the following inequalities to hold simultaneously:

$$\begin{aligned} \Pr(I|A \cap B) &> \Pr(I|A \cap B^c), \\ \Pr(I|A^c \cap B) &> \Pr(I|A^c \cap B^c), \\ \Pr(I|B) &< \Pr(I|B^c). \end{aligned} \tag{10.5.1}$$

The discussion that we have just given in regard to the prevention of Simpson's paradox can be expressed as follows: If  $\Pr(A|B) = \Pr(A|B^c)$ , then it is not possible for all three inequalities in (10.5.1) to hold (see Exercise 5). Similarly, if  $\Pr(B|A) = \Pr(B|A^c)$ , then it is not possible for all three inequalities in (10.5.1) to hold (see Exercise 3).

The possibility of Simpson's paradox lurks within every contingency table. Even though we might take care to design a particular experiment so that Simpson's

paradox cannot occur when we disaggregate with respect to men and women, it is always possible that there is some other variable, such as the age of the subject or the intensity and the stage of the disease, with respect to which disaggregation would lead us to a conclusion directly opposite to that indicated by the aggregated table. Once an experiment is designed to prevent Simpson's paradox with respect to disaggregations that can be identified in advance, subjects are generally assigned randomly to the possible treatments in the hopes of minimizing the chance that Simpson's paradox will arise with respect to an unforeseen disaggregation.

**Example  
10.5.3**

**Comparing Treatments in an Aggregated Table.** In the example of this section, it would be sensible to assign 20 men and 20 women to each of the two treatments. Which 20 men and which 20 women get assigned to each treatment would be determined by randomization in order to minimize the chance of an unforeseen occurrence of Simpson's paradox.

If there were other information, such as severity of disease, that were available at the start of the experiment, the groups of men and women should each be partitioned according to that additional information before being randomly assigned to the treatments. For example, suppose that 12 men and 8 women have more severe cases of the disease before the experiment begins. We should then assign 6 of the men and 4 of the women with more severe cases to each treatment. We should also assign 4 of the men and 6 of the women with less severe cases to each treatment. This balances the factors (sex, severity, and treatment) that are expected to affect the experimental outcome. If there is another unforeseen factor that will affect the outcome, it is still possible, but unlikely, that the random assignment described above will allow Simpson's paradox to arise with regard to that one factor. If there are dozens of additional important factors, some degree of imbalance will be inevitable even with a randomized assignment. ◀

## Summary

Simpson's paradox occurs when the relationship between the two categorical variables in every part of a disaggregated table is the opposite of the relationship between those same two variables in the aggregated table.

## Exercises

---

- Consider two populations I and II. Suppose that 80 percent of the men and 30 percent of the women in population I have a certain characteristic, and that only 60 percent of the men and 10 percent of the women in population II have the characteristic. Explain how, under these conditions, it might be true that the proportion of population II having the characteristic is larger than the proportion of population I having the characteristic.
- Suppose that  $A$  and  $B$  are events such that  $0 < \Pr(A) < 1$  and  $0 < \Pr(B) < 1$ . Show that  $\Pr(A|B) = \Pr(A|B^c)$  if and only if  $\Pr(B|A) = \Pr(B|A^c)$ .
- Show that all three inequalities in (10.5.1) cannot hold if  $\Pr(B|A) = \Pr(B|A^c)$ .
- Suppose that each adult subject in an experiment is given either treatment I or treatment II. Prove that the proportion of men among the subjects who receive treatment I is equal to the proportion of men among the subjects who receive treatment II if and only if the proportion of all men in the experiment who receive treatment I is equal to the proportion of all women who receive treatment I.
- Show that all three inequalities in (10.5.1) cannot hold if  $\Pr(A|B) = \Pr(A|B^c)$ .
- It was believed that a certain university was discriminating against women in its admissions policy because 30 percent of all the male applicants to the university were

admitted, whereas only 20 percent of all the female applicants were admitted. In order to determine which of the five colleges in the university were most responsible for this discrimination, the admissions rates for each college were analyzed separately. Surprisingly, it was found that in each college the proportion of female applicants who were admitted to the college was actually larger than the proportion of male applicants who were admitted. Discuss and explain this result.

**7.** In an experiment involving 800 subjects, each subject received either treatment I or treatment II, and each subject was classified into one of the following four categories: older males, younger males, older females, and younger females. At the end of the experiment, it was determined for each subject whether the treatment that the subject had received was helpful or not. The results for each of the four categories of subjects are given in Table 10.31.

- a. Show that treatment II is more helpful than treatment I within each of the four categories of subjects.
- b. Show that if these four categories are aggregated into only the two categories, older subjects and younger subjects, then treatment I is more helpful than treatment II within each of these categories.

- c. Show that if the two categories in part (b) are aggregated into a single category containing all 800 subjects, then treatment II again appears to be more helpful than treatment I.

**Table 10.31** Data for Exercise 7

	Helpful	Not
Treatment I	120	120
Treatment II	20	10
<b>Younger males</b>		
Treatment I	60	20
Treatment II	40	10
<b>Older females</b>		
Treatment I	10	50
Treatment II	20	50
<b>Younger females</b>		
Treatment I	10	10
Treatment II	160	90

## ★ 10.6 Kolmogorov-Smirnov Tests

In Sec. 10.1, we used the  $\chi^2$  test to test the null hypothesis that a random sample came from a particular continuous distribution against the alternative hypothesis that the sample did not come from that distribution. A more suitable test for these hypotheses is introduced in this section. This test can also be extended to test the null hypothesis that two independent samples came from the same distribution against the alternative hypothesis that they came from two different distributions.

### The Sample Distribution Function

#### Example 10.6.1

**Failure Times of Ball Bearings.** In Example 10.1.6, we used a  $\chi^2$  goodness-of-fit test to test the null hypothesis that the log-failure times of ball bearings came from the normal distribution with mean 3.912 and variance 0.25. That test required us to choose a somewhat arbitrary partition of the real line in order to convert the log-failure times into count data. Is there a test procedure for such problems that does not require an arbitrary aggregation into intervals that may have no physical meaning in the application? ▀

The first step in trying to answer the question in Example 10.6.1 is to construct an estimator of the distribution of the random sample that does not rely on the assumption that the distribution was normal. Suppose that the random variables  $X_1, \dots, X_n$

form a random sample from some continuous distribution, and let  $x_1, \dots, x_n$  denote the observed values of  $X_1, \dots, X_n$ . Since the observations come from a continuous distribution, there is probability 0 that any two of the observed values  $x_1, \dots, x_n$  will be equal. Therefore, we shall assume for simplicity that all  $n$  values are different. We shall consider now a function  $F_n(x)$ , which is constructed from the values  $x_1, \dots, x_n$  and will serve as an estimate of the c.d.f. from which the sample was drawn.

**Definition  
10.6.1**

**Sample (Empirical) Distribution Function.** Let  $x_1, \dots, x_n$  be the observed values of a random sample  $X_1, \dots, X_n$ . For each number  $x$  ( $-\infty < x < \infty$ ), define the value  $F_n(x)$  as the proportion of observed values in the sample that are less than or equal to  $x$ . In other words, if exactly  $k$  of the observed values in the sample are less than or equal to  $x$ , then  $F_n(x) = k/n$ . The function  $F_n(x)$  defined in this way is called the *sample distribution function*, or simply the *sample c.d.f.* Sometimes  $F_n(x)$  is called the *empirical c.d.f.*

The sample c.d.f. for the data discussed in Example 10.6.1 appears in Fig. 10.1 together with the hypothesized normal c.d.f. mentioned in that example.

In general, the sample c.d.f.  $F_n(x)$  can be regarded as the c.d.f. of a discrete distribution that assigns probability  $1/n$  to each of the  $n$  values  $x_1, \dots, x_n$ . Thus,  $F_n(x)$  will be a step function with a jump of magnitude  $1/n$  at each point  $x_i$  ( $i = 1, \dots, n$ ). If we let  $y_1 < y_2 < \dots < y_n$  denote the values of the order statistics of the sample, as defined in Definition 7.8.2, then  $F_n(x) = 0$  for  $x < y_1$ ;  $F_n(x)$  jumps to the value  $1/n$  at  $x = y_1$  and remains at  $1/n$  for  $y_1 \leq x < y_2$ ;  $F_n(x)$  jumps to the value  $2/n$  at  $x = y_2$  and remains at  $2/n$  for  $y_2 \leq x < y_3$ ; and so on.

Now let  $F(x)$  denote the c.d.f. of the distribution from which the random sample  $X_1, \dots, X_n$  was drawn. For each given number  $x$  ( $-\infty < x < \infty$ ), the probability that any particular observation  $X_i$  will be less than or equal to  $x$  is  $F(x)$ . Therefore, it follows from the law of large numbers that as  $n \rightarrow \infty$ , the proportion  $F_n(x)$  of observations in the sample that are less than or equal to  $x$  will converge in probability to  $F(x)$ . In symbols,

$$F_n(x) \xrightarrow{P} F(x) \quad \text{for } -\infty < x < \infty. \quad (10.6.1)$$

The relation (10.6.1) expresses the fact that at each point  $x$ , the sample c.d.f.  $F_n(x)$  will converge to the actual c.d.f.  $F(x)$  of the distribution from which the random sample was taken. A collection of sample c.d.f.'s is sketched in Fig. 10.2 for a few different sized samples from the same distribution.

**Figure 10.1** Sample c.d.f. of log-failure times of ball bearings together with the c.d.f. of the normal distribution with mean 3.912 and variance 0.25.

**Figure 10.2** The sample c.d.f.  $F_n(x)$  for  $n = 4, 8, 16$ .

**Figure 10.3** The value of  $D_n$ .

An even stronger result, known as the Glivenko-Cantelli lemma, states that  $F_n(x)$  will converge to  $F(x)$  uniformly over all values of  $x$ . The proof is beyond the scope of this book.

**Theorem  
10.6.1**

**Glivenko-Cantelli Lemma.** Let  $F_n$  be the sample c.d.f. from an i.i.d. sample  $X_1, \dots, X_n$  from the c.d.f.  $F$ . Define

$$D_n = \sup_{-\infty < x < \infty} |F_n(x) - F(x)|. \quad (10.6.2)$$

Then  $D_n \xrightarrow{P} 0$ . ■

A value of  $D_n$  is illustrated in Fig. 10.3 for a typical example. Before the values of  $X_1, \dots, X_n$  have been observed, the value of  $D_n$  is a random variable.

Theorem 10.6.1 implies that when the sample size  $n$  is large, the sample c.d.f.  $F_n(x)$  is quite likely to be close to the c.d.f.  $F(x)$  over the entire real line. In this sense,

when the c.d.f.  $F(x)$  is unknown, the sample c.d.f.  $F_n(x)$  can be considered to be an estimator of  $F(x)$ . In another sense, however,  $F_n(x)$  is not a very reasonable estimator of  $F(x)$ . As we explained earlier,  $F_n(x)$  will be the c.d.f. of a discrete distribution that is concentrated on  $n$  points, whereas we are assuming in this section that the unknown c.d.f.  $F(x)$  is the c.d.f. of a continuous distribution. Some type of smoothed version of  $F_n(x)$ , from which the jumps have been removed, might yield a reasonable estimator of  $F(x)$ , but we shall not pursue this topic further here.

### The Kolmogorov-Smirnov Test of a Simple Hypothesis

Suppose now that we wish to test the simple null hypothesis that the unknown c.d.f.  $F(x)$  is actually a particular continuous c.d.f.  $F^*(x)$  against the general alternative that the actual c.d.f. is not  $F^*(x)$ . In other words, suppose that we wish to test the following hypotheses:

$$\begin{aligned} H_0: \quad & F(x) = F^*(x) \quad \text{for } -\infty < x < \infty, \\ H_1: \quad & \text{The hypothesis } H_0 \text{ is not true.} \end{aligned} \quad (10.6.3)$$

This problem is a nonparametric problem because the unknown distribution from which the random sample is taken might be any continuous distribution.

In Sec. 10.1, we described how the  $\chi^2$  test of goodness-of-fit can be used to test hypotheses having the form (10.6.3). That test, however, requires grouping the observations into a finite number of intervals in an arbitrary manner. We shall now describe a test of the hypotheses (10.6.3) that does not require such grouping.

As before, we shall let  $F_n(x)$  denote the sample c.d.f. Also, we shall now let  $D_n^*$  denote the following statistic:

$$D_n^* = \sup_{-\infty < x < \infty} |F_n(x) - F^*(x)|. \quad (10.6.4)$$

In other words,  $D_n^*$  is the maximum difference between the sample c.d.f.  $F_n(x)$  and the hypothesized c.d.f.  $F^*(x)$ . When the null hypothesis  $H_0$  in (10.6.3) is true, the probability distribution of  $D_n^*$  will be a certain distribution that is the same for every possible continuous c.d.f.  $F^*(x)$  and does not depend on the particular c.d.f.  $F^*(x)$  being studied in a specific problem. (See Exercise 13.) Tables of this distribution, for various values of the sample size  $n$ , have been developed and are presented in many published collections of statistical tables.

It follows from the Glivenko-Cantelli lemma that the value of  $D_n^*$  will tend to be small if the null hypothesis  $H_0$  is true, and  $D_n^*$  will tend to be larger if the actual c.d.f.  $F(x)$  is different from  $F^*(x)$ . Therefore, a reasonable test procedure for the hypotheses (10.6.3) is to reject  $H_0$  if  $n^{1/2}D_n^* > c$ , where  $c$  is an appropriate constant.

It is convenient to express the test procedure in terms of  $n^{1/2}D_n^*$  rather than simply  $D_n^*$ , because of the following result, which was established in the 1930s by A. N. Kolmogorov and N. V. Smirnov.

**Theorem  
10.6.2**

If the null hypothesis  $H_0$  is true, then for each given value  $t > 0$ ,

$$\lim_{n \rightarrow \infty} \Pr(n^{1/2}D_n^* \leq t) = 1 - 2 \sum_{i=1}^{\infty} (-1)^{i-1} e^{-2it^2}. \quad (10.6.5)$$

Thus, if the null hypothesis  $H_0$  is true, then as  $n \rightarrow \infty$ , the c.d.f. of  $n^{1/2}D_n^*$  will converge to the c.d.f. given by the infinite series on the right side of Eq. (10.6.5). For each value of  $t > 0$ , we shall let  $H(t)$  denote the value on the right side of Eq. (10.6.5). The values of  $H(t)$  are given in Table 10.32.

**Table 10.32** The c.d.f.  $H$  in Eq. (10.6.5)

$t$	$H(t)$	$t$	$H(t)$
0.30	0.0000	1.20	0.8878
0.35	0.0003	1.25	0.9121
0.40	0.0028	1.30	0.9319
0.45	0.0126	1.35	0.9478
0.50	0.0361	1.40	0.9603
0.55	0.0772	1.45	0.9702
0.60	0.1357	1.50	0.9778
0.65	0.2080	1.60	0.9880
0.70	0.2888	1.70	0.9938
0.75	0.3728	1.80	0.9969
0.80	0.4559	1.90	0.9985
0.85	0.5347	2.00	0.9993
0.90	0.6073	2.10	0.9997
0.95	0.6725	2.20	0.9999
1.00	0.7300	2.30	0.9999
1.05	0.7798	2.40	1.0000
1.10	0.8223	2.50	1.0000
1.15	0.8580		

**Definition 10.6.2** Kolmogorov-Smirnov test. A test procedure that rejects  $H_0$  when  $n^{1/2}D_n^* \geq c$  is called a *Kolmogorov-Smirnov test*.

It follows from Eq. (10.6.5) that when the sample size  $n$  is large, the constant  $c$  can be chosen from Table 10.32 to achieve, at least approximately, any specified level of significance  $\alpha_0$  ( $0 < \alpha_0 < 1$ ). In fact, we should choose  $c$  to be the  $1 - \alpha_0$  quantile  $H^{-1}(1 - \alpha_0)$  of the distribution  $H$ . For example, by examining Table 10.32, we see that  $H(1.36) \approx 0.95$ , so  $H^{-1}(1 - 0.05) = 1.36$ . Therefore, if the null hypothesis  $H_0$  is true, then  $\Pr(n^{1/2}D_n^* \geq 1.36) = 0.05$ . It follows that the level of significance of a Kolmogorov-Smirnov test with  $c = 1.36$  will be 0.05.

**Example 10.6.2**

Testing Whether a Sample Comes from a Standard Normal Distribution. Suppose that it is desired to test the null hypothesis that a certain random sample of 25 observations was drawn from a standard normal distribution against the alternative that the random sample was drawn from some other continuous distribution. The 25 observed values in the sample, in order from the smallest to the largest, are designated as  $y_1, \dots, y_{25}$  and are listed in Table 10.33. The table also includes the value  $F_n(y_i)$  of the sample c.d.f. and the value  $\Phi(y_i)$  of the c.d.f. of the standard normal distribution.

By examining the values in Table 10.33, we find that  $D_n^*$ , which is the largest difference between  $F_n(x)$  and  $\Phi(x)$ , occurs when we pass from  $i = 4$  to  $i = 5$ , that is, as  $x$  increases from the point  $x = -0.99$  toward the point  $x = -0.42$ . The comparison of  $F_n(x)$  and  $\Phi(x)$  over this interval is illustrated in Fig. 10.4, from which we

<b>i</b>	$y_i$	$F_n(y_i)$	$\Phi(y_i)$
1	-2.46	0.04	0.0069

**Figure 10.4** The value of  $D_n^*$  in Example 10.6.2.

see that  $D_n^* = 0.3372 - 0.16 = 0.1772$ . Since  $n = 25$  in this example, it follows that  $n^{1/2}D_n^* = 0.886$ . From Table 10.32, we find that  $H(0.886) = 0.6$ . Hence, the tail area corresponding to the observed value of  $n^{1/2}D_n^*$  is 0.4, and we would not reject the null hypothesis at levels  $\alpha_0$  smaller than 0.4.  $\blacktriangleleft$

It is important to emphasize again that when the sample size  $n$  is large, even a small value of the tail area corresponding to the observed value of  $n^{1/2}D_n^*$  would not necessarily indicate that the true c.d.f.  $F(x)$  was much different from the hypothesized c.d.f.  $\Phi(x)$ . When  $n$  itself is large, even a small difference between the c.d.f.  $F(x)$  and the c.d.f.  $\Phi(x)$  would be sufficient to generate a large value of  $n^{1/2}D_n^*$ . Therefore, before a statistician rejects the null hypothesis, he should make certain that there is a plausible alternative c.d.f. with which the sample  $F_n(x)$  provides closer agreement.

## The Kolmogorov-Smirnov Test for Two Samples

### Example 10.6.3

**Calcium Supplements and Blood Pressure.** Exercise 10 in Sec. 9.6 contains data from a study of the effect of a calcium supplement on blood pressure. A group of  $m = 10$  men received a calcium supplement, and another group of  $n = 11$  men received a placebo. At the end of the study, the differences were calculated between each man's blood pressures at the start and at the end of a 12-week period. Suppose that we are not willing to assume that the distributions of the measured differences are normal distributions. Can we still construct a procedure for testing the null hypothesis that the distributions of differences in the treatment and placebo groups are the same versus the alternative hypothesis that the distributions are different?  $\blacktriangleleft$

Consider a problem in which a random sample of  $m$  observations  $X_1, \dots, X_m$  is taken from a distribution for which the c.d.f.  $F(x)$  is unknown, and an independent random sample of  $n$  observations  $Y_1, \dots, Y_n$  is taken from another distribution for which the c.d.f.  $G(x)$  is also unknown. We shall assume that both  $F(x)$  and  $G(x)$  are continuous functions and that it is desired to test the hypothesis that these functions are identical, without specifying their common form. Thus, the following hypotheses are to be tested:

$$\begin{aligned} H_0: \quad & F(x) = G(x) \quad \text{for } -\infty < x < \infty, \\ H_1: \quad & \text{The hypothesis } H_0 \text{ is not true.} \end{aligned} \tag{10.6.6}$$

We shall let  $F_m(x)$  denote the sample c.d.f. calculated from the observed values of  $X_1, \dots, X_m$  and let  $G_n(x)$  denote the sample c.d.f. calculated from the observed values of  $Y_1, \dots, Y_n$ . Furthermore, we shall consider the statistic  $D_{mn}$ , which is defined as follows:

$$D_{mn} = \sup_{-\infty < x < \infty} |F_m(x) - G_n(x)|. \tag{10.6.7}$$

The value of  $D_{mn}$  is illustrated in Fig. 10.5 for a typical example in which  $m = 5$  and  $n = 3$ .

When the null hypothesis  $H_0$  is true and  $F(x)$  and  $G(x)$  are identical functions, the sample c.d.f.'s  $F_m(x)$  and  $G_n(x)$  will tend to be close to each other. In fact, when  $H_0$  is true, it follows from the Glivenko-Cantelli lemma that

$$D_{mn} \xrightarrow{P} 0, \quad \text{as both } m \rightarrow \infty \text{ and } n \rightarrow \infty. \tag{10.6.8}$$

It seems reasonable, therefore, to use a test procedure that specifies rejecting  $H_0$  when  $D_{mn}$  is large. The following theorem, whose proof is beyond the scope of this

**Figure 10.5** A representation of  $F_m(x)$ ,  $G_n(x)$ , and  $D_{mn}$  for  $m = 5$  and  $n = 3$ .

text, gives us the asymptotic distribution of  $D_{mn}$ , which we can use to construct an approximate test.

**Theorem  
10.6.3**

**Two-Sample Kolmogorov-Smirnov Statistic.** For each value of  $t > 0$ , let  $H(t)$  denote the right side of Eq. (10.6.5). If the null hypothesis  $H_0$  in (10.6.6) is true, then

$$\lim_{m \rightarrow \infty, n \rightarrow \infty} \Pr \left[ \left( \frac{mn}{m+n} \right)^{1/2} D_{mn} \leq t \right] = H(t). \quad (10.6.9)$$

Values of the function  $H(t)$  are given in Table 10.32. The large-sample approximate test of the hypotheses in (10.6.6) makes use of the statistic in (10.6.9).

**Definition  
10.6.3**

**Two-Sample Kolmogorov-Smirnov Test.** A test procedure that rejects  $H_0$  when

$$\left( \frac{mn}{m+n} \right)^{1/2} D_{mn} \geq c, \quad (10.6.10)$$

where  $c$  is an appropriate constant, is called a *Kolmogorov-Smirnov two-sample test*.

Hence, when the sample sizes  $m$  and  $n$  are large, the constant  $c$  in the relation (10.6.10) can be chosen from Table 10.32 to achieve, at least approximately, any specified level of significance. For example, if  $m$  and  $n$  are large, and the test is to be carried out at the level of significance 0.05, then it follows from Table 10.32 that we should choose  $c = H^{-1}(0.95) = 1.36$ .

**Example  
10.6.4**

**Calcium Supplements and Blood Pressure.** Return to situation described in Example 10.6.3. We are interested in whether or not the changes in blood pressure for men treated with a calcium supplement have the same distribution as the changes in blood pressure for men treated with a placebo. Figure 10.6 displays the sample c.d.f.'s of the measured changes in the treatment and placebo groups. It is not difficult to see that the maximum difference occurs for  $5 \leq x < 7$ . In fact,  $D_{mn} = 0.409$ , and the test statistic is  $(110/21)^{1/2} \times 0.409 = 0.936$ . From Table 10.32, we see that  $H(0.936)$  is about 0.654. So we would reject the null hypothesis that the two samples were drawn from the same population at every level  $\alpha_0 \geq 0.346$ .  $\blacktriangleleft$

## Summary

We introduced Kolmogorov-Smirnov tests for testing the null hypotheses that a random sample arose from a particular distribution and that two independent random samples arose from the same distribution. For the one-sample test, we compute  $D_n$ , the largest difference between the sample c.d.f. and the null hypothesis c.d.f., and we reject the null hypothesis at level  $\alpha_0$  if  $n^{1/2}D_n^* \geq H^{-1}(1 - \alpha_0)$ , where  $H$  is the c.d.f. shown in Table 10.32. For the two-sample test, we compute  $D_{mn}$ , the largest

**Figure 10.6** The sample c.d.f.'s for two samples in Example 10.6.4.

difference between the two sample c.d.f.'s from the two different samples. We then reject the null hypothesis that the two samples arose from the same distribution at level  $\alpha_0$  if  $(mn/(m+n))^{1/2} D_{mn} \geq H^{-1}(1 - \alpha_0)$ .

## Exercises

- Suppose that the ordered values in a random sample of five observations are  $y_1 < y_2 < y_3 < y_4 < y_5$ . Let  $F_n(x)$  denote the sample c.d.f. constructed from these values, let  $F(x)$  be a continuous c.d.f., and let  $D_n$  be defined by Eq. (10.6.2). Prove that the minimum possible value of  $D_n$  is 0.1, and prove that  $D_n = 0.1$  if and only if  $F(y_1) = 0.1$ ,  $F(y_2) = 0.3$ ,  $F(y_3) = 0.5$ ,  $F(y_4) = 0.7$ , and  $F(y_5) = 0.9$ .
- Consider again the conditions of Exercise 1. Prove that  $D_n \leq 0.2$  if and only if  $F(y_1) \leq 0.2 \leq F(y_2) \leq 0.4 \leq F(y_3) \leq 0.6 \leq F(y_4) \leq 0.8 \leq F(y_5)$ .
- Use the data in Example 10.1.6. In that example, we used a  $\chi^2$  goodness-of-fit test to test the null hypothesis that the logarithms of failure times for ball bearings had the normal distribution with mean 3.912 and variance 0.25. Now, use the Kolmogorov-Smirnov test to test that same null hypothesis.
- Use the Kolmogorov-Smirnov test to test the hypothesis that the 25 values in Table 10.34 form a random sample from the uniform distribution on the interval  $[0, 1]$ .

**Table 10.34** Data for Exercise 4

	0.42	0.06	0.88	0.40	0.90
	0.38	0.78	0.71	0.57	0.66
	0.48	0.35	0.16	0.22	0.08
	0.11	0.29	0.79	0.75	0.82
	0.30	0.23	0.01	0.41	0.09

- Use the Kolmogorov-Smirnov test to test the hypothesis that the 25 values given in Exercise 4 form a random sample from the continuous distribution for which the p.d.f.  $f(x)$  is as follows:

$$f(x) = \begin{cases} \frac{3}{2} & \text{for } 0 < x \leq \frac{1}{2}, \\ \frac{1}{2} & \text{for } \frac{1}{2} < x < 1, \\ 0 & \text{otherwise.} \end{cases}$$

- Consider again the conditions of Exercise 4 and 5. Suppose that the prior probability is 1/2 that the 25 values given in Table 10.34 were obtained from the uniform distribution on the interval  $[0, 1]$ , and 1/2 that they were obtained from the distribution for which the p.d.f. is as given in Exercise 5. Find the posterior probability that they were obtained from a uniform distribution.
- Use the Kolmogorov-Smirnov test to test the hypothesis that the 50 values in Table 10.35 form a random sample from the normal distribution for which the mean is 26 and the variance is 4.

**Table 10.35** Data for Exercise 8

25.088	26.615	25.468	27.453	23.845
25.996	26.516	28.240	25.980	30.432
26.560	25.844	26.964	23.382	25.282
24.432	23.593	24.644	26.849	26.801
26.303	23.016	27.378	25.351	23.601
24.317	29.778	29.585	22.147	28.352
29.263	27.924	21.579	25.320	28.129
28.478	23.896	26.020	23.750	24.904
24.078	27.228	27.433	23.341	28.923
24.466	25.153	25.893	26.796	24.743

**8.** Use the Kolmogorov-Smirnov test to test the hypothesis that the 50 values given in Table 10.35 form a random sample from the normal distribution for which the mean is 24 and the variance is 4.

**9.** Suppose that 25 observations are selected at random from a distribution for which the c.d.f.  $F(x)$  is unknown, and that the values given in Table 10.36 are obtained. Suppose also that 20 observations are selected at random from another distribution for which the c.d.f.  $G(x)$  is unknown, and the values given in Table 10.37 are obtained. Use the Kolmogorov-Smirnov test to test the hypothesis that  $F(x)$  and  $G(x)$  are identical functions.

**Table 10.36** First sample for Exercise 9

0.61	0.29	0.06	0.59	-1.73
-0.74	0.51	-0.56	-0.39	1.64
0.05	-0.06	0.64	-0.82	0.31
1.77	1.09	-1.28	2.36	1.31
1.05	-0.32	-0.40	1.06	-2.47

**Table 10.37** Second sample for Exercise 9

2.20	1.66	1.38	0.20
0.36	0.00	0.96	1.56
0.44	1.50	-0.30	0.66
2.31	3.29	-0.27	-0.37
0.38	0.70	0.52	-0.71

**10.** Consider again the conditions of Exercise 9. Let  $X$  denote a random variable for which the c.d.f. is  $F(x)$ , and let  $Y$  denote a random variable for which the c.d.f. is  $G(x)$ . Use the Kolmogorov-Smirnov test to test the hypothesis

that the random variables  $X + 2$  and  $Y$  have the same distribution.

**11.** Consider again the conditions of Exercises 9 and 10. Use the Kolmogorov-Smirnov test to test the hypothesis that the random variables  $X$  and  $3Y$  have the same distribution.

**12.** In Example 9.6.3, we compared two samples of aluminum oxide measurements taken from Roman-era pottery that was found in two different locations in Britain. The  $m = 14$  measurements taken from the Llanederyn region are

$$\begin{aligned} & 10.1, 10.9, 11.1, 11.5, 11.6, 12.4, 12.5, 12.7, \\ & 13.1, 13.4, 13.8, 13.8, 14.4, 14.6. \end{aligned}$$

The  $n = 5$  measurements from Ashley Rails are

$$14.8, 16.7, 17.7, 18.3, 19.1.$$

Use the Kolmogorov-Smirnov two-sample test to test the null hypothesis that the two distributions from which these samples are drawn are the same.

**13.** Suppose that  $X_1, \dots, X_n$  form a random sample with unknown c.d.f.  $F$ . Prove the claim made after Eq. (10.6.4) that the distribution of the statistic  $D_n^*$ , given that the null hypothesis in (10.6.3) is true, is the same for all continuous  $F^*$ . Hint: Let  $Z_i = F^*(X_i)$  for  $i = 1, \dots, n$ , and consider testing the null hypothesis that  $Z_1, \dots, Z_n$  have the uniform distribution on the interval  $[0, 1]$ . Show that the statistic  $D_n^*$  for this modified problem is identical to the original  $D_n^*$ .

**14.** Perform the Kolmogorov-Smirnov test of the null hypothesis in Example 10.6.1. Report the result of the test by giving the  $p$ -value. The sample data appear in Example 10.1.6.

## ★ 10.7 Robust Estimation

*In many statistical problems, we might not feel comfortable assuming that the distribution of our data  $\mathbf{X}$  is a member of a single parametric family. Suppose that we consider using an estimator  $T = r(\mathbf{X})$  of some parameter  $\theta$ . It might be that  $T$  has good properties if  $\mathbf{X}$  is a random sample from, say, a normal distribution. On the other hand, we might be concerned about how  $T$  would behave if  $\mathbf{X}$  were actually a sample from a different distribution. In this section, we introduce a new class of distributions and several new statistics. We then compare the behaviors of these statistics (and some old ones) when the data arise from one of the new distributions (and from some old ones). An estimator is called robust if it performs well, compared to other estimators, regardless of the distribution that gives rise to the data.*

## Estimating the Median

**Example  
10.7.1**

**Rain from Seeded Clouds.** In Fig. 8.3, we presented the histogram of log-rainfalls from 26 seeded clouds, which is slightly asymmetric. A scientist might be uncomfortable treating the log-rainfalls as normal random variables. Nevertheless, one may still wish to estimate the median or some other feature of the distribution of log-rainfalls. One might wish to use a method of estimation that does not rely for its justification on the assumption that the data form a random sample from a normal distribution. ◀

Suppose that the random variables  $X_1, \dots, X_n$  form a random sample from a continuous distribution for which the p.d.f.  $f(x)$  is unknown, but may be assumed to be a symmetric function with respect to some unknown point  $\theta$  ( $-\infty < \theta < \infty$ ). Because of this symmetry, the point  $\theta$  will be a median of the unknown distribution. We shall estimate the value of  $\theta$  from the observations  $X_1, \dots, X_n$ .

If we know that the observations actually come from a normal distribution, then the sample mean  $\bar{X}_n$  will be the M.L.E. of  $\theta$ . Without any strong prior information indicating that the value of  $\theta$  might be quite different from the observed value of  $\bar{X}_n$ , we may assume that  $\bar{X}_n$  will be a reasonable estimator of  $\theta$ . Suppose, however, that the observations might come from a distribution for which the p.d.f.  $f(x)$  has much thicker tails than the p.d.f. of a normal distribution; that is, suppose that as  $x \rightarrow \infty$  or  $x \rightarrow -\infty$ , the p.d.f.  $f(x)$  might come down to 0 much more slowly than does the p.d.f. of a normal distribution. In this case, the sample mean  $\bar{X}_n$  may be a poor estimator of  $\theta$  because its M.S.E. may be much larger than that of some other possible estimator.

**Example  
10.7.2**

**Shifted Cauchy Sample.** If the underlying distribution is the Cauchy distribution centered at an unknown point  $\theta$ , as defined in Example 7.6.5, then the M.S.E. of  $\bar{X}_n$  will be infinite. In this case, the M.L.E. of  $\theta$  will have a finite M.S.E. and will be a much better estimator than  $\bar{X}_n$ . In fact, for a large value of  $n$ , the M.S.E. of the M.L.E. is approximately  $2/n$ , no matter what the true value of  $\theta$  is. However, as pointed out in Example 7.6.5, this estimator is very complicated and must be determined by a numerical calculation for each given set of observations. A relatively simple and reasonable estimator for this problem is the *sample median*, which was defined in Example 7.9.3. It can be shown that the M.S.E. of the sample median for a large value of  $n$  is approximately  $2.47/n$  when the data have the Cauchy distribution. ◀

It follows from Example 10.7.2 and the preceding discussion that if we could assume that the underlying distribution is normal or nearly normal, then we might use the sample mean as an estimator of  $\theta$ . On the other hand, if we believe that the underlying distribution is Cauchy or nearly Cauchy, then we might use the sample median. However, we typically do not know whether the underlying distribution is nearly normal, is nearly Cauchy, or does not correspond closely to either of these types of distributions. For this reason, we should try to find an estimator of  $\theta$  that will have a small M.S.E. for several different possible types of distributions. An estimator that performs well for several different types of distributions, even though it may not be the best available estimator for any particular type of distribution, is called a *robust estimator*. In this section, we shall define a class of distributions called *contaminated normals* that we shall use for assessing the performance of various estimators. We shall also introduce special types of robust estimators known as *trimmed means* and *M-estimators*. The term *robust* was introduced by G. E. P. Box in 1953, and the term *trimmed mean* was introduced by J. W. Tukey in 1962. However, the first mathematical treatment of trimmed means was given by P. Daniell in 1920. *M-estimators* were introduced by Huber (1964).

## Contaminated Normal Distributions

One reason that experimenters might be hesitant to behave as if their data were sampled from a normal distribution is the possibility that random errors might occur in the data. Once in a while, a data value is recorded incorrectly or is collected under circumstances that are different from those under study. The one observation (or possibly a few) will have a distribution that might be much different from that of the majority of the observations. For example, suppose that the bulk of the data in which we are interested comprise a sample from the normal distribution with unknown mean  $\mu$  and variance  $\sigma^2$ . But suppose that, for each observation, there is a small probability  $\epsilon$  that the observation actually comes from a different distribution with p.d.f.  $g$ . That is, the p.d.f. of our observable data is actually

$$f(x) = (1 - \epsilon)(2\pi\sigma^2)^{-1/2} \exp\left(-\frac{1}{2\sigma^2}[x - \mu]^2\right) + \epsilon g(x). \quad (10.7.1)$$

**Definition 10.7.1**

**Contaminated Normal Distributions.** A distribution whose p.d.f. has the form of Eq. (10.7.1) is called a *contaminated normal*, and the distribution with p.d.f.  $g$  is called the *contaminating distribution*.

If the contaminating distribution in Eq. (10.7.1) has a high variance or has a mean very different from  $\mu$ , there is a good chance that the observations we obtain from the contaminating distribution will be far away from the other observations. In order for an estimator to perform well for a large class of contaminated normal distributions, the estimator will have to be somewhat insensitive to one (or a few) observation(s) not close to the bulk of the data. Obviously, if  $\epsilon \geq 1/2$ , it becomes difficult to tell which distribution is contaminating which. So we shall assume that  $\epsilon < 1/2$ . A simple example of a contaminated normal distribution is one in which  $g$  is the p.d.f. of a normal distribution with mean  $\mu$  and variance  $100\sigma^2$ . In this case, Eq. (10.7.1) becomes

$$\begin{aligned} f(x) = & (1 - \epsilon)(2\pi\sigma^2)^{-1/2} \exp\left(-\frac{1}{2\sigma^2}[x - \mu]^2\right) \\ & + \epsilon(200\pi\sigma^2)^{-1/2} \exp\left(-\frac{1}{200\sigma^2}[x - \mu]^2\right). \end{aligned} \quad (10.7.2)$$

Figure 10.7 shows a standard normal p.d.f. together with the p.d.f. of a contaminated normal of the form of Eq. (10.7.2) with  $\mu = 0$ ,  $\sigma^2 = 1$ , and  $\epsilon = 0.05$ . The two

**Figure 10.7** p.d.f.'s of standard normal distribution and  $\epsilon = 0.05$  contaminated normal with mean 0 and variance 100.

**Figure 10.8** Sample size times variances of sample median and sample mean for a random sample from a contaminated normal distribution with the p.d.f. in Eq. (10.7.2) with  $\sigma = 1$  as a function of the amount of contamination  $\epsilon$ . The line for the median uses the asymptotic result Eq. (10.7.3).

p.d.f.'s are quite similar, but we shall see shortly how much effect the contamination can have on the problem of estimation.

Two important properties of the distribution of an estimator of the median are its mean and its variance. In the situation in which the data have the p.d.f. (10.7.2), both the sample mean and the sample median have mean  $\mu$ . Next, we shall compare the variances of these two estimators when the data are a random sample with the p.d.f. (10.7.2). The variance of the average of a sample of size  $n$  is  $(1 + 99\epsilon)\sigma^2/n$ . (You can prove this in Exercise 7.) The variance of the sample median is a bit more difficult to compute. However, using the large-sample properties that will be introduced on page 676, we can see that the variance is approximately

$$\frac{1}{4nf^2(\mu)} = \frac{\sigma^2}{n} \frac{50\pi}{(10 - 9\epsilon)^2}. \quad (10.7.3)$$

Figure 10.8 shows a comparison of  $(50\pi)/(10 - 9\epsilon)^2$  and  $(1 + 99\epsilon)\sigma^2/n$  for  $0 \leq \epsilon \leq 0.5$ . Notice that the variance of the sample median is only slightly larger than the variance of the sample mean for  $\epsilon < 0.0058$ , and it is substantially smaller for  $\epsilon$  in the range of 0.01 to 0.5. For example, if  $\epsilon = 0.05$  (as in Fig. 10.7), the variance of the sample median is only about 29 percent of the variance of the sample mean.

### Trimmed Means

Suppose that  $X_1, \dots, X_n$  form a random sample from an unknown continuous distribution for which the p.d.f.  $f(x)$  is assumed to be symmetric with respect to an unknown point  $\theta$ . For this discussion, we shall let  $Y_1 < Y_2 < \dots < Y_n$  denote the order statistics of the sample. The sample mean  $\bar{X}_n$  is simply the average of these  $n$  order statistics. However, if we suspect that the p.d.f.  $f(x)$  might have thicker tails than a normal distribution has, then we may wish to estimate  $\theta$  by using a weighted average of the order statistics, which assigns less weight to the extreme observations such as  $Y_1, Y_2, Y_{n-1}$ , and  $Y_n$ , and assigns more weight to the middle observations. The sample median is a special example of a weighted average. When  $n$  is odd, it assigns zero weight to every observation except the middle one. When  $n$  is even, it assigns the weight  $1/2$  to each of the two middle observations and zero weight to all other observations.

The following class of estimators also consists of weighted averages of the order statistics.

**Definition 10.7.2** **Trimmed Means.** For each positive integer  $k$  such that  $k < n/2$ , ignore the  $k$  smallest observations  $Y_1, \dots, Y_k$  and the  $k$  largest observations  $Y_n, Y_{n-1}, \dots, Y_{n-k+1}$  in the sample. The average of the remaining  $n - 2k$  intermediate observations is called the  $k$ th level trimmed mean.

Clearly, the  $k$ th level trimmed mean can be represented as a weighted average of the order statistics having the form

$$\frac{1}{n-2k} \sum_{i=k+1}^{n-k} Y_i. \quad (10.7.4)$$

The sample median is an example of a trimmed mean. When  $n$  is odd, the sample median is the  $[(n-1)/2]$ th level trimmed mean. When  $n$  is even, it is the  $[(n-2)/2]$ th level trimmed mean. In either case, the sample median is the  $k$ th level trimmed mean, where  $k = \lfloor (n-1)/2 \rfloor$  is the largest integer less than or equal to  $(n-1)/2$ .

### Robust Estimation of Scale

In addition to the median of a distribution, there are other parameters that might be worth estimating even when we are not willing to model our data as arising from a particular parametric family. For example, scale parameters might be valuable for giving an idea of how spread out a distribution is. The standard deviation, if it exists, is one such measure. The general class of scale parameters is defined here.

**Definition 10.7.3** **Scale Parameters.** An arbitrary parameter  $\sigma$  is a *scale parameter* for the distribution of  $X$  if, for all  $a > 0$  and all real  $b$ , the corresponding parameter for the distribution of  $aX + b$  is  $a\sigma$ .

Although the standard deviation is a scale parameter, there are many distributions (such as the Cauchy) for which the standard deviation does not exist. There are alternative measures of spread to the standard deviation that exist and are finite for all distributions.

One scale parameter that exists for every distribution is the interquartile range (IQR) as defined in Definition 4.3.2 on page 233. For example, if  $F$  is the normal distribution with mean  $\mu$  and variance  $\sigma^2$ , then the IQR is  $2\Phi^{-1}(0.75)\sigma = 1.349\sigma$  (see Exercise 15). The IQR of the Cauchy distribution is 2 (see Example 4.3.9). It is not difficult to show (see Exercise 11) that if the IQR of  $X$  is  $\sigma$  and if  $a > 0$ , then  $aX + b$  has IQR equal to  $a\sigma$ . An estimator of the IQR is the sample IQR, the difference between the 0.75 and 0.25 sample quantiles. (Sample quantiles are just quantiles of the sample c.d.f.)

Another scale parameter that exists for every random variable  $X$  is the *median absolute deviation*

**Definition 10.7.4** **Median Absolute Deviation.** The *median absolute deviation* of a random variable  $X$  is the median of the distribution of  $|X - m|$ , where  $m$  is the median of  $X$ .

If the distribution of  $X$  is symmetric around its median, then the median absolute deviation is one-half of the IQR. For asymmetric distributions, the median absolute deviation is the half-length of the symmetric interval around the median that contains 50 percent of the distribution, while the IQR is the length of the interval around the median that contains half of the distribution below the median and half of the distribution above the median. For example, if  $X$  has the  $\chi^2$  distribution with five

degrees of freedom, the IQR is 3.95, while the median absolute deviation is 1.895, a little less than one-half of the IQR. An estimator of the median absolute deviation is the sample median absolute deviation. The sample median absolute deviation is the sample median of the values  $|X_i - M_n|$ , where  $M_n$  is the sample median of  $X_1, \dots, X_n$ .

Two other scale parameters that are useful are the IQR divided by 1.349 and the median absolute deviation divided by 0.6745. These parameters were chosen to have the property that if the data come from a normal distribution, then these parameters equal the standard deviation (see Exercise 15). Typical estimators of these parameters are the sample IQR divided by 1.349 and the sample median absolute deviation divided by 0.6745.

### M-Estimators of the Median

The sample mean is heavily influenced by one extreme observation. For example, if one observation  $x$  in a sample of size  $n$  is replaced by  $x + \Delta$ , the sample mean changes by  $\Delta/n$ . If  $\Delta$  is large, this will be a big change. The sample median, on the other hand, is influenced very little, or not at all, by a change in one observation. However, the sample median is inefficient in that it makes use of very few of the observed values. Trimmed means are one attempt to compromise between the sample median and the sample mean by forming estimators that make use of more than just the one or two observations in the middle of the sample while maintaining insensitivity to extreme observations. There are other estimators that also attempt to effect this same type of compromise. These other estimators are M.L.E.'s of  $\theta$  under different assumptions about the p.d.f. of the observations.

The sample mean is the M.L.E. of  $\theta$  if we assume that  $X_1, \dots, X_n$  form a random sample from a normal distribution with mean (and median)  $\theta$  and arbitrary variance. The sample median is also an M.L.E. It is the M.L.E. of  $\theta$  if we assume that  $X_1, \dots, X_n$  form a random sample from one of the following distributions.

**Definition 10.7.5** Laplace Distributions. Let  $\sigma > 0$  and  $\theta$  be real numbers. The distribution whose p.d.f. is

$$f(x|\theta, \sigma) = \frac{1}{2\sigma} e^{-|x-\theta|/\sigma} \quad (10.7.5)$$

is called the *Laplace distribution with parameters  $\theta$  and  $\sigma$* .

See Exercise 9 to prove that the M.L.E. of  $\theta$  is indeed the sample median when the sample comes from a Laplace distribution.

In order to see why the M.L.E.'s for the Laplace and normal distributions are so different, we can examine the two equations that the M.L.E.'s solve for those two cases. These equations say that the derivatives with respect to  $\theta$  of the logarithms of the respective likelihoods must equal 0. In both cases, the derivative of the logarithm of the likelihood is the sum of  $n$  terms, one for each observation. For the normal case, the term corresponding to an observation  $x_i$  is  $(x_i - \theta)/\sigma^2$ . For the Laplace case, the term corresponding to an observation  $x_i$  equals  $1/\sigma$  if  $\theta < x_i$ , and it equals  $-1/\sigma$  if  $\theta > x_i$ . The derivative does not exist at  $\theta = x_i$ . We illustrate these two derivatives in Fig. 10.9 for the cloud-seeding data introduced in Example 8.3.2. A change of size  $\Delta$  in a single observation will vertically shift the entire normal distribution line in Fig. 10.9 by  $\Delta/[n\sigma^2]$ . The same-sized change in the same observation will only affect the Laplace graph in Fig. 10.9 in the vicinity of the changed observation. The actual values of the most extreme observations do not affect where the graph crosses 0.

It would be nice to have a compromise between these two types of behavior without arbitrarily discarding a fixed amount of data. We would like the derivative

**Figure 10.9** Derivatives of the logarithms of the Laplace and normal likelihoods (with  $\sigma = 1$ ) using the cloud-seeding data.

of the logarithm of the likelihood to be approximately proportional to  $\sum(x_i - \theta)$  for  $\theta$  near the middle of the data, where the summation is only over the middle observations. This will allow the estimator to make use of more data than just the very middle observation. Also, we would like the derivative to flatten out like the Laplace case for  $\theta$  near the extremes so that the actual values of the extreme observations do not affect the estimate. A p.d.f. with these properties is the following:

$$g_k(x|\theta, \sigma) = c_k e^{h_k([x-\theta]/\sigma)}, \quad (10.7.6)$$

where  $\sigma$  is a scale parameter,

$$h_k(y) = \begin{cases} -0.5y^2 & \text{if } -k < y < k, \\ 0.5k^2 - k|y| & \text{otherwise,} \end{cases}$$

and  $c_k$  is a constant that makes the integral of  $g$  equal to 1. The number  $k$  must be chosen somehow, usually to reflect some idea of how far from  $\theta$  we think that extreme observations are likely to be. The derivative of the logarithm of  $g_k(x|\theta, \sigma)$  with respect to  $\theta$  is linear in  $\theta$  for  $|\theta - x| < k\sigma$ , but it flattens out like the derivative of the logarithm of the Laplace p.d.f. does when  $|\theta - x| > k\sigma$ . Now, we see that  $k$  can be chosen to reflect how many multiples of  $\sigma$  a data value can be away from  $\theta$  before we think that it starts to lose importance for estimating  $\theta$ . Typical choices are  $1 \leq k \leq 2.5$ . If we suppose that  $X_1, \dots, X_n$  form a random sample from a distribution with p.d.f.  $g_k(x|\theta, \sigma)$ , the M.L.E. of  $\theta$  will be a compromise between the sample median and the sample mean.

**Definition 10.7.6** *M-Estimators.* The M.L.E. of  $\theta$  under the assumption that the data have p.d.f.  $g_k$  in Eq. (10.7.6) is called an *M-estimator*.

*M*-estimators were proposed as robust estimators by Huber (1977). The name derives from the fact that they are found by maximizing a function that might not be the likelihood.

The *M*-estimator found by maximizing  $\prod_{i=1}^n g_k(x_i|\theta, \sigma)$  cannot be obtained in closed form, but there is a simple iterative algorithm for finding it if we can first estimate  $\sigma$ . Typically, one replaces  $\sigma$  by  $\hat{\sigma}$  equal to one of the robust scale estimates described earlier in this section. One popular choice is the sample median absolute deviation divided by 0.6745. Treating  $\prod_{i=1}^n g_k(x_i|\theta, \hat{\sigma})$  as a function of  $\theta$ , we can take the derivative of the logarithm and set it equal to 0 to try to find the maximum. The

derivative of the logarithm is  $-\sum_{i=1}^n \psi_k([x_i - \theta]/\hat{\sigma})/\hat{\sigma}$ , where

$$\psi_k(y) = \begin{cases} -k & \text{if } y < -k, \\ y & \text{if } -k \leq y \leq k, \\ k & \text{if } y > k. \end{cases}$$

Typically, one solves  $\sum_{i=1}^n \psi_k([x_i - \theta]/\hat{\sigma}) = 0$  as follows: Rewrite the equation as  $\sum_{i=1}^n w_i(\theta)(x_i - \theta) = 0$ , where  $w_i(\theta)$  is defined as

$$w_i(\theta) = \begin{cases} \frac{\psi_k([x_i - \theta]/\hat{\sigma})}{x_i - \theta} & \text{if } x_i \neq \theta, \\ 1 & \text{if } x_i = \theta. \end{cases}$$

Then  $\theta = \sum_{i=1}^n w_i(\theta)x_i / \sum_{i=1}^n w_i(\theta)$  solves the equation. Clearly, we need to know  $\theta$  before we can compute  $w_i(\theta)$ , but we can solve the equation iteratively using these steps:

1. Pick a starting value  $\theta_0$  such as the sample median and set  $j = 0$ .
2. Let

$$\theta_{j+1} = \frac{\sum_{i=1}^n w_i(\theta_j)x_i}{\sum_{i=1}^n w_i(\theta_j)}.$$

3. Increment  $j$  to  $j + 1$ , and return to step 2.

This procedure will typically converge in a small number of iterations to the  $M$ -estimate  $\tilde{\theta}$ .

The iterative procedure actually makes it clear why  $\tilde{\theta}$  is robust and why it is a compromise between the sample mean and the sample median. Note that  $\tilde{\theta}$  is a weighted average of the values  $x_1, \dots, x_n$ . The weight on  $x_i$  is proportional to  $w_i(\tilde{\theta})$ . If  $|x_i - \tilde{\theta}| \leq k\hat{\sigma}$ , then  $w_i(\tilde{\theta}) = 1/\hat{\sigma}$ . If  $|x_i - \tilde{\theta}| > k\hat{\sigma}$ , then  $w_i(\tilde{\theta}) = k/|x_i - \tilde{\theta}|$ , which decreases as  $x_i$  becomes more extreme. If  $\tilde{\theta}$  is near the middle of the distribution (as we would hope it would be), then the observations near the middle of the distribution get more weight in the estimate, and those far away get less weight.

**Note: M-Estimators and Symmetric Distributions.** At the start of this section, we assumed that the unknown p.d.f.  $f$  of the data was symmetric about an unknown value  $\theta$ , which must be the median of the distribution. The  $M$ -estimator described above can be calculated even if we do not assume that the data come from a symmetric distribution. However, the  $M$ -estimator will not necessarily estimate the median of the distribution if the distribution is not symmetric. Instead, the  $M$ -estimator estimates the number  $\gamma$  such that

$$E \left[ \psi_k \left( \frac{X_i - \gamma}{\sigma} \right) \right] = 0. \quad (10.7.7)$$

If the distribution of  $X_i$  is symmetric around  $\theta$ , then  $\gamma = \theta$  will solve Eq. (10.7.7). If the distribution of  $X_i$  is not symmetric, then some number other than the median might solve Eq. (10.7.7).

---

**Example  
10.7.3**

**Rain from Seeded Clouds.** Using the seeded cloud data again, we shall find the value of the  $M$ -estimator with  $k = 1.5$ . We start with the sample median of the log-rainfalls,  $\theta_0 = 5.396$ . We also use  $\hat{\sigma}$  equal to the median absolute deviation 0.7318 divided by 0.6745, that is,  $\hat{\sigma} = 1.085$ . The six smallest and three largest observations are not within  $1.5\hat{\sigma}$  of the sample median. These nine observations each get less weight than the other 17 observations in the calculation of the next iteration. For example,

the smallest observation is 1.411, which gets weight  $1.5/|1.411 - 5.396| = 0.3764$ , compared to weight 0.9217 for the 17 central observations. The weighted average of the observations is then  $\theta_1 = 5.315$ . We repeat the weighting and averaging until we get no change. After 10 more iterations, we get  $\theta_{11} = 5.283$ , which agrees with  $\theta_{10}$ .  $\blacktriangleleft$

**Note: Simultaneous M-Estimators Exist for the Median and Scale Parameters.** It is possible to estimate the median and a scale parameter simultaneously using a method very similar to that described for  $M$ -estimators. That is, instead of just picking a value for  $\hat{\sigma}$  in the  $M$ -estimator algorithm, we can construct a more complicated algorithm that estimates both the median and a scale parameter. Readers interested in more examples of robust procedures can read Huber (1981) and Hampel et al. (1986).

### Comparison of the Estimators

We have mentioned the desirability of using a robust estimator in a situation in which it is suspected that the observations  $X_1, \dots, X_n$  may form a random sample from a distribution for which the tails of the p.d.f. are thicker than the tails of the p.d.f. of a normal distribution. The use of a robust estimator is also desirable when a few of the observations in the sample appear to be unusually large or unusually small. In this situation, a statistician might suspect that most of the observations in the sample came from one normal distribution, whereas the few extreme observations may have come from a different normal distribution with a much larger variance than the first one. (This is the contaminated normal case.) The extreme observations, which are called *outliers*, will substantially affect the value of  $\bar{X}_n$  and make it an unreliable estimator of  $\theta$ . Since the values of these outliers would be given less weight in a robust estimator, the robust estimator will usually be a more reliable estimator than  $\bar{X}_n$ .

It is acknowledged that a robust estimator will perform better than  $\bar{X}_n$  in a situation of the type just described. However, if  $X_1, \dots, X_n$  actually do form a random sample from a normal distribution, then  $\bar{X}_n$  will perform better than a robust estimator. Since we are typically not certain which situation obtains in a particular problem, it is important to know how much larger the M.S.E. of a robust estimator will be than the M.S.E. of  $\bar{X}_n$  when the actual distribution is normal. In other words, it is important to know how much is lost if we use a robust estimator when the actual distribution is normal. We shall now consider this question.

When  $X_1, \dots, X_n$  form a random sample from the normal distribution with mean  $\theta$  and variance  $\sigma^2$ , the probability distribution of  $\bar{X}_n$  and the probability distribution of each of the robust estimators described in this chapter will be symmetric with respect to the value  $\theta$ . Therefore, the mean of each of these estimators will be  $\theta$ , the M.S.E. of each estimator will be equal to its variance, and this M.S.E. will have a certain constant value for each estimator regardless of the true value of  $\theta$ . The values of several of these M.S.E.'s for a normal distribution when the sample size  $n$  is 10 or 20 are presented in Table 10.38. The values in Table 10.38 are from Andrews et al. (1972). They were computed using simulation methods that will be introduced in Chapter 12. It should be noted that when  $n = 10$ , the trimmed mean for  $k = 4$  and the sample median are the same estimator.

It can be seen from Table 10.38 that when the underlying distribution is actually a normal distribution, the M.S.E.'s of the  $M$ -estimator and the trimmed means are not much larger than the M.S.E. of  $\bar{X}_n$ . In fact, when  $n = 20$ , the M.S.E. of the second-level trimmed mean ( $k = 2$ ), in which four of the 20 observed values in the sample

**Table 10.38** Comparison of M.S.E.'s for sample mean and several robust estimators. The data have a normal distribution with variance  $\sigma^2$ . The M.S.E. is the tabulated value times  $\sigma^2/n$ . The  $M$ -estimator uses  $k = 1.5$  and  $\hat{\sigma}$  equal to the sample median absolute deviation divided by 0.6745.

Estimator	$n = 10$	$n = 20$
Sample mean $\bar{X}_n$	1.00	1.00
Trimmed mean for $k = 1$	1.05	1.02
Trimmed mean for $k = 2$	1.12	1.06
Trimmed mean for $k = 3$	1.21	1.10
Trimmed mean for $k = 4$	1.37	1.14
Sample median	1.37	1.50
$M$ -estimator	1.05	1.05

**Table 10.39** Comparison of M.S.E.'s for sample mean and several robust estimators. The data have a Cauchy distribution. The M.S.E. is the tabulated value divided by  $n$ . The  $M$ -estimator uses  $k = 1.5$  and  $\hat{\sigma}$  equal to the sample median absolute deviation divided by 0.6745.

Estimator	$n = 10$	$n = 20$
Sample mean $\bar{X}_n$	$\infty$	$\infty$
Trimmed mean for $k = 1$	27.22	23.98
Trimmed mean for $k = 2$	8.57	7.32
Trimmed mean for $k = 3$	3.86	4.57
Trimmed mean for $k = 4$	3.66	3.58
Sample median	3.66	2.88
$M$ -estimator	6.00	4.50

are omitted, is only 1.06 times as large as the M.S.E. of  $\bar{X}_n$ . Even the M.S.E. of the sample median is only 1.5 times that of  $\bar{X}_n$ . These values illustrate the price of using a robust estimator when one is not needed.

We shall now consider the improvement in the M.S.E. that can be achieved by using a robust estimator when the underlying distribution is not normal. If  $X_1, \dots, X_n$  form a random sample of size  $n$  from a Cauchy distribution, then the M.S.E. of  $\bar{X}_n$  is infinite. The M.S.E.'s of robust estimators for a Cauchy distribution when the sample size  $n$  is 10 or 20 are given in Table 10.39. The values in Table 10.39 are from Andrews et al. (1972).

Finally, the M.S.E.'s for two contaminated normal distributions are illustrated in Table 10.40. The two distributions have p.d.f.'s as in Eq. (10.7.2) with  $\epsilon = 0.05$  and

**Table 10.40** Comparison of M.S.E.'s for sample mean and several robust estimators. The data consist of  $n = 20$  observations from a contaminated normal distribution with p.d.f. (10.7.2) using  $\epsilon = 0.05$  and  $\epsilon = 0.10$ . The M.S.E. is the tabulated value divided by  $n$ . The  $M$ -estimator uses  $k = 1.5$  and  $\hat{\sigma}$  equal to the sample median absolute deviation divided by 0.6745.

Estimator	$\epsilon = 0.05$	$\epsilon = 0.1$
Sample mean $\bar{X}_n$	5.95	10.90
Trimmed mean for $k = 1$	1.87	3.92
Trimmed mean for $k = 2$	1.32	2.01
Trimmed mean for $k = 3$	1.27	1.57
Trimmed mean for $k = 4$	1.29	1.50
Sample median	1.62	1.81
$M$ -estimator	1.27	1.58

$\epsilon = 0.1$ . The values in Table 10.40 were computed using simulation methods described in Chapter 12.

It can be seen from Tables 10.39 and 10.40 that the M.S.E. of a robust estimator can be substantially smaller than that of  $\bar{X}_n$ . When a trimmed mean or an  $M$ -estimator is to be used as an estimator of  $\theta$ , it is evident that a specific value of  $k$  must be chosen. No general rule for choosing  $k$  will be best under all conditions. If there is reason to believe that the p.d.f.  $f(x)$  is approximately normal, then  $\theta$  might be estimated by using a trimmed mean, which is obtained by omitting about 10 or 15 percent of the observed values at each end of the ordered sample. Alternatively, an  $M$ -estimator with  $k = 2$  or 2.5 could be used. If the p.d.f.  $f(x)$  might be far from normal or if several of the observations might be outliers, then the sample median might be used to estimate  $\theta$ , or one could use an  $M$ -estimator with  $k = 1$  or 1.5.

We could also compare various scale estimators in a similar fashion. Such a comparison is complicated by the fact that there are several choices of scale parameter to estimate, such as standard deviation, IQR, and median absolute deviation. We shall not present such a comparison here.

### Large-Sample Properties of Sample Quantiles

Earlier in this section, we made use of the sample median as well as the sample 0.25 and 0.75 quantiles to estimate the median and scale features of a distribution. The distributions of these, and other, sample quantiles are difficult to derive exactly. Approximations are available to the distributions of sample quantiles if the sample sizes are large. It can be shown that if  $X_1, \dots, X_n$  form a large random sample from a continuous distribution for which the p.d.f. is  $f(x)$  and for which there is a unique  $p$  quantile  $\theta_p$ , then the distribution of the sample  $p$  quantile will be approximately a normal distribution. Specifically, it must be assumed that  $f(\theta_p) > 0$ .

**Theorem  
10.7.1**

**Asymptotic Distribution of Sample Quantile.** Under the conditions above, let  $\tilde{\theta}_{p,n}$  denote the sample  $p$  quantile. Then, as  $n \rightarrow \infty$ , the c.d.f. of  $n^{1/2}(\tilde{\theta}_{p,n} - \theta_p)$  will converge to the c.d.f. of the normal distribution with mean 0 and variance  $p(1-p)/f^2(\theta_p)$ .

In other words, when  $n$  is large, the distribution of the sample  $p$  quantile  $\tilde{\theta}_{p,n}$  will be approximately the normal distribution with mean  $\theta_p$  and variance  $p(1-p)/[nf^2(\theta_p)]$ .

Also, suppose that  $\tilde{\theta}_{q,n}$  denotes the sample  $q$  quantile for some  $q > p$ , and suppose that  $\theta_q$  is the unique  $q$  quantile of the distribution of the data. Then the joint distribution of  $(\tilde{\theta}_{p,n}, \tilde{\theta}_{q,n})$  is approximately the bivariate normal distribution with means  $\theta_p$  and  $\theta_q$ , variances  $p(1-p)/[nf^2(\theta_p)]$  and  $q(1-q)/[nf^2(\theta_q)]$ , and covariance  $p(1-q)/[nf(\theta_p)f(\theta_q)]$ . See Schervish (1995, section 7.2) for a rigorous derivation of these results.

## Summary

We have introduced a number of estimators of the median and scale parameters that are more robust than the sample average and sample standard deviation. To say that the new estimators are more robust, we mean that they perform well compared to the old estimators, in terms of M.S.E., regardless of which distribution (in some large class) gives rise to the data. The robust estimators of the median include trimmed means, the sample median, and  $M$ -estimators obtained by maximizing a function that is similar to a likelihood function. Robust estimators of scale include the sample interquartile range (IQR), the sample median absolute deviation, and multiples of these that are designed to estimate the standard deviation when the data come from a normal distribution.

## Exercises

1. Suppose that a sample comprises the 15 observed values in Table 10.41. Calculate the values of **(a)** the sample mean, **(b)** the trimmed means for  $k = 1, 2, 3$ , and 4, **(c)** the sample median, and **(d)** the  $M$ -estimator with  $k = 1.5$  and  $\hat{\sigma}$  equal to the sample median absolute deviation divided by 0.6745.

**Table 10.41** Data for Exercise 1

23.0	21.5	63.0
22.5	2.1	22.1
22.4	2.2	21.7
21.7	22.2	22.9
21.3	21.8	22.1

2. Suppose that a sample comprises the 14 observed values in Table 10.42. Calculate the values of **(a)** the sample mean, **(b)** the trimmed means for  $k = 1, 2, 3$ , and 4, **(c)** the

sample median, and **(d)** the  $M$ -estimator with  $k = 1.5$  and  $\hat{\sigma}$  equal to the sample median absolute deviation divided by 0.6745.

**Table 10.42** Data for Exercise 2

1.24	0.36	0.23
0.24	1.78	-2.00
-0.11	0.69	0.24

3. Suppose that a random sample of  $n = 100$  observations is taken from the normal distribution with unknown mean  $\theta$  and known variance 1, and let  $\tilde{\theta}_{.5,n}$  denote the sample median. Determine (approximately) the value of  $\Pr(|\tilde{\theta}_{.5,n} - \theta| \leq 0.1)$ .

- 4.** Suppose that a random sample of  $n = 100$  observations is taken from the Cauchy distribution centered at an unknown point  $\theta$ , and let  $\tilde{\theta}_{.5,n}$  denote the sample median. Determine (approximately) the value of  $\Pr(|\tilde{\theta}_{.5,n} - \theta| \leq 0.1)$ .
- 5.** Let  $f(x)$  denote the p.d.f. of the contaminated normal distribution given in Eq. (10.7.1) with  $\epsilon = 1/2$ ,  $\sigma^2 = 1$ , and  $g$  being the p.d.f. of a normal distribution with mean  $\mu$  and variance 4. Suppose that 100 observations are selected at random from a distribution for which the p.d.f. is  $f(x)$ . Determine the M.S.E. of the sample mean and (approximately) the M.S.E. of the sample median.
- 6.** Use the data in Table 10.6 on page 640. We want an estimate of the median of the logarithms of sulfur dioxide. Find **(a)** the sample mean, **(b)** the trimmed means for  $k = 1, 2, 3$ , and 4, **(c)** the sample median, and **(d)** the  $M$ -estimator with  $k = 1.5$  and  $\hat{\sigma}$  equal to the sample median absolute deviation divided by 0.6745.
- 7.** Suppose that  $X_1, \dots, X_n$  are i.i.d. with a distribution that has the p.d.f. in Eq. (10.7.2). Let  $\bar{X}_n = \frac{1}{n} \sum_{i=1}^n X_i$ .
- Prove that  $E(\bar{X}_n) = \mu$ .
  - Prove that  $\text{Var}(\bar{X}_n) = (1 + 99\epsilon)\sigma^2/n$ .
- 8.** If Fig. 10.8 were extended all the way to  $\epsilon = 1$ , the variance of the sample median would rise above the variance of the sample mean. Indeed, the ratio of the two variances would be the same at  $\epsilon = 1$  as it is at  $\epsilon = 0$ . Explain why this should be true.
- 9.** Assume that  $X_1, \dots, X_n$  form a random sample from the distribution with p.d.f. given in Eq. (10.7.5). Prove that the M.L.E. of  $\theta$  is the sample median. (*Hint:* Let  $X$  have c.d.f. equal to the sample c.d.f. of  $X_1, \dots, X_n$ . Then apply Theorem 4.5.3.)
- 10.** Let  $X_1, \dots, X_n$  be i.i.d. with the p.d.f. in Eq. (10.7.5). Assume that  $\sigma$  is known. Let  $\theta$  be between two of the observed values  $x_1, \dots, x_n$ . Prove that the derivative of the logarithm of the likelihood at  $\theta$  equals  $1/\sigma$  times the difference between the number of observations greater than  $\theta$  and the number of observations less than  $\theta$ .
- 11.** Let  $X$  be a random variable with a continuous distribution such that the interquartile range (IQR) is  $\sigma$ . Prove that the IQR of  $aX + b$  is  $a\sigma$  for all  $a > 0$  and all  $b$ .
- 12.** Let  $X$  be a random variable with a continuous distribution such that the median absolute deviation is  $\sigma$ . Prove that the median absolute deviation of  $aX + b$  is  $a\sigma$  for all  $a > 0$  and all  $b$ .
- 13.** Find the median absolute deviation of the Cauchy distribution.
- 14.** Let  $X$  have the exponential distribution with parameter  $\lambda$ . Prove that the median absolute deviation of  $X$  is smaller than one-half of the IQR. (You can do this without actually calculating the median absolute deviation.)
- 15.** Let  $X$  have a normal distribution with standard deviation  $\sigma$ .
- Prove that the IQR is  $2\Phi^{-1}(0.75)\sigma$ .
  - Prove that the median absolute deviation is  $\Phi^{-1}(0.75)\sigma$ .
- 16.** Darwin (1876, p. 16) reported the results of an experiment in which he grew 15 pairs of *Zea mays* (corn) plants. Each pair consisted of a self-fertilized and a cross-fertilized plant that were grown in the same pot. The numbers below are the differences between heights (in eighths of an inch) of the two plants in each pair (cross-fertilized minus self-fertilized).
- 49, -67, 8, 16, 6, 23, 28, 41, 14, 29, 56, 24, 75, 60, -48
- Find the **(a)** the sample mean, **(b)** the trimmed means for  $k = 1, 2, 3$ , and 4, **(c)** the sample median, and **(d)** the  $M$ -estimator with  $k = 1.5$  and  $\hat{\sigma}$  equal to the sample median absolute deviation divided by 0.6745.
- 17.** Let  $X_1, \dots, X_n$  be a large random sample from a distribution with p.d.f.  $f$ . Assume that  $f$  is symmetric about the median of the distribution. Find the large-sample distribution of the sample IQR.

## ★ 10.8 Sign and Rank Tests

*In this section, we describe some popular nonparametric tests for hypotheses about the median of a distribution or about the difference between two distributions.*

### One-Sample Procedures

#### Example 10.8.1

**Calorie Counts in Hot Dogs.** Consider the  $n = 20$  calorie counts for beef hot dogs given in Exercise 7 in Sec. 8.5. Suppose that we are interested in testing hypotheses about the median calorie count, but we are not willing to assume that the calorie counts follow a normal distribution or any other familiar distribution. Are there methods

that are appropriate when we are not willing to make assumptions about the form of the distribution? 

Suppose that  $X_1, \dots, X_n$  form a random sample from an unknown distribution. In Chapter 9, we considered the case in which the form of the unknown distribution was known, but there were some specific parameters that were still unknown. For example, the distribution might be a normal distribution with unknown mean and/or variance. Now we shall assume only that the distribution is continuous. Since we shall not assume that the distribution of the data has a mean, then we cannot test hypotheses about the mean of the distribution. However, every continuous distribution has a median  $\mu$  that satisfies  $\Pr(X_i \leq \mu) = 0.5$ . The median is a popular measure of location for general distributions, and we shall now present a test procedure for testing hypotheses of the form

$$\begin{aligned} H_0: \quad & \mu \leq \mu_0, \\ H_1: \quad & \mu > \mu_0. \end{aligned} \tag{10.8.1}$$

The test is based on the following simple fact:  $\mu \leq \mu_0$  if and only if  $\Pr(X_i \leq \mu_0) \geq 0.5$ . For  $i = 1, \dots, n$ , let  $Y_i = 1$  if  $X_i \leq \mu_0$ , and let  $Y_i = 0$  otherwise. Define  $p = \Pr(Y_i = 1)$ . Then testing whether  $\mu \leq \mu_0$  is equivalent to testing whether  $p \geq 0.5$ . Since  $X_1, \dots, X_n$  are independent, then so too are  $Y_1, \dots, Y_n$ . This makes  $Y_1, \dots, Y_n$  a random sample from the Bernoulli distribution with parameter  $p$ . We already know how to test the null hypothesis that  $p \geq 0.5$ . (See Example 9.1.9.) We compute  $W = Y_1 + \dots + Y_n$  and reject the null hypothesis if  $W$  is too small. To make the test have level of significance  $\alpha_0$ , choose  $c$  so that

$$\sum_{w=0}^c \binom{n}{w} \left(\frac{1}{2}\right)^n \leq \alpha_0 < \sum_{w=0}^{c+1} \binom{n}{w} \left(\frac{1}{2}\right)^n.$$

Then the test would reject  $H_0$  if  $W \leq c$ .

The test that we have just described is called the *sign test* because it is based on the number of observations for which  $X_i - \mu_0$  is negative. A similar test can be constructed if we wish to test the hypotheses

$$\begin{aligned} H_0: \quad & \mu = \mu_0, \\ H_1: \quad & \mu \neq \mu_0. \end{aligned}$$

Once again, let  $p = \Pr(X_i \leq \mu_0)$ . The null hypothesis  $H_0$  is now equivalent to  $p = 0.5$ . To perform the test at level of significance  $\alpha_0$ , we would choose a number  $c$  such that

$$\sum_{w=0}^c \binom{n}{w} \left(\frac{1}{2}\right)^n \leq \frac{\alpha_0}{2} < \sum_{w=0}^{c+1} \binom{n}{w} \left(\frac{1}{2}\right)^n.$$

We would then reject  $H_0$  if either  $W \leq c$  or  $W \geq n - c$ . We use the symmetric rejection region because the binomial distribution with parameters  $n$  and  $1/2$  is symmetric about  $n/2$ .

---

**Example  
10.8.2**

**Calorie Counts in Hot Dogs.** Consider again the calorie counts for beef hot dogs in Example 10.8.1. Let  $\mu$  stand for the median of the distribution of calories in beef hot dogs. Suppose that we are interested in testing the hypotheses  $H_0: \mu = 150$  versus  $H_1: \mu \neq 150$ . Since 9 of the 20 calorie counts are below 150, we have  $W = 9$ . The two-sided  $p$ -value for this observation is 0.8238, so we would not reject the null hypothesis at level  $\alpha_0$  unless  $\alpha_0 \geq 0.8238$ . 

The power function of the sign test is easy to compute for each value of  $p = \Pr(X_i \leq \mu_0)$ . For example, for the one-sided test of the hypotheses (10.8.1), the power is

$$\Pr(W \leq c) = \sum_{w=0}^c \binom{n}{w} p^w (1-p)^{n-w}.$$

## Comparing Two Distributions

**Example  
10.8.3**

**Comparing Copper Ores.** Consider again the comparison of copper ores in Example 9.6.5. Suppose that we are not comfortable assuming that the distributions of copper ores are normal distributions. Can we still test hypotheses about whether the distributions are the same or whether they have the same medians?  $\blacktriangleleft$

Next, we shall consider a problem in which a random sample of  $m$  observations  $X_1, \dots, X_m$  is taken from a continuous distribution for which the c.d.f.  $F(x)$  is unknown, and an independent random sample of  $n$  observations  $Y_1, \dots, Y_n$  is taken from another continuous distribution for which the c.d.f.  $G(x)$  is also unknown. We desire to test the hypotheses

$$\begin{aligned} H_0: \quad & F = G \\ H_1: \quad & F \neq G. \end{aligned} \tag{10.8.2}$$

One way to test the hypotheses (10.8.2) is to use the Kolmogorov-Smirnov test for two samples described in Sec. 10.6. Furthermore, if we are willing to assume that the two samples are actually drawn from normal distributions with the same unknown variance, then testing the hypotheses (10.8.2) is the same as testing whether two normal distributions have the same mean. Therefore, under this assumption, we could use a two-sample  $t$  test as described in Sec. 9.6.

In this section we shall present another procedure for testing the hypotheses (10.8.2). This procedure, which was introduced separately by F. Wilcoxon and by H. B. Mann and D. R. Whitney in the 1940s, is known as the *Wilcoxon-Mann-Whitney ranks test*.

**The Wilcoxon-Mann-Whitney Ranks Test** In this procedure, we begin by arranging the  $m + n$  observations in the two samples in a single sequence from the smallest value that appears in the two samples to the largest value that appears. Since all the observations come from continuous distributions, it may be assumed that no two of the  $m + n$  observations have the same value. Thus, a total ordering of these  $m + n$  values can be obtained. Each observation in this total ordering is then assigned a rank from 1 to  $m + n$  corresponding to its position in the ordering.

The Wilcoxon-Mann-Whitney ranks test is based on the property that if the null hypothesis  $H_0$  is true and the two samples are actually drawn from the same distribution, then the observations  $X_1, \dots, X_m$  will tend to be dispersed throughout the ordering of all  $m + n$  observations, rather than be concentrated among the smaller values or among the larger values. In fact, when  $H_0$  is true, the ranks that are assigned to the  $m$  observations  $X_1, \dots, X_m$  will be the same as if they were a random sample of  $m$  ranks drawn at random without replacement from a box containing the  $m + n$  ranks 1, 2, ...,  $m + n$ .

Let  $S$  denote the sum of the ranks that are assigned to the  $m$  observations  $X_1, \dots, X_m$ . Since the average of the ranks 1, 2, ...,  $m + n$  is  $(1/2)(m + n + 1)$ , it

**Table 10.43** Sorted data for Example 10.8.4

Observed			Observed		
Rank	Value	Sample	Rank	Value	Sample
1	2.120	y	10	2.431	x
2	2.153	y	11	2.556	x
3	2.183	x	12	2.558	y
4	2.213	y	13	2.587	y
5	2.240	y	14	2.629	x
6	2.245	y	15	2.641	x
7	2.266	y	16	2.715	x
8	2.281	y	17	2.805	x
9	2.336	y	18	2.840	x

follows from the discussion just given that when  $H_0$  is true,

$$E(S) = \frac{m(m + n + 1)}{2}. \quad (10.8.3)$$

Also, it can be shown that when  $H_0$  is true,

$$\text{Var}(S) = \frac{mn(m + n + 1)}{12}. \quad (10.8.4)$$

Furthermore, when the sample sizes  $m$  and  $n$  are large and  $H_0$  is true, the distribution of  $S$  will be approximately the normal distribution for which the mean and the variance are given by Eqs. (10.8.3) and (10.8.4). The Wilcoxon-Mann-Whitney ranks test rejects  $H_0$  if the value of  $S$  deviates very far from its mean value given by Eq. (10.8.3). In other words, the test specifies rejecting  $H_0$  if  $|S - (1/2)m(m + n + 1)| \geq c$ , where the constant  $c$  is chosen appropriately. In particular, when the approximate normal distribution of  $S$  is used, the constant  $c = [\text{Var}(S)]^{1/2}\Phi^{-1}(1 - \alpha_0/2)$  makes the test have level of significance  $\alpha_0$ .

**Example  
10.8.4**

**Comparing Copper Ores.** Consider again the comparison of copper ores in Example 10.8.3. Suppose that the  $m = 8$  measurements in the first sample are

$$2.183, 2.431, 2.556, 2.629, 2.641, 2.715, 2.805, 2.840,$$

while the  $n = 10$  measurements in the second sample are

$$2.120, 2.153, 2.213, 2.240, 2.245, 2.266, 2.281, 2.336, 2.558, 2.587.$$

The 18 values in the two samples are ordered from smallest to largest in Table 10.43. Each observed value in the first sample is identified by the symbol  $x$ , and each observed value in the second sample is identified by the symbol  $y$ . The sum  $S$  of the ranks of the 10 observed values in the first sample is found to be 104.

Suppose that we use the normal distribution approximation. Then if  $H_0$  is true,  $S$  has approximately the normal distribution with mean 76 and variance 126.67. The standard deviation of  $S$  is therefore  $(126.67)^{1/2} = 11.25$ . Hence, if  $H_0$  is true, the random variable  $Z = (S - 76)/(11.25)$  will have approximately the standard normal distribution. Since  $S = 104$  in this example, it follows that  $Z = 2.49$ . The  $p$ -value

corresponding to this value of  $Z$  is 0.0128. Hence, the null hypothesis would be rejected at every level of significance  $\alpha_0 \geq 0.0128$ .  $\blacktriangleleft$

For small values of  $m$  and  $n$ , the normal approximation to the distribution of  $S$  will not be appropriate. Tables of the exact distributions of  $S$  for small sample sizes are given in many published collections of statistical tables. Many statistical software packages also calculate the c.d.f. and quantiles of the exact distribution of  $S$ .

**Note: Tests for Paired Data.** Versions of the sign test and ranks test for paired data are developed in Exercises 1 and 15.

## Ties

The theory of the Wilcoxon-Mann-Whitney ranks test is based on the assumption that all of the observed values of the  $X_i$  and  $Y_j$  will be distinct. Since the measurements in an actual experiment may be made with only limited precision, however, there may actually be observed values that appear more than once. For example, suppose that a Wilcoxon-Mann-Whitney ranks test is to be performed, and it is found that  $X_i = Y_j$  for one or more pairs  $(i, j)$ . In this case, the ranks test should be carried out twice. In the first test, for each pair with  $X_i = Y_j$ , it should be assumed that each  $X_i < Y_j$ . In the second test, assume that  $X_i > Y_j$ . If the tail areas found from the two tests are roughly equal, then the ties are a relatively unimportant part of the data. If, on the other hand, the tail areas are quite different, then the ties can seriously affect the inferences that are to be made. In this case the data may be inconclusive.

**Example  
10.8.5**

**Calcium Supplements and Blood Pressure.** Consider the data from Exercise 10 in Sec. 9.6, which we used to illustrate the Kolmogorov-Smirnov test in Example 10.6.4. The observed values  $-5$  and  $-3$  appear in both samples. First, we shall assign the smaller ranks to those values in the group that received the calcium supplement (the  $X_i$ 's) and then assign the smaller rank to the placebo group (the  $Y_j$ 's). For example, in the combined sample, the  $-3$  values are the fifth, sixth, and seventh smallest. In the first test, we shall assign rank 5 to the  $X_i$  that equals  $-3$  and ranks 6 and 7 to the two  $Y_j$ 's that equal  $-3$ . In the second test, we shall assign rank 7 to the  $X_i$  that equals  $-3$  and ranks 5 and 6 to the  $Y_j$ 's. For the first test, the sum of the  $X$  ranks is 123, and in the second test, the sum of the  $X$  ranks is 126. In this problem,  $m = 10$  and  $n = 11$ , so the mean and variance of  $S$  when the null hypothesis is true are 110 and 201.7, respectively. The two-sided tail areas corresponding to the two assignments are 0.36 and 0.26. Neither of these would lead to rejecting the null hypothesis at level  $\alpha_0$  unless  $\alpha_0 \geq 0.26$ .  $\blacktriangleleft$

Other reasonable methods for handling ties have been proposed. When two or more values are the same, one simple method is to consider the successive ranks that are to be assigned to these values and then assign the average of these ranks to each of the tied values. When this method is used, the value of  $\text{Var}(S)$  must be corrected because of the ties.

## Power of the Wilcoxon-Mann-Whitney Ranks Test

The Wilcoxon-Mann-Whitney ranks test rejects the null hypothesis that the two distributions are the same when the sum  $S$  of the  $X$  ranks is either too large or too small. This would be a sensible thing to do if one thought that the most important

alternatives were those in which the  $X_i$  values tended to be larger than the  $Y_j$  values or those in which the  $X_i$  values tended to be smaller than the  $Y_j$  values. However, there are other situations in which  $F \neq G$ , but  $S$  tends to be close to the mean in Eq. (10.8.3). For example, suppose that all  $X_1, \dots, X_m$  have the uniform distribution on the interval  $[0, 1]$  and  $Y_1, \dots, Y_n$  have the following p.d.f.:

$$g(y) = \begin{cases} 0.5 & \text{if } -1 < y < 0 \text{ or } 1 < y < 2, \\ 0 & \text{otherwise.} \end{cases}$$

Then it is not difficult to show that  $E(S)$  is the same as Eq. (10.8.3) and  $\text{Var}(S) = m^2n/4$ . In such a case, the power of the test (the probability of rejecting  $H_0$ ) would not be much larger than the level of significance  $\alpha_0$ . Indeed, if one were concerned about alternatives of this sort, one would wish to reject  $H_0$  if the  $X$  ranks were too closely clustered regardless of whether they were large or small.

The Wilcoxon-Mann-Whitney ranks test is designed to have high power when  $F$  and  $G$  have a special relationship to each other, defined next.

### Definition

#### 10.8.1

**Stochastically Larger.** Let  $X$  be a random variable with c.d.f.  $F$ , and let  $Y$  be a random variable with c.d.f.  $G$ . Let  $F^{-1}$  and  $G^{-1}$  denote the respective quantile functions. We say that  $F$  is *stochastically larger* than  $G$  or, equivalently, that  $X$  is *stochastically larger* than  $Y$  if  $F^{-1}(p) \geq G^{-1}(p)$  for all  $0 < p < 1$ ; that is, every quantile of  $X$  is at least as large as the corresponding quantile of  $Y$ .

It is easy to see that if  $X_i$  is stochastically larger than  $Y_j$ , then the ranks of the  $X_i$ 's in the combined sample will tend to be at least as large as the ranks of the  $Y_j$ 's. This will make large values of  $S$  more likely than small values. Similarly, if  $Y_j$  is stochastically larger than  $X_i$ ,  $S$  will tend to be small.

When neither  $X_i$  nor  $Y_j$  is stochastically larger than the other, it is difficult to make any general claim about the distribution of  $S$ . For large sample sizes, a normal approximation still holds for the distribution of  $S$ , even when  $F \neq G$ . However, the mean and variance of  $S$  depend on the two c.d.f.'s  $F$  and  $G$ . For example, using the result in Exercise 11, one can show that

$$E(S) = nm \Pr(X_1 \geq Y_1) + \frac{m(m+1)}{2}. \quad (10.8.5)$$

Using this same approach, one can also show that

$$\begin{aligned} \text{Var}(S) = nm & \left[ \Pr(X_1 \geq Y_1) - (m+n-1) \Pr(X_1 \geq Y_1)^2 \right. \\ & \left. + (n-1) \Pr(X_1 \geq Y_1, X_1 \geq Y_2) + (m-1) \Pr(X_1 \geq Y_1, X_2 \geq Y_1) \right]. \end{aligned} \quad (10.8.6)$$

In principle, all of these probabilities could be computed for each specific choice of  $F$  and  $G$ . For particular choices of  $F$  and  $G$ , one could use simulation methods (see Chapter 12) to approximate the necessary probabilities. After computing or approximating these probabilities, one can then approximate the power of the level  $\alpha_0$  Wilcoxon-Mann-Whitney ranks test as follows: First, recall that the test rejects the null hypothesis that  $F = G$  if  $S \leq c_1$  or  $S \geq c_2$ , where

$$\begin{aligned} c_1 &= \frac{m(m+n+1)}{2} - \Phi^{-1} \left( 1 - \frac{\alpha_0}{2} \right) \left[ \frac{mn(m+n+1)}{12} \right]^{1/2}, \\ c_2 &= \frac{m(m+n+1)}{2} + \Phi^{-1} \left( 1 - \frac{\alpha_0}{2} \right) \left[ \frac{mn(m+n+1)}{12} \right]^{1/2}. \end{aligned}$$

Then the power of the test is

$$\Phi\left(\frac{c_1 - E(S)}{\text{Var}(S)^{1/2}}\right) + 1 - \Phi\left(\frac{c_2 - E(S)}{\text{Var}(S)^{1/2}}\right),$$

where  $E(S)$  and  $\text{Var}(S)$  are given by Eqs. (10.8.5) and (10.8.6), respectively.

## Summary

The sign test was introduced as a nonparametric test for hypotheses about the median of an unknown distribution. The Wilcoxon-Mann-Whitney ranks test was developed as another nonparametric test for hypotheses about the equality of two c.d.f.'s. The Wilcoxon-Mann-Whitney ranks test was designed to have large power function when one of the two distributions is stochastically larger than the other.

## Exercises

- 1.** Suppose that  $(X_1, Y_1), \dots, (X_n, Y_n)$  are i.i.d. pairs of random variables with a continuous joint distribution. Let  $p = \Pr(X_i \leq Y_i)$ , and suppose that we want to test the hypotheses

$$\begin{aligned} H_0: \quad p &\leq 1/2, \\ H_1: \quad p &> 1/2. \end{aligned} \quad (10.8.7)$$

Describe a version of the sign test to use for testing these hypotheses.

- 2.** Consider again the data in Example 10.8.4. Test the hypotheses (10.8.2) by applying the Kolmogorov-Smirnov test for two samples.

- 3.** Consider again the data in Example 10.8.4. Test the hypotheses (10.8.2) by assuming that the observations are taken from two normal distributions with the same variance, and apply a  $t$  test of the type described in Sec. 9.6.

- 4.** In an experiment to compare the effectiveness of two drugs  $A$  and  $B$  in reducing blood glucose concentrations, drug  $A$  was administered to 25 patients, and drug  $B$  was administered to 15 patients. The reductions in blood glucose concentrations for the 25 patients who received drug  $A$  are given in Table 10.44. The reductions in concentrations for the 15 patients who received drug  $B$  are given in Table 10.45. Test the hypothesis that the two drugs are equally effective in reducing blood glucose concentrations by using the Wilcoxon-Mann-Whitney ranks test.

**Table 10.44** Data for patients who receive drug  $A$  in Exercise 4

0.35	1.12	1.54	0.13	0.77
0.16	1.20	0.40	1.38	0.39
0.58	0.04	0.44	0.75	0.71
1.64	0.49	0.90	0.83	0.28
1.50	1.73	1.15	0.72	0.91

**Table 10.45** Data for patients who receive drug  $B$  in Exercise 4

1.78	1.25	1.01
1.82	1.95	1.81
0.68	1.48	1.59
0.89	0.86	1.63
1.26	1.07	1.31

- 5.** Consider again the data in Exercise 4. Test the hypothesis that the two drugs are equally effective by applying the Kolmogorov-Smirnov test for two samples.

- 6.** Consider again the data in Exercise 4. Test the hypothesis that the two drugs are equally effective by assuming that the observations are taken from two normal distributions with the same variance and applying a  $t$  test of the type described in Sec. 9.6.

- 7.** Suppose that  $X_1, \dots, X_m$  form a random sample of  $m$  observations from a continuous distribution for which the p.d.f.  $f(x)$  is unknown, and that  $Y_1, \dots, Y_n$  form an independent random sample of  $n$  observations from another continuous distribution for which the p.d.f.  $g(x)$  is also unknown. Suppose also that  $f(x) = g(x - \theta)$  for  $-\infty < x < \infty$ , where the value of the parameter  $\theta$  is unknown ( $-\infty < \theta < \infty$ ). Let  $F^{-1}$  be the quantile function of the  $X_i$ 's, and let  $G^{-1}$  be the quantile function of the  $Y_j$ 's. Show that  $F^{-1}(p) = \theta + G^{-1}(p)$  for all  $0 < p < 1$ .

- 8.** Consider again the conditions of Exercise 7. Describe how to carry out a one-sided Wilcoxon-Mann-Whitney ranks test of the following hypotheses:

$$\begin{aligned} H_0: \quad \theta &\leq 0, \\ H_1: \quad \theta &> 0. \end{aligned}$$

- 9.** Consider again the conditions of Exercise 7. Describe how to carry out a two-sided Wilcoxon-Mann-Whitney ranks test of the following hypotheses for a specified value of  $\theta_0$ :

$$\begin{aligned} H_0: \quad \theta = \theta_0, \\ H_1: \quad \theta \neq \theta_0. \end{aligned}$$

- 10.** Consider again the conditions of Exercise 9. Describe how to use the Wilcoxon-Mann-Whitney ranks test to determine a confidence interval for  $\theta$  with confidence coefficient  $1 - \alpha_0$ . Hint: For which values of  $\theta_0$  would you accept the null hypothesis  $H_0: \theta = \theta_0$  at level of significance  $\alpha_0$ ?

- 11.** Let  $X_1, \dots, X_m$  and  $Y_1, \dots, Y_n$  be the observations in two samples, and suppose that no two of these observations are equal. Consider the  $mn$  pairs

$$\begin{array}{lll} (X_1, Y_1) & \dots & (X_1, Y_n), \\ (X_2, Y_1) & \dots & (X_2, Y_n), \\ \vdots & & \\ (X_m, Y_1) & \dots & (X_m, Y_n). \end{array}$$

Let  $U$  denote the number of these pairs for which the value of the  $X$  component is greater than the value of the  $Y$  component. Show that

$$U = S - \frac{1}{2}m(m+1),$$

where  $S$  is the sum of the ranks assigned to  $X_1, \dots, X_m$ , as defined in this section.

- 12.** Let  $X_1, \dots, X_m$  be i.i.d. with c.d.f.  $F$  independently of  $Y_1, \dots, Y_n$ , which are i.i.d. with c.d.f.  $G$ . Let  $S$  be as defined in this section. Prove that Eq. (10.8.5) gives the mean of  $S$ .

- 13.** Under the conditions of Exercise 12, prove that Eq. (10.8.6) gives the variance of  $S$ .

- 14.** Under the conditions of Exercises 12 and 13, suppose further that  $F = G$ . Prove that Eqs. (10.8.5) and (10.8.6) agree with Eqs. (10.8.3) and (10.8.4), respectively.

- 15.** Consider again the conditions of Exercise 1. This time, let  $D_i = X_i - Y_i$ . Wilcoxon (1945) developed the following test of the hypotheses (10.8.7). Order the absolute values  $|D_1|, \dots, |D_n|$  from smallest to largest, and assign ranks from 1 to  $n$  to the values. Then  $S_W$  is set equal to the sum of all the ranks of those  $|D_i|$  such that  $D_i > 0$ . If the distribution of  $D_i$  is symmetric around 0, then the mean and variance of  $S_W$  are

$$E(S_W) = \frac{n(n+1)}{4}, \quad (10.8.8)$$

$$\text{Var}(S_W) = \frac{n(n+1)(2n+1)}{24}. \quad (10.8.9)$$

The test rejects  $H_0$  if  $S_W \geq c$ , where  $c$  is chosen to make the test have level of significance  $\alpha_0$ . This test is called the *Wilcoxon signed ranks test*. If  $n$  is large, a normal distribution approximation allows us to use  $c = E(S_W) + \Phi^{-1}(1 - \alpha_0) \text{Var}(S_W)^{1/2}$ .

- a.** Let  $W_i = 1$  if the  $|D_i|$  that gets rank  $i$  has  $D_i > 0$  and  $W_i = 0$  if not. Show that  $S_W = \sum_{i=1}^n i W_i$ .
- b.** Prove that  $E(S_W)$  is as stated in Eq. (10.8.8) under the assumption that the distribution of  $D_i$  is symmetric around 0. Hint: You may wish to use Eq. (4.7.13).
- c.** Prove that  $\text{Var}(S_W)$  is as stated in Eq. (10.8.9) under the assumption that the distribution of  $D_i$  is symmetric around 0. Hint: You may wish to use Eq. (4.7.14).
- 16.** In an experiment to compare two different materials  $A$  and  $B$  that might be used for manufacturing the heels of men's dress shoes, 15 men were selected and fitted with a new pair of shoes on which one heel was made of material  $A$  and one heel was made of material  $B$ . At the beginning of the experiment, each heel was 10 millimeters thick. After the shoes had been worn for one month, the remaining thickness of each heel was measured. The results are given in Table 10.46. Test the null hypothesis that material  $A$  is not more durable than material  $B$  against the alternative that material  $A$  is more durable than material  $B$ , by using **(a)** the sign test of Exercise 1, **(b)** the Wilcoxon signed-ranks test of Exercise 15, and **(c)** the paired  $t$  test.

**Table 10.46** Data for Exercise 16

Pair	Material A	Material B
1	6.6	7.4
2	7.0	5.4
3	8.3	8.8
4	8.2	8.0
5	5.2	6.8
6	9.3	9.1
7	7.9	6.3
8	8.5	7.5
9	7.8	7.0
10	7.5	6.6
11	6.1	4.4

13	6.1	4.2
14	9.4	9.4
15	9.1	9.1

## 10.9 Supplementary Exercises

- 1.** Describe how to use the sign test to form a coefficient  $1 - \alpha_0$  confidence interval for the median  $\theta$  of an unknown distribution. Use the data in Exercise 7 in Sec. 8.5 to construct the observed coefficient 0.95 confidence interval. Hint: For which values of  $\theta_0$  would you fail to reject the null hypothesis  $H_0 : \theta = \theta_0$  at level of significance  $\alpha_0$ ?

- 2.** Suppose that 400 persons are chosen at random from a large population, and that each person in the sample specifies which one of five breakfast cereals she most prefers. For  $i = 1, \dots, 5$ , let  $p_i$  denote the proportion of the population that prefers cereal  $i$ , and let  $N_i$  denote the number of persons in the sample who prefer cereal  $i$ . It is desired to test the following hypotheses at the level of significance 0.01:

$$H_0: p_1 = p_2 = \dots = p_5,$$

$H_1$ : The hypothesis  $H_0$  is not true.

For what values of  $\sum_{i=1}^5 N_i^2$  would  $H_0$  be rejected?

- 3.** Consider a large population of families that have exactly three children, and suppose that it is desired to test the null hypothesis  $H_0$  that the distribution of the number of boys in each family is a binomial distribution with parameters  $n = 3$  and  $p = 1/2$  against the general alternative  $H_1$  that  $H_0$  is not true. Suppose also that in a random sample of 128 families it is found that 26 families have no boys, 32 families have one boy, 40 families have two boys, and 30 families have three boys. At what levels of significance should  $H_0$  be rejected?

- 4.** Consider again the conditions of Exercise 3, including the observations in the random sample of 128 families, but suppose now that it is desired to test the composite null hypothesis  $H_0$  that the distribution of the number of boys in each family is a binomial distribution for which  $n = 3$ , and the value of  $p$  is not specified against the general alternative  $H_1$  that  $H_0$  is not true. At what levels of significance should  $H_0$  be rejected?

- 5.** In order to study the genetic history of three different large groups of Americans, a random sample of 50 persons is drawn from group 1, a random sample of 100 persons is drawn from group 2, and a random sample of 200 persons is drawn from group 3. The blood type of each person in the samples is classified as  $A$ ,  $B$ ,  $AB$ , or  $O$ , and the results are as given in Table 10.47. Test the hypothesis that the distribution of blood types is the same in all three groups at the level of significance 0.1.

**Table 10.47** Data for Exercises 5 and 6

	A	B	AB	O	Total
Group 1	24	6	5	15	50
Group 2	43	24	7	26	100
Group 3	69	47	22	62	200

- 6.** Consider again the conditions of Exercise 5. Explain how to change the numbers in Table 10.47 in such a way that each row total and each column total remains unchanged, but the value of the  $\chi^2$  test statistic is increased.

- 7.** Consider a  $\chi^2$  test of independence that is to be applied to the elements of a  $2 \times 2$  contingency table. Show that the quantity  $(N_{ij} - \hat{E}_{ij})^2$  has the same value for each of the four cells of the table.

- 8.** Consider again the conditions of Exercise 7. Show that the  $\chi^2$  statistic  $Q$  can be written in the form

$$Q = \frac{n(N_{11}N_{22} - N_{12}N_{21})^2}{N_{1+}N_{2+}N_{+1}N_{+2}}.$$

- 9.** Suppose that a  $\chi^2$  test of independence at the level of significance 0.01 is to be applied to the elements of a  $2 \times 2$  contingency table containing  $4n$  observations, and that the data have the form given in Table 10.48. For what values of  $a$  would the null hypothesis be rejected?

**Table 10.48** Form of the data for Exercise 9

$n+a$	$n-a$
$n-a$	$n+a$

- 10.** Suppose that a  $\chi^2$  test of independence at the level of significance 0.005 is to be applied to the elements of a  $2 \times 2$  contingency table containing  $2n$  observations, and that for some  $\alpha \in (0, 1)$  the data have the form given in Table 10.49. For what values of  $\alpha$  would the null hypothesis be rejected?

**Table 10.49** Form of the data for Exercise 10

$\alpha n$	$(1-\alpha)n$
$(1-\alpha)n$	$\alpha n$

- 11.** In a study of the health effects of air pollution, it was found that the proportion of the total population of city  $A$  that suffered from respiratory diseases was larger than the proportion for city  $B$ . Since city  $A$  was generally regarded as being less polluted and more healthful than city  $B$ , this result was considered surprising. Therefore, separate investigations were made for the younger population (under age 40) and for the older population (age 40 or older). It

was found that the proportion of the younger population suffering from respiratory diseases was smaller for city *A* than for city *B*, and also that the proportion of the older population suffering from respiratory diseases was smaller for city *A* than for city *B*. Discuss and explain these results.

**12.** Suppose that an achievement test in mathematics was given to students from two different high schools *A* and *B*. When the results of the test were tabulated, it was found that the average score for the freshmen at school *A* was higher than the average for the freshmen at school *B*, and that the same relationship existed for the sophomores, the juniors, and the seniors at the two schools. On the other hand, it was found also that the average score of all the students at school *A* was lower than that of all the students at school *B*. Discuss and explain these results. Give an example of how this could happen.

**13.** A random sample of 100 hospital patients suffering from depression received a particular treatment over a period of three months. Prior to the beginning of the treatment, each patient was classified as being at one of five levels of depression, where level 1 represented the most severe level of depression and level 5 represented the mildest level. At the end of the treatment, each patient was again classified according to the same five levels of depression. The results are given in Table 10.50. Discuss the use of this table for determining whether the treatment has been helpful in alleviating depression.

**Table 10.50** Data for Exercise 13

Level of depression before treatment	Level of depression after treatment				
	1	2	3	4	5
1	7	3	0	0	0
2	1	27	14	2	0
3	0	0	19	8	2
4	0	1	2	12	0
5	0	0	1	1	0

**14.** Suppose that a random sample of three observations is drawn from a distribution with the following p.d.f.:

$$f(x) = \begin{cases} \theta x^{\theta-1} & \text{for } 0 < x < 1, \\ 0 & \text{otherwise,} \end{cases}$$

where  $\theta > 0$ . Determine the p.d.f. of the sample median.

**15.** Suppose that a random sample of  $n$  observations is drawn from a distribution for which the p.d.f. is as given in Exercise 14. Determine the asymptotic distribution of the sample median.

**16.** Suppose that a random sample of  $n$  observations is drawn from a  $t$  distribution with  $\alpha > 2$  degrees of free-

dom. Show that the asymptotic distributions of both the sample mean  $\bar{X}_n$  and the sample median  $\tilde{X}_n$  are normal, and determine the positive integers  $\alpha$  for which the variance of the asymptotic distribution is smaller for  $\bar{X}_n$  than for  $\tilde{X}_n$ .

**17.** Suppose that  $X_1, \dots, X_n$  form a large random sample from a distribution for which the p.d.f. is  $h(x|\theta) = \alpha f(x|\theta) + (1 - \alpha)g(x|\theta)$ . Here  $f(x|\theta)$  is the p.d.f. of the normal distribution with unknown mean  $\theta$  and variance 1,  $g(x|\theta)$  is the p.d.f. of the normal distribution with the same unknown mean  $\theta$  and variance  $\sigma^2$ , and  $0 \leq \alpha \leq 1$ . Let  $\bar{X}_n$  and  $\tilde{X}_n$  denote the sample mean and the sample median, respectively.

- a. For  $\sigma^2 = 100$ , determine the values of  $\alpha$  for which the M.S.E. of  $\tilde{X}_n$  will be smaller than the M.S.E. of  $\bar{X}_n$ .
- b. For  $\alpha = 1/2$ , determine the values of  $\sigma^2$  for which the M.S.E. of  $\tilde{X}_n$  will be smaller than the M.S.E. of  $\bar{X}_n$ .

**18.** Suppose that  $X_1, \dots, X_n$  form a random sample from a distribution with p.d.f.  $f(x)$ , and let  $Y_1 < Y_2 < \dots < Y_n$  denote the order statistics of the sample. Prove that the joint p.d.f. of  $Y_1, \dots, Y_n$  is as follows:

$$g(y_1, \dots, y_n) = \begin{cases} n!f(y_1) \cdots f(y_n) & \text{for } y_1 < y_2 < \cdots < y_n \\ 0 & \text{otherwise.} \end{cases}$$

**19.** Let  $Y_1 < Y_2 < Y_3$  denote the order statistics of a random sample of three observations from the uniform distribution on the interval  $[0, 1]$ . Determine the conditional distribution of  $Y_2$  given that  $Y_1 = y_1$  and  $Y_3 = y_3$  ( $0 < y_1 < y_3 < 1$ ).

**20.** Suppose that a random sample of 20 observations is drawn from an unknown continuous distribution, and let  $Y_1 < \dots < Y_{20}$  denote the order statistics of the sample. Also, let  $\theta$  denote the 0.3 quantile of the distribution, and suppose that it is desired to present a confidence interval for  $\theta$  that has the form  $(Y_r, Y_{r+3})$ . Determine the value of  $r$  ( $r = 1, 2, \dots, 17$ ) for which this interval will have the largest confidence coefficient  $\gamma$ , and determine the value of  $\gamma$ .

**21.** Suppose that  $X_1, \dots, X_m$  form a random sample from a continuous distribution for which the p.d.f.  $f(x)$  is unknown;  $Y_1, \dots, Y_n$  form an independent random sample from another continuous distribution for which the p.d.f.  $g(x)$  also is unknown; and  $f(x) = g(x - \theta)$  for  $-\infty < x < \infty$ , where the value of the parameter  $\theta$  is unknown ( $-\infty < \theta < \infty$ ). Suppose that it is desired to carry out a Wilcoxon-Mann-Whitney ranks test of the following hypotheses at a specified level of significance  $\alpha$  ( $0 < \alpha < 1$ ):

$$\begin{aligned} H_0: \quad \theta &= \theta_0, \\ H_1: \quad \theta &\neq \theta_0. \end{aligned}$$

Assume that no two of the observations are equal, and

let  $U_{\theta_0}$  denote the number of pairs  $(X_i, Y_j)$  such that  $X_i - Y_j > \theta_0$ , where  $i = 1, \dots, m$  and  $j = 1, \dots, n$ . Show that for large values of  $m$  and  $n$ , the hypothesis  $H_0$  should not be rejected if and only if

$$\frac{mn}{2} - \Phi^{-1}\left(1 - \frac{\alpha}{2}\right) \left[ \frac{mn(m+n+1)}{12} \right]^{1/2} \\ < U_{\theta_0} < \frac{mn}{2} + \Phi^{-1}\left(1 - \frac{\alpha}{2}\right) \left[ \frac{mn(m+n+1)}{12} \right]^{1/2},$$

where  $\Phi^{-1}$  is the quantile function of the standard normal distribution. *Hint:* See Exercise 11 of Sec. 10.8.

**22.** Consider again the conditions of Exercise 21. Show that a confidence interval for  $\theta$  with confidence coefficient  $1 - \alpha$  can be obtained by the following procedure: Let  $k$  be the largest integer less than or equal to

$$\frac{mn}{2} - \Phi^{-1}\left(1 - \frac{\alpha}{2}\right) \left[ \frac{mn(m+n+1)}{12} \right]^{1/2}.$$

Also, let  $A$  be the  $k$ th smallest of the  $mn$  differences  $X_i - Y_j$ , where  $i = 1, \dots, m$  and  $j = 1, \dots, n$ , and let  $B$  be the  $k$ th largest of these  $mn$  differences. Then the interval  $A < \theta < B$  is a confidence interval of the required type.

**23.** The sign test can be extended to a test of hypotheses about an arbitrary quantile of a distribution rather than just the median. Let  $\theta_p$  be the  $p$  quantile of a distribution, and suppose that  $X_1, \dots, X_n$  form an i.i.d. sample from this distribution.

- a. Let  $b$  be an arbitrary number. Explain how to construct a version of the sign test for the hypotheses

$$H_0: \theta_p = b, \\ H_1: \theta_p \neq b,$$

at level of significance  $\alpha_0$ . (Construct an equal-tailed test if you wish.)

- b. Show how to use this version of the sign test to form a coefficient  $1 - \alpha_0$  confidence interval for  $\theta_p$ .

## 11.1 The Method of Least Squares

*When each observation from an experiment is a pair of numbers, it is often important to try to predict one of the numbers from the other. Least squares is a method for constructing a predictor of one of the variables from the other by making use of a sample of observed pairs.*

### Fitting a Straight Line

**Example**  
**11.1.1**

**Blood Pressure.** Suppose that each of 10 patients is treated with the same amount of two different drugs that can affect blood pressure. To be specific, each patient is first treated with a standard drug  $A$ , and their change in blood pressure is measured. After the effect of the drug wears off, the patient is treated with an equal amount of a new drug  $B$ , and their change in blood pressure is measured again. These changes in blood pressure will be called the *reaction* of the patient to each drug. For  $i = 1, \dots, 10$ , we shall let  $x_i$  denote the reaction, measured in appropriate units, of the  $i$ th patient to drug  $A$ , and we shall let  $y_i$  denote her reaction to drug  $B$ . The observed values of the reactions are as given in Table 11.1. The 10 points  $(x_i, y_i)$  for  $i = 1, \dots, 10$  are plotted in Fig. 11.1. One purpose of the study is to try to predict a patient's reaction to drug  $B$  if their reaction to the standard drug  $A$  is already known. ▀

In Example 11.1.1, suppose that we are interested in describing the relationship between the reaction  $y$  of a patient to drug  $B$  and her reaction  $x$  to drug  $A$ . In order to obtain a simple expression for this relationship, we might wish to fit a straight line to the 10 points plotted in Fig. 11.1. Although these 10 points obviously do not lie exactly on a straight line, we might believe that the deviations from such a line are caused by the fact that the observed change in the blood pressure of each patient is affected not only by the two drugs but also by various other factors. In other words, we might believe that if it were possible to control all of these other factors, the observed points would actually lie on a straight line. We might believe further that if we measured the reactions to the two drugs for a very large number of patients, instead of for just 10 patients, we would then find that the observed points tend to

**Table 11.1** Reactions to two drugs

$i$	$x_i$	$y_i$
1	1.9	0.7
2	0.8	-1.0
3	1.1	-0.2
4	0.1	-1.2
5	-0.1	-0.1
6	4.4	3.4
7	4.6	0.0
8	1.6	0.8
9	5.5	3.7
10	3.4	2.0

**Figure 11.1** A plot of the observed values in Table 11.1.

cluster along a straight line. Perhaps we might also wish to be able to predict the reaction  $y$  of a future patient to the new drug  $B$  on the basis of her reaction  $x$  to the standard drug  $A$ . One procedure for making such a prediction would be to fit a straight line to the points in Fig. 11.1, and to use this line for predicting the value of  $y$  corresponding to each value of  $x$ .

It can be seen from Fig. 11.1 that if we did not have to consider the point  $(4.6, 0.0)$ , which is obtained from the patient for whom  $i = 7$  in Table 11.1, then the other nine points lie roughly along a straight line. One arbitrary line that fits reasonably well to these nine points is sketched in Fig. 11.2. However, if we wish to fit a straight line to all 10 points, it is not clear just how much the line in Fig. 11.2 should be adjusted in order to accommodate the anomalous point. We shall now describe a method for fitting such a line.

**Figure 11.2** A straight line fitted to nine of the points in Table 11.1.

**Figure 11.3** Vertical deviations of the plotted points from a straight line.

## The Least-Squares Line

### Example 11.1.2

**Blood Pressure.** In Example 11.1.1, suppose that we are interested in fitting a straight line to the points plotted in Fig. 11.1 in order to obtain a simple mathematical relationship for expressing the reaction  $y$  of a patient to the new drug  $B$  as a function of her reaction  $x$  to the standard drug  $A$ . In other words, our main objective is to be able to predict closely a patient's reaction  $y$  to drug  $B$  from her reaction  $x$  to drug  $A$ . We are interested, therefore, in constructing a straight line such that, for each observed reaction  $x_i$ , the corresponding value of  $y$  on the straight line will be as close as possible to the actual observed reaction  $y_i$ . The vertical deviations of the 10 plotted points from the line drawn in Fig. 11.2 are sketched in Fig. 11.3. ◀

One method of constructing a straight line to fit the observed values is called *the method of least squares*, which chooses the line to minimize the sum of the squares of the vertical deviations of all the points from the line. We shall now study the method of least squares in more detail.

**Theorem 11.1.1** **Least Squares.** Let  $(x_1, y_1), \dots, (x_n, y_n)$  be a set of  $n$  points. The straight line that minimizes the sum of the squares of the vertical deviations of all the points from the line has the following slope and intercept:

$$\hat{\beta}_1 = \frac{\sum_{i=1}^n (y_i - \bar{y})(x_i - \bar{x})}{\sum_{i=1}^n (x_i - \bar{x})^2}, \quad (11.1.1)$$

$$\hat{\beta}_0 = \bar{y} - \hat{\beta}_1 \bar{x},$$

where  $\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i$  and  $\bar{y} = \frac{1}{n} \sum_{i=1}^n y_i$ .

**Proof** Consider an arbitrary straight line  $y = \beta_0 + \beta_1 x$ , in which the values of the constants  $\beta_0$  and  $\beta_1$  are to be determined. When  $x = x_i$ , the height of this line is  $\beta_0 + \beta_1 x_i$ . Therefore, the vertical distance between the point  $(x_i, y_i)$  and the line is  $|y_i - (\beta_0 + \beta_1 x_i)|$ . Suppose that the line is to be fitted to  $n$  points. The sum of the squares of the vertical distances at the  $n$  points is

$$Q = \sum_{i=1}^n [y_i - (\beta_0 + \beta_1 x_i)]^2. \quad (11.1.2)$$

We shall minimize  $Q$  with respect to  $\beta_0$  and  $\beta_1$  by taking the partial derivatives and setting them to 0. We have

$$\frac{\partial Q}{\partial \beta_0} = -2 \sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_i) \quad (11.1.3)$$

and

$$\frac{\partial Q}{\partial \beta_1} = -2 \sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_i) x_i. \quad (11.1.4)$$

By setting each of these two partial derivatives equal to 0, we obtain the following pair of equations:

$$\begin{aligned} \beta_0 n + \beta_1 \sum_{i=1}^n x_i &= \sum_{i=1}^n y_i, \\ \beta_0 \sum_{i=1}^n x_i + \beta_1 \sum_{i=1}^n x_i^2 &= \sum_{i=1}^n x_i y_i. \end{aligned} \quad (11.1.5)$$

The equations (11.1.5) are called the *normal equations* for  $\beta_0$  and  $\beta_1$ . By considering the second-order derivatives of  $Q$ , we can show that the values of  $\beta_0$  and  $\beta_1$  that satisfy the normal equations will be the values for which the sum of squares  $Q$  in Eq. (11.1.2) is minimized. Solving (11.1.5) yields the values in (11.1.1). ■

**Definition 11.1.1** **Least-Squares Line.** Let  $\hat{\beta}_0$  and  $\hat{\beta}_1$  be as defined in (11.1.1). The line defined by the equation  $y = \hat{\beta}_0 + \hat{\beta}_1 x$  is called the *least-squares line*.

For the values given in Table 11.1,  $n = 10$ , and it is found from Eq. (11.1.1) that  $\hat{\beta}_0 = -0.786$  and  $\hat{\beta}_1 = 0.685$ . Hence, the equation of the least-squares line is  $y = -0.786 + 0.685x$ . This line is sketched in Fig. 11.4.

Virtually all statistical computer software will compute the least-squares regression line. Even some handheld calculators will do the calculation.

**Figure 11.4** The least-squares straight line.

### Fitting a Polynomial by the Method of Least Squares

Suppose now that instead of simply fitting a straight line to  $n$  plotted points, we wish to fit a polynomial of degree  $k$  ( $k \geq 2$ ). Such a polynomial will have the following form:

$$y = \beta_0 + \beta_1 x + \beta_2 x^2 + \cdots + \beta_k x^k. \quad (11.1.6)$$

The method of least squares specifies that the constants  $\beta_0, \dots, \beta_k$  should be chosen so that the sum  $Q$  of the squares of the vertical deviations of the points from the curve is a minimum. In other words, these constants should be chosen so as to minimize the following expression for  $Q$ :

$$Q = \sum_{i=1}^n [y_i - (\beta_0 + \beta_1 x_i + \cdots + \beta_k x_i^k)]^2. \quad (11.1.7)$$

If we calculate the  $k+1$  partial derivatives  $\partial Q / \partial \beta_0, \dots, \partial Q / \partial \beta_k$ , and we set each of these derivatives equal to 0, we obtain the following  $k+1$  linear equations involving the  $k+1$  unknown values  $\beta_0, \dots, \beta_k$ :

$$\begin{aligned} \beta_0 n + \beta_1 \sum_{i=1}^n x_i + \cdots + \beta_k \sum_{i=1}^n x_i^k &= \sum_{i=1}^n y_i, \\ \beta_0 \sum_{i=1}^n x_i + \beta_1 \sum_{i=1}^n x_i^2 + \cdots + \beta_k \sum_{i=1}^n x_i^{k+1} &= \sum_{i=1}^n x_i y_i, \\ &\vdots \\ \beta_0 \sum_{i=1}^n x_i^k + \beta_1 \sum_{i=1}^n x_i^{k+1} + \cdots + \beta_k \sum_{i=1}^n x_i^{2k} &= \sum_{i=1}^n x_i^k y_i. \end{aligned} \quad (11.1.8)$$

As before, these equations are called the *normal equations*. If the normal equations have a unique solution, that solution provides the minimum value for  $Q$ . A necessary and sufficient condition for a unique solution is that the determinant of the  $(k+1) \times (k+1)$  matrix formed by the coefficients of  $\beta_0, \dots, \beta_k$  in Eq. (11.1.8) is not zero. We shall now assume that this is the case. If we denote the solution as  $(\hat{\beta}_0, \dots, \hat{\beta}_k)$ , then the least-squares polynomial is  $y = \hat{\beta}_0 + \hat{\beta}_1 x + \cdots + \hat{\beta}_k x^k$ .

**Figure 11.5** The least-squares parabola.

**Example  
11.1.3**

Fitting a Parabola. Suppose that we wish to fit a polynomial of the form  $y = \beta_0 + \beta_1x + \beta_2x^2$  (which represents a parabola) to the 10 points given in Table 11.1. In this example, it is found that the normal equations 11.1.8 are as follows:

$$\begin{aligned} 10\beta_0 + 23.3\beta_1 + 90.37\beta_2 &= 8.1, \\ 23.3\beta_0 + 90.37\beta_1 + 401.0\beta_2 &= 43.59, \\ 90.37\beta_0 + 401.0\beta_1 + 1892.7\beta_2 &= 204.55. \end{aligned} \quad (11.1.9)$$

The unique values of  $\beta_0$ ,  $\beta_1$ , and  $\beta_2$  that satisfy these three equations are  $\hat{\beta}_0 = -0.744$ ,  $\hat{\beta}_1 = 0.616$ , and  $\hat{\beta}_2 = 0.013$ . Hence, the least-squares parabola is

$$y = -0.744 + 0.616x + 0.013x^2. \quad (11.1.10)$$

This curve is sketched in Fig. 11.5 together with the least-squares straight line. Because the coefficient of  $x^2$  in Eq. (11.1.10) is so small, the least-squares parabola and the least-squares straight line are very close together over the range of values included in Fig. 11.5. ◀

**Example  
11.1.4**

Gasoline Mileage. Heavenrich and Hellman (1999) report several variables measured on 173 different cars. Among those variables are gasoline mileage (in miles per gallon) and engine horsepower. A plot of miles per gallon versus horsepower is shown in Fig. 11.6 together with a parabola fit by least squares. Even without the curve

**Figure 11.6** Plot of miles per gallon versus engine horsepower for 173 cars in Example 11.1.4. The least-squares parabola is also drawn in the plot.

drawn in Fig. 11.6, it is clear that a straight line would not provide an adequate fit to the relationship between these two variables. Some sort of curved relationship must be fit. The least-squares parabola curves up for the largest values of horsepower, which is somewhat counterintuitive. Indeed, this might be an example in which it would pay to use some prior information to impose a constraint on the fitted curve. Alternatively, we could replace gasoline mileage by a curved function of miles per gallon and use this curved function as the  $y$  variable.  $\blacktriangleleft$

### Fitting a Linear Function of Several Variables

We shall now consider an extension of the example discussed at the beginning of this section, in which we were interested in representing a patient's reaction to a new drug  $B$  as a linear function of her reaction to drug  $A$ . Suppose that we wish to represent a patient's reaction to drug  $B$  as a linear function involving not only her reaction to drug  $A$  but also some other relevant variables. For example, we may wish to represent the patient's reaction  $y$  to drug  $B$  as a linear function involving her reaction  $x_1$  to drug  $A$ , her heart rate  $x_2$ , and blood pressure  $x_3$  before she receives any drugs, and other relevant variables  $x_4, \dots, x_k$ .

Suppose that for each patient  $i$  ( $i = 1, \dots, n$ ) we measure her reaction  $y_i$  to drug  $B$ , her reaction  $x_{i1}$  to drug  $A$ , and also her values  $x_{i2}, \dots, x_{ik}$  for the other variables. Suppose also that in order to fit these observed values for the  $n$  patients, we wish to consider a linear function having the form

$$y = \beta_0 + \beta_1 x_1 + \dots + \beta_k x_k. \quad (11.1.11)$$

In this case, also, the values of  $\beta_0, \dots, \beta_k$  can be determined by the method of least squares. For each given set of observed values  $x_{i1}, \dots, x_{ik}$ , we again consider the difference between the observed reaction  $y_i$  and the value  $\beta_0 + \beta_1 x_{i1} + \dots + \beta_k x_{ik}$  of the linear function given in Eq. (11.1.11). As before, it is required to minimize the sum  $Q$  of the squares of these differences. Here,

$$Q = \sum_{i=1}^n [y_i - (\beta_0 + \beta_1 x_{i1} + \dots + \beta_k x_{ik})]^2. \quad (11.1.12)$$

We minimize this the same way that we minimized (11.1.7), namely, by setting the partial derivatives of  $Q$  with respect to each  $\beta_j$  equal to 0 for  $j = 0, \dots, k$ . In this case, the  $k + 1$  normal equations have the following form:

$$\begin{aligned} \beta_0 n + \beta_1 \sum_{i=1}^n x_{i1} + \dots + \beta_k \sum_{i=1}^n x_{ik} &= \sum_{i=1}^n y_i, \\ \beta_0 \sum_{i=1}^n x_{i1} + \beta_1 \sum_{i=1}^n x_{i1}^2 + \dots + \beta_k \sum_{i=1}^n x_{i1} x_{ik} &= \sum_{i=1}^n x_{i1} y_i, \\ &\vdots \\ \beta_0 \sum_{i=1}^n x_{ik} + \beta_1 \sum_{i=1}^n x_{ik} x_{i1} + \dots + \beta_k \sum_{i=1}^n x_{ik}^2 &= \sum_{i=1}^n x_{ik} y_i. \end{aligned} \quad (11.1.13)$$

If the normal equations have a unique solution, we shall denote that solution  $(\hat{\beta}_0, \dots, \hat{\beta}_k)$ , and the least-squares linear function will then be  $y = \hat{\beta}_0 + \hat{\beta}_1 x_1 + \dots + \hat{\beta}_k x_k$ . As before, a necessary and sufficient condition for a unique solution is that the determinant of the  $(k + 1) \times (k + 1)$  matrix formed by the coefficients of  $\beta_0, \dots, \beta_k$  in Eq. (11.1.13) is not zero.

<b>i</b>	$x_{i1}$	$x_{i2}$	$y_i$
1	1.9	66	0.7
2	0.8	62	-1.0
3	1.1	64	-0.2
4	0.1	61	-1.2
5	-0.1	63	-0.1
6	4.4	70	3.4
7	4.6	68	0.0
8	1.6	62	0.8
9	5.5	68	3.7
10	3.4	66	2.0

**Example  
11.1.5**

Fitting a Linear Function of Two Variables. Suppose that we expand Table 11.1 to include the values given in the third column in Table 11.2. Here, for each patient  $i$  ( $i = 1, \dots, 10$ ),  $x_{i1}$  denotes her reaction to the standard drug  $A$ ,  $x_{i2}$  denotes her heart rate, and  $y_i$  denotes her reaction to the new drug  $B$ . Suppose also that we wish to fit a linear function to these values having the form  $y = \beta_0 + \beta_1 x_1 + \beta_2 x_2$ .

In this example, it is found that the normal equations (11.1.13) are

$$\begin{aligned} 10\beta_0 + 23.3\beta_1 + 650\beta_2 &= 8.1, \\ 23.3\beta_0 + 90.37\beta_1 + 1563.6\beta_2 &= 43.59, \\ 650\beta_0 + 1563.6\beta_1 + 42,334\beta_2 &= 563.1. \end{aligned} \quad (11.1.14)$$

The unique values of  $\beta_0$ ,  $\beta_1$ , and  $\beta_2$  that satisfy these three equations are  $\hat{\beta}_0 = -11.4527$ ,  $\hat{\beta}_1 = 0.4503$ , and  $\hat{\beta}_2 = 0.1725$ . Hence, the least-squares linear function is

$$y = -11.4527 + 0.4503x_1 + 0.1725x_2. \quad (11.1.15)$$

It should be noted that the problem of fitting a polynomial of degree  $k$  involving only one variable, as specified by Eq. (11.1.6), can be regarded as a special case of the problem of fitting a linear function involving several variables, as specified by Eq. (11.1.11). To make Eq. (11.1.11) applicable to the problem of fitting a polynomial having the form given in Eq. (11.1.6), we define the  $k$  variables  $x_1, \dots, x_k$  simply as  $x_1 = x$ ,  $x_2 = x^2, \dots, x_k = x^k$ .

A polynomial involving more than one variable can also be represented in the form of Eq. (11.1.11). For example, suppose that the values of four variables  $r$ ,  $s$ ,  $t$ , and  $y$  are observed for several different patients, and we wish to fit to these observed values a function having the following form:

$$y = \beta_0 + \beta_1 r + \beta_2 r^2 + \beta_3 rs + \beta_4 s^2 + \beta_5 t^3 + \beta_6 rst. \quad (11.1.16)$$

We can regard the function in Eq. (11.1.16) as a linear function having the form given in Eq. (11.1.11) with  $k = 6$  if we define the six variables  $x_1, \dots, x_6$  as follows:  $x_1 = r$ ,  $x_2 = r^2$ ,  $x_3 = rs$ ,  $x_4 = s^2$ ,  $x_5 = t^3$ , and  $x_6 = rst$ .

## Summary

The method of least squares allows the calculation of a predictor for one variable ( $y$ ) based on one or more other variables ( $x_1, \dots, x_k$ ) of the form  $\beta_0 + \beta_1 x_1 + \dots + \beta_k x_k$ . The coefficients  $\beta_0, \dots, \beta_k$  are chosen so that the sum of squared differences between observed values of  $y$  and observed values of  $\beta_0 + \beta_1 x_1 + \dots + \beta_k x_k$  is as small as possible. Algebraic formulas for the coefficients are given for the case  $k = 1$ , but most statistical computer software will calculate the coefficients more easily.

## Exercises

1. Prove that  $\sum_{i=1}^n (c_1 x_i + c_2)^2 = c_1^2 \sum_{i=1}^n (x_i - \bar{x})^2 + n(c_1 \bar{x} + c_2)^2$ .

2. Show that the value of  $\hat{\beta}_1$  in Eq. (11.1.1) can be rewritten in each of the following three forms:

$$\text{a. } \hat{\beta}_1 = \frac{\sum_{i=1}^n x_i y_i - n \bar{x} \bar{y}}{\sum_{i=1}^n x_i^2 - n \bar{x}^2}$$

$$\text{b. } \hat{\beta}_1 = \frac{\sum_{i=1}^n (x_i - \bar{x}) y_i}{\sum_{i=1}^n (x_i - \bar{x})^2}$$

$$\text{c. } \hat{\beta}_1 = \frac{\sum_{i=1}^n x_i (y_i - \bar{y})}{\sum_{i=1}^n (x_i - \bar{x})^2}$$

3. Show that the least-squares line  $y = \hat{\beta}_0 + \hat{\beta}_1 x$  passes through the point  $(\bar{x}, \bar{y})$ .

4. For  $i = 1, \dots, n$ , let  $\hat{y}_i = \beta_0 + \beta_1 x_i$ . Show that  $\hat{\beta}_0$  and  $\hat{\beta}_1$ , as given by Eq. (11.1.1), are the unique values of  $\beta_0$  and  $\beta_1$  such that

$$\sum_{i=1}^n (y_i - \hat{y}_i) = 0 \quad \text{and} \quad \sum_{i=1}^n x_i (y_i - \hat{y}_i) = 0.$$

5. Fit a straight line to the observed values given in Table 11.1 so that the sum of the squares of the *horizontal* deviations of the points from the line is a minimum. Sketch on the same graph both this line and the least-squares line given in Fig. 11.4.

6. Suppose that both the least-squares line and the least-squares parabola were fitted to the same set of points. Explain why the sum of the squares of the deviations of the points from the parabola cannot be larger than the sum of the squares of the deviations of the points from the straight line.

7. Suppose that eight specimens of a certain type of alloy were produced at different temperatures, and the durability of each specimen was then observed. The observed values are given in Table 11.3, where  $x_i$  denotes the temperature (in coded units) at which specimen  $i$  was pro-

duced and  $y_i$  denotes the durability (in coded units) of that specimen.

8	4.0	42

- a. Fit a straight line of the form  $y = \beta_0 + \beta_1 x$  to these values by the method of least squares.  
b. Fit a parabola of the form  $y = \beta_0 + \beta_1 x + \beta_2 x^2$  to these values by the method of least squares.  
c. Sketch on the same graph the eight data points, the line found in part (a), and the parabola found in part (b).  
8. Let  $(x_i, y_i)$  for  $i = 1, \dots, k+1$ , denote  $k+1$  given points in the  $xy$ -plane such that no two of these points have the same  $x$ -coordinate. Show that there is a unique polynomial having the form  $y = \beta_0 + \beta_1 x + \dots + \beta_k x^k$  that passes through these  $k+1$  points.  
9. The resilience  $y$  of a certain type of plastic is to be represented as a linear function of both the temperature  $x_1$  at which the plastic is baked and the number of minutes  $x_2$  for which it is baked. Suppose that 10 pieces of plastic are prepared by using different values of  $x_1$  and  $x_2$ , and the observed values in appropriate units are as given in Table 11.4. Fit a function having the form  $y = \beta_0 + \beta_1 x_1 + \beta_2 x_2$  to these observed values by the method of least squares.

- 10.** Consider again the observed values presented in Table 11.4. Fit a function having the form  $y = \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_2^2$  to these values by the method of least squares.

- 11.** Consider again the observed values presented in Table 11.4, and consider also the two functions that were fitted to these values in Exercises 9 and 10. Which of these two functions fits the observed values better?

## 11.2 Regression

In Sec. 11.1, we introduced the method of least squares. This method computes coefficients for a linear function to predict one variable  $y$  based on other variables  $x_1, \dots, x_k$ . In this section, we assume that the  $y$  values are observed values of a collection of random variables. In this case, there is a statistical model in which the method of least squares turns out to produce the maximum likelihood estimates of the parameters of the model.

### Regression Functions

**Example  
11.2.1**

Pressure and the Boiling Point of Water. Forbes (1857) reports the results from experiments that were trying to obtain a method for estimating altitude. A formula is available for altitude in terms of barometric pressure, but it was difficult to carry a barometer to high altitudes in Forbes' day. However, it might be easy for travelers to carry a thermometer and measure the boiling point of water. Table 11.5 contains the measured barometric pressures and boiling points of water from 17 experiments. We can use the method of least squares to fit a linear relationship between boiling point and pressure. Let  $y_i$  be the pressure for one of Forbes' observations, and let  $x_i$  be the corresponding boiling point for  $i = 1, \dots, 17$ . Using the data in Table 11.5, we can compute the least-squares line. The intercept and slope are, respectively,  $\hat{\beta}_0 = -81.06$  and  $\hat{\beta}_1 = 0.5229$ . Of course, we do not expect that the line  $y = -81.06 + 0.5229x$  precisely gives the relationship between boiling point  $x$  and pressure  $y$ . If we learn the boiling point  $x$  of water and want to compute the conditional distribution of the unknown pressure  $Y$ , is there a statistical model that allows us to say what the (conditional) distribution of pressure is given that the boiling point is  $x$ ? ◀

In this section, we shall describe a statistical model for problems such as the one in Example 11.2.1. Fitting this statistical model will make use of the method of least squares. We shall study problems in which we are interested in learning about the conditional distribution of some random variable  $Y$  for given values of some other variables  $X_1, \dots, X_k$ . The variables  $X_1, \dots, X_k$  may be random variables whose values are to be observed in an experiment along with the values of  $Y$ , or they may be *control variables* whose values are to be chosen by the experimenter. In general, some

**Table 11.5** Boiling point of water in degrees Fahrenheit and atmospheric pressure in inches of mercury from Forbes' experiments. These data are taken from Weisberg (1985, p. 3).

Boiling Point	Pressure
194.5	20.79
194.3	20.79
197.9	22.40
198.4	22.67
199.4	23.15

208.6	27.76
210.7	29.04
211.9	29.88
212.2	30.06

of these variables might be random variables, and some might be control variables. In any case, we can study the conditional distribution of  $Y$  given  $X_1, \dots, X_k$ . We begin with some terminology.

**Definition**

**11.2.1**

**Response/Predictor/Regression.** The variables  $X_1, \dots, X_k$  are called *predictors*, and the random variable  $Y$  is called the *response*. The conditional expectation of  $Y$  for given values  $x_1, \dots, x_k$  of  $X_1, \dots, X_k$  is called the *regression function of  $Y$  on  $X_1, \dots, X_k$* , or simply the *regression of  $Y$  on  $X_1, \dots, X_k$* .

The regression of  $Y$  on  $X_1, \dots, X_k$  is a function of the values  $x_1, \dots, x_k$  of  $X_1, \dots, X_k$ . In symbols, this function is  $E(Y|x_1, \dots, x_k)$ .

In this chapter, we shall assume that the regression function  $E(Y|x_1, \dots, x_k)$  is a linear function having the following form:

$$E(Y|x_1, \dots, x_k) = \beta_0 + \beta_1 x_1 + \dots + \beta_k x_k. \quad (11.2.1)$$

The coefficients  $\beta_0, \dots, \beta_k$  in Eq. (11.2.1) are called *regression coefficients*. We shall suppose that these regression coefficients are unknown. Therefore, they are to be regarded as parameters whose values are to be estimated. We shall suppose also that  $n$  vectors of observations are obtained. For  $i = 1, \dots, n$ , we shall assume that the  $i$ th vector  $(x_{i1}, \dots, x_{ik}, y_i)$  consists of a set of controlled or observed values of  $X_1, \dots, X_k$  and the corresponding observed value of  $Y$ .

One set of estimators of the regression coefficients  $\beta_0, \dots, \beta_k$  that can be calculated from these observations is the set of values  $\hat{\beta}_0, \dots, \hat{\beta}_k$  that are obtained by the method of least squares, as described in Sec. 11.1. These estimators are called the *least-squares estimators* of  $\beta_0, \dots, \beta_k$ . We shall now specify some further assumptions about the conditional distribution of  $Y$  given  $X_1, \dots, X_k$  in order to be able to determine in greater detail the properties of these least-squares estimators.

## Simple Linear Regression

We shall consider first a problem in which we wish to study the regression of  $Y$  on just a single variable  $X$ . We shall assume that for each value  $X = x$ , the random variable  $Y$  can be represented in the form  $Y = \beta_0 + \beta_1 x + \varepsilon$ , where  $\varepsilon$  is a random variable that has the normal distribution with mean 0 and variance  $\sigma^2$ . It follows from this assumption that the conditional distribution of  $Y$  given  $X = x$  is the normal distribution with mean  $\beta_0 + \beta_1 x$  and variance  $\sigma^2$ .

A problem of this type is called a problem of *simple linear regression*. Here the term *simple* refers to the fact that we are considering the regression of  $Y$  on just a single variable  $X$ , rather than on more than one variable; the term *linear* refers to the fact that the regression function  $E(Y|x) = \beta_0 + \beta_1 x$  is a linear function of the parameters  $\beta_0$  and  $\beta_1$ . For example, a problem in which  $E(Y|x)$  is a polynomial, like the right side of Eq. (11.1.6), would also be a linear regression problem, but not simple.

Throughout this section (and the next two sections), we shall consider the problem in which we shall observe  $n$  pairs  $(x_1, Y_1), \dots, (x_n, Y_n)$ . We shall make the following five assumptions. Each of these assumptions has a natural generalization to the case in which there is more than one predictor, but we shall postpone discussion of that case until Sec. 11.5.

<b>Assumption 11.2.1</b>	Predictor is known. Either the values $x_1, \dots, x_n$ are known ahead of time or they are the observed values of random variables $X_1, \dots, X_n$ on whose values we condition before computing the joint distribution of $(Y_1, \dots, Y_n)$ .
<b>Assumption 11.2.2</b>	Normality. For $i = 1, \dots, n$ , the conditional distribution of $Y_i$ given the values $x_1, \dots, x_n$ is a normal distribution.
<b>Assumption 11.2.3</b>	Linear Mean. There are parameters $\beta_0$ and $\beta_1$ such that the conditional mean of $Y_i$ given the values $x_1, \dots, x_n$ has the form $\beta_0 + \beta_1 x_i$ for $i = 1, \dots, n$ .
<b>Assumption 11.2.4</b>	Common Variance. There is a parameter $\sigma^2$ such that the conditional variance of $Y_i$ given the values $x_1, \dots, x_n$ is $\sigma^2$ for $i = 1, \dots, n$ . This assumption is often called <i>homoscedasticity</i> . Random variables with different variances are called <i>heteroscedastic</i> .
<b>Assumption 11.2.5</b>	Independence. The random variables $Y_1, \dots, Y_n$ are independent given the observed $x_1, \dots, x_n$ .

A brief word is in order about Assumption 11.2.1. In Example 11.1.1, we saw that the reaction  $x_i$  of patient  $i$  to standard drug  $A$  is observed as part of the experiment along with the reaction  $y_i$  to drug  $B$ . Hence, the predictors are not known in advance. In this case, all probability statements that we make in this example are conditional on  $(x_1, \dots, x_n)$ . In other examples, one might be trying to predict an economic variable using the year in which it was measured. In such cases, such as Example 11.5.1, which

we will see later, the values of at least some of the predictors are truly known in advance.

Assumptions 11.2.1–11.2.5 specify the conditional joint distribution of  $Y_1, \dots, Y_n$  given the vector  $\mathbf{x} = (x_1, \dots, x_n)$  and the parameters  $\beta_0, \beta_1$ , and  $\sigma^2$ . In particular, the conditional joint p.d.f. of  $Y_1, \dots, Y_n$  is

$$f_n(\mathbf{y}|\mathbf{x}, \beta_0, \beta_1, \sigma^2) = \frac{1}{(2\pi\sigma^2)^{n/2}} \exp\left[-\frac{1}{2\sigma^2} \sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_i)^2\right]. \quad (11.2.2)$$

We can now find the M.L.E.'s of  $\beta_0$ ,  $\beta_1$ , and  $\sigma^2$ .

**Theorem  
11.2.1**

Simple Linear Regression M.L.E.'s. Assume Assumptions 11.2.1–11.2.5. The M.L.E.'s of  $\beta_0$  and  $\beta_1$  are the least-squares estimates, and the M.L.E. of  $\sigma^2$  is

$$\hat{\sigma}^2 = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i)^2. \quad (11.2.3)$$

**Proof** For each observed vector  $\mathbf{y} = (y_1, \dots, y_n)$ , the p.d.f. (11.2.2) will be the likelihood function of the parameters  $\beta_0$ ,  $\beta_1$ , and  $\sigma^2$ . In Eq. (11.2.2),  $\beta_0$  and  $\beta_1$  appear only in the sum of squares

$$Q = \sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_i)^2,$$

which in turn appears in the exponent multiplied by  $-1/[2\sigma^2]$ . Regardless of the value of  $\sigma^2$ , the exponent is maximized over  $\beta_0$  and  $\beta_1$  by minimizing  $Q$ . It follows that the M.L.E.'s can be found in sequence by first minimizing  $Q$  over  $\beta_0$  and  $\beta_1$ , then inserting the values  $\hat{\beta}_0$  and  $\hat{\beta}_1$  that provide the minimum of  $Q$ , and finally minimizing the result over  $\sigma^2$ . The reader will note that  $Q$  is the same as the sum of squares in Eq. (11.1.2), which is minimized by the method of least squares. Thus, the M.L.E.'s of the regression coefficients  $\beta_0$  and  $\beta_1$  are precisely the same as the least-squares estimates. The exact form of these estimates  $\hat{\beta}_0$  and  $\hat{\beta}_1$  was given in Eq. (11.1.1).

To find the M.L.E. of  $\sigma^2$ , perform the the second and third steps described in the preceding paragraph, namely, first replace  $\beta_0$  and  $\beta_1$  in Eq. (11.2.2) by their M.L.E.'s  $\hat{\beta}_0$  and  $\hat{\beta}_1$ , and then maximize the resulting expression with respect to  $\sigma^2$ . The details are left to Exercise 1 at the end of this section, and the result is (11.2.3). ■

### The Distribution of the Least-Squares Estimators

We shall now present the joint distribution of the estimators  $\hat{\beta}_0$  and  $\hat{\beta}_1$  when they are regarded as functions of the random variables  $Y_1, \dots, Y_n$  for given values of  $x_1, \dots, x_n$ . Specifically, the estimators are

$$\begin{aligned}\hat{\beta}_1 &= \frac{\sum_{i=1}^n (Y_i - \bar{Y})(x_i - \bar{x})}{\sum_{i=1}^n (x_i - \bar{x})^2}, \\ \hat{\beta}_0 &= \bar{Y} - \hat{\beta}_1 \bar{x},\end{aligned}$$

where  $\bar{Y} = \frac{1}{n} \sum_{i=1}^n Y_i$ .

It is convenient, both for this section and the next, to introduce the symbol

$$s_x = \left( \sum_{i=1}^n (x_i - \bar{x})^2 \right)^{1/2}. \quad (11.2.4)$$

**Theorem 11.2.2** **Distributions of Least-Squares Estimators.** Under Assumptions 11.2.1–11.2.5, the distribution of  $\hat{\beta}_1$  is the normal distribution with mean  $\beta_1$  and variance  $\sigma^2/s_x^2$ . The distribution of  $\hat{\beta}_0$  is the normal distribution with mean  $\beta_0$  and variance

$$\sigma^2 \left( \frac{1}{n} + \frac{\bar{x}^2}{s_x^2} \right). \quad (11.2.5)$$

Finally, the covariance of  $\hat{\beta}_1$  and  $\hat{\beta}_0$  is

$$\text{Cov}(\hat{\beta}_0, \hat{\beta}_1) = -\frac{\bar{x}\sigma^2}{s_x^2}. \quad (11.2.6)$$

(All of the distributional statements in this theorem are conditional on  $X_i = x_i$  for  $i = 1, \dots, n$  if  $X_1, \dots, X_n$  are random variables.)

**Proof** To determine the distribution of  $\hat{\beta}_1$ , it is convenient to write  $\hat{\beta}_1$  as follows (see Exercise 2 at the end of Sec. 11.1):

$$\hat{\beta}_1 = \frac{\sum_{i=1}^n (x_i - \bar{x})Y_i}{s_x^2}. \quad (11.2.7)$$

It can be seen from Eq. (11.2.7) that  $\hat{\beta}_1$  is a linear function of  $Y_1, \dots, Y_n$ . Because the random variables  $Y_1, \dots, Y_n$  are independent and each has a normal distribution, it follows that  $\hat{\beta}_1$  will also have a normal distribution. Furthermore, the mean of this distribution will be

$$E(\hat{\beta}_1) = \frac{\sum_{i=1}^n (x_i - \bar{x})E(Y_i)}{s_x^2}.$$

Because  $E(Y_i) = \beta_0 + \beta_1 x_i$  for  $i = 1, \dots, n$ , it can now be found (see Exercise 2 at the end of this section) that

$$E(\hat{\beta}_1) = \beta_1. \quad (11.2.8)$$

Furthermore, because the random variables  $Y_1, \dots, Y_n$  are independent and each has variance  $\sigma^2$ , it follows from Eq. (11.2.7) that

$$\text{Var}(\hat{\beta}_1) = \frac{\sum_{i=1}^n (x_i - \bar{x})^2 \text{Var}(Y_i)}{s_x^4} = \frac{\sigma^2}{s_x^2}. \quad (11.2.9)$$

Next, consider the distribution of  $\hat{\beta}_0 = \bar{Y} - \hat{\beta}_1 \bar{x}$ . Because both  $\bar{Y}$  and  $\hat{\beta}_1$  are linear functions of  $Y_1, \dots, Y_n$ , it follows that  $\hat{\beta}_0$  is also a linear function of  $Y_1, \dots, Y_n$ . Hence,  $\hat{\beta}_0$  will have a normal distribution. The mean of  $\hat{\beta}_0$  can be determined from the relation  $E(\hat{\beta}_0) = E(\bar{Y}) - \bar{x}E(\hat{\beta}_1)$ . It can be shown (see Exercise 3) that  $E(\hat{\beta}_0) = \beta_0$ . Furthermore, it can be shown (see Exercise 4) that  $\text{Var}(\hat{\beta}_0)$  is given by (11.2.5). Finally, it can be shown (see Exercise 5) that the value of the covariance between  $\hat{\beta}_0$  and  $\hat{\beta}_1$  is given by (11.2.6). ■

A simple corollary to Theorem 11.2.2 is that  $\hat{\beta}_0$  and  $\hat{\beta}_1$  are, respectively, unbiased estimators of the corresponding parameters  $\beta_0$  and  $\beta_1$ .

To complete the description of the joint distribution of  $\hat{\beta}_0$  and  $\hat{\beta}_1$ , it will be shown in Sec. 11.3 that this joint distribution is the bivariate normal distribution for which the means, variances, and covariance are as stated in Theorem 11.2.2.

**Example  
11.2.2**

**Pressure and the Boiling Point of Water.** In Example 11.2.1, we found the least-squares line for predicting pressure from boiling point of water. Suppose that we use the linear regression model just described as a model for the data in this experiment. That is, let  $Y_i$  be the pressure for one of Forbes' observations, and let  $x_i$  be the corresponding boiling point for  $i = 1, \dots, 17$ . We model the  $Y_i$  as being independent with means  $\beta_0 + \beta_1 x_i$  and variance  $\sigma^2$ . The average temperature is  $\bar{x} = 202.95$  and  $s_x^2 = 530.78$  with  $n = 17$ . From these values, we can now compute the variances and covariances of the least-squares estimators using the formulas derived in this section. For example,

$$\begin{aligned}\text{Var}(\hat{\beta}_1) &= \frac{\sigma^2}{530.78} = 0.00188\sigma^2, \\ \text{Var}(\hat{\beta}_0) &= \sigma^2 \left( \frac{1}{17} + \frac{202.95^2}{530.78} \right) = 77.66\sigma^2, \\ \text{Cov}(\hat{\beta}_0, \hat{\beta}_1) &= -\frac{202.95\sigma^2}{530.78} = -0.382\sigma^2.\end{aligned}$$

It is easy to see that we expect to get a much more precise estimate of  $\beta_1$  than of  $\beta_0$ . 

The statement at the end of Example 11.2.2 about getting more precise estimates of  $\beta_1$  than of  $\beta_0$  is a bit deceptive. We must multiply  $\beta_1$  by a number on the order of 200 before it is on the same scale as  $\beta_0$ . Hence, it might make more sense to compare the variance of  $200\hat{\beta}_1$  to the variance of  $\hat{\beta}_0$ . In general, we can find the variance of any linear combination of the least-squares estimators.

**Example  
11.2.3**

**The Variance of a Linear Combination.** Very often, we need to compute the variance of a linear combination of the least-squares estimators. One example is prediction, as discussed later in this section. Suppose that we wish to compute the variance of  $T = c_0\hat{\beta}_0 + c_1\hat{\beta}_1 + c_*$ . The variance of  $T$  can be found by substituting the values of  $\text{Var}(\hat{\beta}_0)$ ,  $\text{Var}(\hat{\beta}_1)$ , and  $\text{Cov}(\hat{\beta}_0, \hat{\beta}_1)$  given in Eqs. (11.2.5), (11.2.9), and (11.2.6) in the following relation:

$$\text{Var}(T) = c_0^2 \text{Var}(\hat{\beta}_0) + c_1^2 \text{Var}(\hat{\beta}_1) + 2c_0c_1 \text{Cov}(\hat{\beta}_0, \hat{\beta}_1).$$

When these substitutions have been made, the result can be written in the following form:

$$\text{Var}(T) = \sigma^2 \left( \frac{c_0^2}{n} + \frac{(c_0\bar{x} - c_1)^2}{s_x^2} \right). \quad (11.2.10)$$

For the specific case of Example 11.2.2, we have  $c_0 = 0$  and  $c_1 = 200$ , so the variance of  $200\hat{\beta}_1$  is  $200^2\sigma^2/s_x^2 = 75.36\sigma^2$ . This is pretty close to the variance of  $\hat{\beta}_0$ , namely,  $77.66\sigma^2$ . 

## Prediction

**Example  
11.2.4**

**Predicting Pressure from the Boiling Point of Water.** In Example 11.2.1, Forbes was trying to find a way to use the boiling point of water to estimate the barometric pressure. Suppose that a traveler measures the boiling point of water to be 201.5 degrees. What estimate of barometric pressure should they give and how much uncertainty is there about this estimate? 

Suppose that  $n$  pairs of observations  $(x_1, Y_1), \dots, (x_n, Y_n)$  are to be obtained in a problem of simple linear regression, and on the basis of these  $n$  pairs, it is necessary to predict the value of an independent observation  $Y$  that will be obtained when a certain specified value  $x$  is assigned to the control variable. Since the observation  $Y$  will have the normal distribution with mean  $\beta_0 + \beta_1 x$  and variance  $\sigma^2$ , it is natural to use the value  $\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1 x$  as the predicted value of  $Y$ . We shall now determine the M.S.E.  $E[(\hat{Y} - Y)^2]$  of this prediction, where both  $\hat{Y}$  and  $Y$  are random variables.

**Theorem**  
**11.2.3**

M.S.E. of Prediction. In the prediction problem just described,

$$E[(\hat{Y} - Y)^2] = \sigma^2 \left[ 1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2} \right]. \quad (11.2.11)$$

**Proof** In this problem,  $E(\hat{Y}) = E(Y) = \beta_0 + \beta_1 x$ . Thus, if we let  $\mu = \beta_0 + \beta_1 x$ , then

$$\begin{aligned} E[(\hat{Y} - Y)^2] &= E\{[(\hat{Y} - \mu) - (Y - \mu)]^2\} \\ &= \text{Var}(\hat{Y}) + \text{Var}(Y) - 2 \text{Cov}(\hat{Y}, Y). \end{aligned} \quad (11.2.12)$$

However, the random variables  $\hat{Y}$  and  $Y$  are independent, because  $\hat{Y}$  is a function of the first  $n$  pairs of observations and  $Y$  is an independent observation. Therefore,  $\text{Cov}(\hat{Y}, Y) = 0$ , and it follows that

$$E[(\hat{Y} - Y)^2] = \text{Var}(\hat{Y}) + \text{Var}(Y). \quad (11.2.13)$$

Finally, because  $\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1 x$ , the value of  $\text{Var}(\hat{Y})$  is given by Eq. (11.2.10) with  $c_0 = 1$  and  $c_1 = x$ . Also  $\text{Var}(Y) = \sigma^2$ . Substituting these into Eq. (11.2.13) gives (11.2.11). ■

**Example**  
**11.2.5**

Predicting Pressure from the Boiling Point of Water. In Example 11.2.4, we wanted to predict barometric pressure when the boiling point of water is 201.5 degrees. The least-squares line is  $y = -81.06 + 0.5229x$ , and  $\hat{\sigma}^2 = 0.0478$ . Fig. 11.7 shows the data plotted together with the least-squares regression line and the location of the point on the line that has  $x = 201.5$ . The M.S.E. of the prediction of pressure  $Y$  is obtained from Eq. (11.2.11):

$$E[(\hat{Y} - Y)^2] = \sigma^2 \left[ 1 + \frac{1}{17} + \frac{(201.5 - 202.95)^2}{530.78} \right] = 1.0628\sigma^2,$$

and the observed value of the prediction is  $\hat{Y} = -81.06 + 0.5229 \times 201.5 = 24.30$ . The calculation of  $\hat{Y}$  is illustrated in Fig. 11.7. The M.S.E.  $1.0628\sigma^2$  can be interpreted as follows: If we knew the values of  $\beta_0$  and  $\beta_1$  and tried to predict  $Y$ , the M.S.E. would be  $\text{Var}(Y) = \sigma^2$ . Having to estimate  $\beta_0$  and  $\beta_1$  only costs us an additional  $0.0628\sigma^2$  in M.S.E. ■

**Note: M.S.E. of Prediction Increases as  $x$  Moves Away from Observed Data.** The M.S.E. in Eq. (11.2.11) increases as  $x$  moves away from  $\bar{x}$ , and it is smallest when  $x = \bar{x}$ . This indicates that it is harder to predict  $Y$  when  $x$  is not near the center of the observed values  $x_1, \dots, x_n$ . Indeed, if  $x$  is larger than the largest observed  $x_i$  or smaller than the smallest one, it is quite difficult to predict  $Y$  with much precision. Such predictions outside the range of the observed data are called *extrapolations*.

**Figure 11.7** Plot of pressure versus boiling point with regression line for Example 11.2.5. Dotted line illustrates prediction of pressure when boiling point is 201.5.

## ◆ Design of the Experiment

Consider a problem of simple linear regression in which the variable  $X$  is a control variable whose values  $x_1, \dots, x_n$  can be chosen by the experimenter. We shall discuss methods for choosing these values so as to obtain good estimators of the regression coefficients  $\beta_0$  and  $\beta_1$ .

Suppose first that the values  $x_1, \dots, x_n$  are to be chosen so as to minimize the M.S.E. of the least-squares estimator  $\hat{\beta}_0$ . Since  $\hat{\beta}_0$  is an unbiased estimator of  $\beta_0$ , the M.S.E. of  $\hat{\beta}_0$  is equal to  $\text{Var}(\hat{\beta}_0)$ , as given in Eq. (11.2.5). It follows from Eq. (11.2.5) that  $\text{Var}(\hat{\beta}_0) \geq \sigma^2/n$  for all values  $x_1, \dots, x_n$ , and there will be equality in this relation if and only if  $\bar{x} = 0$ . Hence,  $\text{Var}(\hat{\beta}_0)$  will attain its minimum value  $\sigma^2/n$  whenever  $\bar{x} = 0$ . Of course, this will be impossible in any application in which  $X$  is constrained to be positive.

Suppose next that the values  $x_1, \dots, x_n$  are to be chosen so as to minimize the M.S.E. of the estimator  $\hat{\beta}_1$ . Again, the M.S.E. of  $\hat{\beta}_1$  will be equal to  $\text{Var}(\hat{\beta}_1)$ , as given in Eq. (11.2.9). It can be seen from Eq. (11.2.9) that  $\text{Var}(\hat{\beta}_1)$  will be minimized by choosing the values  $x_1, \dots, x_n$  so that the value of  $s_x^2$  is maximized. If the values  $x_1, \dots, x_n$  must be chosen from some bounded interval  $(a, b)$  of the real line, and if  $n$  is an even integer, then the value of  $s_x^2$  will be maximized by choosing  $x_i = a$  for exactly  $n/2$  values and choosing  $x_i = b$  for the other  $n/2$  values. If  $n$  is an odd integer, all the values should again be chosen at the endpoints  $a$  and  $b$ , but one endpoint must now receive one more observation than the other endpoint.

It follows from this discussion that if the experiment is to be designed so as to minimize both the M.S.E. of  $\hat{\beta}_0$  and the M.S.E. of  $\hat{\beta}_1$ , then the values  $x_1, \dots, x_n$  should be chosen so that exactly, or approximately,  $n/2$  values are equal to some number  $c$  that is as large as is feasible in the given experiment, and the remaining values are equal to  $-c$ . In this way, the value of  $\bar{x}$  will be exactly, or approximately, equal to 0, and the value of  $s_x^2$  will be as large as possible.

Finally, suppose that the linear combination  $\theta = c_0\beta_0 + c_1\beta_1 + c_*$  is to be estimated, where  $c_0 \neq 0$ , and that the experiment is to be designed so as to minimize the M.S.E. of  $\hat{\theta}$ , that is, to minimize  $\text{Var}(\hat{\theta})$ . For example, if  $Y$  is a future observation with corresponding predictor  $x$ , then we could set  $c_0 = 1$ ,  $c_2 = x$ , and  $c_* = 0$  in order to make  $\theta = E(Y|x)$ . In Example 11.2.3, we computed  $\text{Var}(T)$ , where  $T = \hat{\theta}$ , as the sum of two nonnegative terms in Eq. (11.2.10). The second term is the only one that

depends on the values of  $x_1, \dots, x_n$ , and it equals 0 (its smallest possible value) if and only if  $\bar{x} = c_1/c_0$ . In this case,  $\text{Var}(\hat{\theta})$  will attain its minimum value  $c_0^2\sigma^2/n$ .

In practice, an experienced statistician would not usually choose all the values  $x_1, \dots, x_n$  at a single point or at just the two endpoints of the interval  $(a, b)$ , as the optimal designs that we have just derived would dictate. The reason is that when all  $n$  observations are taken at just one or two values of  $X$ , the experiment provides no possibility of checking the assumption that the regression of  $Y$  on  $X$  is a linear function. In order to check this assumption without unduly increasing the M.S.E. of the least-squares estimators, many of the values  $x_1, \dots, x_n$  should be chosen at the endpoints  $a$  and  $b$ , but at least some of the values should be chosen at a few interior points of the interval. Linearity can then be checked by visual inspection of the plotted points and the fitting of a polynomial of degree two or higher.

## Summary

We considered the following statistical model. The values  $x_1, \dots, x_n$  are assumed known. The random variables  $Y_1, \dots, Y_n$  are independent with  $Y_i$  having the normal distribution with mean  $\beta_0 + \beta_1 x_i$  and variance  $\sigma^2$ . Here,  $\beta_0$ ,  $\beta_1$ , and  $\sigma^2$  are unknown parameters. These are the assumptions of the simple linear regression model. Under this model, the joint distribution of the least-squares estimators  $\hat{\beta}_0$  and  $\hat{\beta}_1$  is a bivariate normal distribution with  $\hat{\beta}_i$  having mean  $\beta_i$  for  $i = 1, 2$ . The variances are given in Eqs. (11.2.5) and (11.2.9). The covariance is given in Eq. (11.2.6). If we consider predicting a future  $Y$  value with corresponding predictor  $x$ , we might use the prediction  $\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1 x$ . In this case,  $Y - \hat{Y}$  has the normal distribution with mean 0 and variance given by Eq. (11.2.11).

## Exercises

1. Show that the M.L.E. of  $\sigma^2$  is given by Eq. (11.2.3).
2. Show that  $E(\hat{\beta}_1) = \beta_1$ .
3. Show that  $E(\hat{\beta}_0) = \beta_0$ .
4. Show that  $\text{Var}(\hat{\beta}_0)$  is as given in Eq. (11.2.5).
5. Show that  $\text{Cov}(\hat{\beta}_0, \hat{\beta}_1)$  is as given in Eq. (11.2.6). *Hint:* Use the result in Exercise 8 in Sec. 4.6.
6. Show that in a problem of simple linear regression, the estimators  $\hat{\beta}_0$  and  $\hat{\beta}_1$  will be independent if  $\bar{x} = 0$ .
7. Consider a problem of simple linear regression in which a patient's reaction  $Y$  to a new drug  $B$  is to be related to his reaction  $X$  to a standard drug  $A$ . Suppose that the 10 pairs of observed values given in Table 11.1 are obtained.
  - a. Determine the values of the M.L.E.'s  $\hat{\beta}_0$ ,  $\hat{\beta}_1$ , and  $\hat{\sigma}^2$ .
  - b. Determine the values of  $\text{Var}(\hat{\beta}_0)$  and  $\text{Var}(\hat{\beta}_1)$ .

8. Consider again the conditions of Exercise 7, and suppose that it is desired to estimate the value of  $\theta = 3\beta_0 - 2\beta_1 + 5$ . Determine an unbiased estimator of  $\theta$  and find its M.S.E.
9. Consider again the conditions of Exercise 7, and let  $\theta = 3\beta_0 + c_1\beta_1$ , where  $c_1$  is a constant. Determine an unbiased estimator  $\hat{\theta}$  of  $\theta$ . For what value of  $c_1$  will the M.S.E. of  $\hat{\theta}$  be smallest?
10. Consider again the conditions of Exercise 7. If a particular patient's reaction to drug  $A$  has the value  $x = 2$ , what is the predicted value of his reaction to drug  $B$ , and what is the M.S.E. of this prediction?
11. Consider again the conditions of Exercise 7. For what value  $x$  of a patient's reaction to drug  $A$  can his reaction to drug  $B$  be predicted with the smallest M.S.E.?

**12.** Consider a problem of simple linear regression in which the durability  $Y$  of a certain type of alloy is to be related to the temperature  $X$  at which it was produced. Suppose that the eight pairs of observed values given in Table 11.3 are obtained. Determine the values of the M.L.E.'s  $\hat{\beta}_0$ ,  $\hat{\beta}_1$ , and  $\hat{\sigma}^2$ , and also the values of  $\text{Var}(\hat{\beta}_0)$  and  $\text{Var}(\hat{\beta}_1)$ .

**13.** For the conditions of Exercise 12, determine the value of the correlation of  $\hat{\beta}_0$  and  $\hat{\beta}_1$ .

**14.** Consider again the conditions of Exercise 12, and suppose that it is desired to estimate the value of  $\theta = 5 - 4\beta_0 + \beta_1$ . Find an unbiased estimator  $\hat{\theta}$  of  $\theta$ . Determine the value of  $\hat{\theta}$  and the M.S.E. of  $\hat{\theta}$ .

**15.** Consider again the conditions of Exercise 12, and let  $\theta = c_1\beta_1 - \beta_0$ , where  $c_1$  is a constant. Determine an unbiased estimator  $\hat{\theta}$  of  $\theta$ . For what value of  $c_1$  will the M.S.E. of  $\hat{\theta}$  be smallest?

**16.** Consider again the conditions of Exercise 12. If a specimen of the alloy is to be produced at the temperature  $x = 3.25$ , what is the predicted value of the durability of the specimen, and what is the M.S.E. of this prediction?

**17.** Consider again the conditions of Exercise 12. For what value of the temperature  $x$  can the durability of a specimen of the alloy be predicted with the smallest M.S.E.?

**18.** Moore and McCabe (1999, p. 174) report prices paid for several species of seafood in 1970 and 1980. These values are in Table 11.6. If we were interested in trying to predict 1980 seafood prices from 1970 prices, a linear regression model might be used.

- a. Find the least-squares regression coefficients for predicting 1980 prices from 1970 prices.
- b. If an additional species sold for 21.4 in 1970, what would you predict for the 1980 selling price?

- c. What is the M.S.E. for predicting the 1980 price of a species that sold for 21.4 in 1970?

**Table 11.6** Fish prices in 1970 and 1980 for Exercise 18

1970	1980	1970	1980
13.1	27.3	26.7	80.1
15.3	42.4	47.5	150.7
25.8	38.7	6.6	20.3
1.8	4.5	94.7	189.7
4.9	23	61.1	131.3
55.4	166.3	135.6	404.2
39.3	109.7	47.6	149

**19.** In the 1880s, Francis Galton studied the inheritance of physical characteristics. Galton found that the sons of tall men tended to be taller than average, but shorter than their fathers. Similarly, sons of short men tended to be shorter than average, but taller than their fathers. Thus, the average heights of the sons were closer to the mean height of the population, regardless of whether the fathers were taller or shorter than average. From these observations, one might conclude that the variability of height decreases over successive generations, both tall persons and short persons tend to be eliminated, and the population “regresses” toward some average height. This conclusion is an example of the *regression fallacy*. In this problem you will prove that the regression fallacy arises in the bivariate normal distribution even when both coordinates have the same variance. In particular, assume that the vector  $(X_1, X_2)$  has the bivariate normal distribution with common mean  $\mu$ , common variance  $\sigma^2$ , and positive correlation  $\rho < 1$ . Prove that  $E(X_2|x_1)$  is closer to  $\mu$  than  $x_1$  is to  $\mu$  for every value  $x_1$ . (This occurs despite the fact that  $X_1$  and  $X_2$  have the same mean and the same variance.)

## 11.3 Statistical Inference in Simple Linear Regression

Many of the inference procedures introduced in Chapters 8 and 9 that were used for samples from a normal distribution can be extended to the simple linear regression model. The theorems that allowed us to conclude that various statistics had  $t$  distributions will continue to apply in the regression case.

### Joint Distribution of the Estimators

**Example**  
**11.3.1**

**Pressure and the Boiling Point of Water.** Consider the traveler in Example 11.2.4, who is interested in the barometric pressure when the boiling point of water is 201.5 degrees. Suppose that this traveler would like to know whether the pressure is 24.5. For example, the traveler might wish to test the null hypothesis  $H_0 : \beta_0 + 201.5\beta_1 = 24.5$ .

Alternatively, the traveler might desire an interval estimate of  $\beta_0 + 201.5\beta_1$ . Such inferences are possible once we find the joint distribution of the estimators of all of the parameters ( $\beta_0$ ,  $\beta_1$ , and  $\sigma^2$ ) of the regression model.  $\blacktriangleleft$

It was stated after the proof of Theorem 11.2.2 that, in a problem of simple linear regression, the joint distribution of the M.L.E.'s  $\hat{\beta}_0$  and  $\hat{\beta}_1$  is the bivariate normal distribution for which the means, the variances, and the covariance are specified in Theorem 11.2.2. In this section, we shall prove this fact. We shall also consider the M.L.E.  $\hat{\sigma}^2$ , which was presented in Eq. (11.2.3), and we shall derive the joint distribution of  $\hat{\beta}_0$ ,  $\hat{\beta}_1$ , and  $\hat{\sigma}^2$ . In particular, we shall show that the estimator  $\hat{\sigma}^2$  is independent of  $\hat{\beta}_0$  and  $\hat{\beta}_1$ .

We continue to make Assumptions 11.2.1–11.2.5. The derivation of the joint distribution of  $\hat{\beta}_0$ ,  $\hat{\beta}_1$ , and  $\hat{\sigma}^2$ , which we shall present, is based on the properties of orthogonal matrices, as described in Sec. 8.3.

We shall continue to use the definition of  $s_x$  in Eq. (11.2.4). Also, let  $\mathbf{a}_1 = (a_{11}, \dots, a_{1n})$  and  $\mathbf{a}_2 = (a_{21}, \dots, a_{2n})$  be  $n$ -dimensional vectors, which are defined as follows:

$$a_{1j} = \frac{1}{n^{1/2}} \quad \text{for } j = 1, \dots, n, \quad (11.3.1)$$

and

$$a_{2j} = \frac{1}{s_x} (x_j - \bar{x}) \quad \text{for } j = 1, \dots, n. \quad (11.3.2)$$

It is easily verified that  $\sum_{j=1}^n a_{1j}^2 = 1$ ,  $\sum_{j=1}^n a_{2j}^2 = 1$ , and  $\sum_{j=1}^n a_{1j}a_{2j} = 0$ .

Because the vectors  $\mathbf{a}_1$  and  $\mathbf{a}_2$  have these properties, it is possible to construct an  $n \times n$  orthogonal matrix  $\mathbf{A}$  such that the coordinates of  $\mathbf{a}_1$  form the first row of  $\mathbf{A}$ , and coordinates of  $\mathbf{a}_2$  form the second row of  $\mathbf{A}$ . (To see how this is done, consult a linear algebra text, such as Cullen, 1972, p. 162, for the *Gram-Schmidt* method.) We shall assume that such a matrix  $\mathbf{A}$  has been constructed:

$$\mathbf{A} = \begin{bmatrix} a_{11} & \cdots & a_{1n} \\ a_{21} & \cdots & a_{2n} \\ \vdots & \ddots & \vdots \\ a_{n1} & \cdots & a_{nn} \end{bmatrix}.$$

We shall now define a new random vector  $\mathbf{Z}$  by the relation  $\mathbf{Z} = \mathbf{AY}$ , where

$$\mathbf{Y} = \begin{bmatrix} Y_1 \\ \vdots \\ Y_n \end{bmatrix} \quad \text{and} \quad \mathbf{Z} = \begin{bmatrix} Z_1 \\ \vdots \\ Z_n \end{bmatrix}.$$

The joint distribution of  $Z_1, \dots, Z_n$  can be found from the following theorem, which is an extension of Theorem 8.3.4.

**Theorem  
11.3.1**

Suppose that the random variables  $Y_1, \dots, Y_n$  are independent, and each has a normal distribution with the same variance  $\sigma^2$ . If  $\mathbf{A}$  is an orthogonal  $n \times n$  matrix and  $\mathbf{Z} = \mathbf{AY}$ , then the random variables  $Z_1, \dots, Z_n$  also are independent, and each has a normal distribution with variance  $\sigma^2$ .

**Proof** Let  $E(Y_i) = \mu_i$  for  $i = 1, \dots, n$  (it is not assumed in the theorem that  $Y_1, \dots, Y_n$  have the same mean), and let

$$\boldsymbol{\mu} = \begin{bmatrix} \mu_1 \\ \vdots \\ \mu_n \end{bmatrix}.$$

Also, let  $\mathbf{X} = (1/\sigma)(\mathbf{Y} - \boldsymbol{\mu})$ . Since it is assumed that the coordinates of the random vector  $\mathbf{Y}$  are independent, then the coordinates of the random vector  $\mathbf{X}$  will also be independent. Furthermore, each coordinate of  $\mathbf{X}$  will have the standard normal distribution. Therefore, it follows from Theorem 8.3.4 that the coordinates of the  $n$ -dimensional random vector  $\mathbf{AX}$  will also be independent, and each will have the standard normal distribution.

But

$$\mathbf{AX} = \frac{1}{\sigma}\mathbf{A}(\mathbf{Y} - \boldsymbol{\mu}) = \frac{1}{\sigma}\mathbf{Z} - \frac{1}{\sigma}\mathbf{A}\boldsymbol{\mu}.$$

Hence,

$$\mathbf{Z} = \sigma\mathbf{AX} + \mathbf{A}\boldsymbol{\mu}. \quad (11.3.3)$$

Since the coordinates of the random vector  $\mathbf{AX}$  are independent, and each has the standard normal distribution, then the coordinates of the random vector  $\sigma\mathbf{AX}$  will also be independent, and each will have the normal distribution with mean 0 and variance  $\sigma^2$ . When the vector  $\mathbf{A}\boldsymbol{\mu}$  is added to the random vector  $\sigma\mathbf{AX}$ , the mean of each coordinate will be shifted, but the coordinates will remain independent, and the variance of each coordinate will be unchanged. It now follows from Eq. (11.3.3) that the coordinates of the random vector  $\mathbf{Z}$  will be independent, and each will have a normal distribution with variance  $\sigma^2$ . ■

In a problem of simple linear regression, the observations  $Y_1, \dots, Y_n$  satisfy the conditions of Theorem 11.3.1. Therefore, the coordinates of the random vector  $\mathbf{Z} = \mathbf{AY}$  will be independent, and each will have a normal distribution with variance  $\sigma^2$ . We can use these facts to find the joint distribution of  $(\hat{\beta}_0, \hat{\beta}_1, \hat{\sigma}^2)$ .

### Theorem

#### 11.3.2

In the simple linear regression problem described above, the joint distribution of  $(\hat{\beta}_0, \hat{\beta}_1)$  is the bivariate normal distribution for which the means, variances, and covariance are as stated in Theorem 11.2.2. Also, if  $n \geq 3$ ,  $\hat{\sigma}^2$  is independent of  $(\hat{\beta}_0, \hat{\beta}_1)$  and  $n\hat{\sigma}^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - 2$  degrees of freedom.

**Proof** The first two coordinates  $Z_1$  and  $Z_2$  of the random vector  $\mathbf{Z}$  can easily be derived. The first coordinate is

$$Z_1 = \sum_{j=1}^n a_{1j} Y_j = \frac{1}{n^{1/2}} \sum_{j=1}^n Y_j = n^{1/2} \bar{Y}. \quad (11.3.4)$$

Since  $\hat{\beta}_0 = \bar{Y} - \bar{x}\hat{\beta}_1$ , we may also write

$$Z_1 = n^{1/2}(\hat{\beta}_0 + \bar{x}\hat{\beta}_1). \quad (11.3.5)$$

The second coordinate is

$$Z_2 = \sum_{j=1}^n a_{2j} Y_j = \frac{1}{s_x} \sum_{j=1}^n (x_j - \bar{x}) Y_j. \quad (11.3.6)$$

By Eq. (11.2.7), we may also write

$$Z_2 = s_x \hat{\beta}_1. \quad (11.3.7)$$

Together, Eqs. (11.3.5) and (11.3.7) imply that

$$\begin{aligned}\hat{\beta}_0 &= n^{-1/2} Z_1 - \frac{\bar{x}}{s_x} Z_2, \\ \hat{\beta}_1 &= \frac{1}{s_x} Z_2.\end{aligned}\tag{11.3.8}$$

Since  $Z_1$  and  $Z_2$  are independent normal random variables, they have a bivariate normal joint distribution. Eqs. (11.3.8) express  $\hat{\beta}_0$  and  $\hat{\beta}_1$  as linear combinations of  $Z_1$  and  $Z_2$ . These linear combinations satisfy the conditions of Exercise 10 of Sec. 5.10, which says in turn that  $\hat{\beta}_0$  and  $\hat{\beta}_1$  have a bivariate normal distribution. We already calculated the means, variances, and covariance in Theorem 11.2.2.

Now let the random variable  $S^2$  be defined as follows:

$$S^2 = \sum_{i=1}^n (Y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i)^2.\tag{11.3.9}$$

(It is easy to see that the M.L.E. of  $\sigma^2$ , as given in Eq. (11.2.3), is  $\hat{\sigma}^2 = S^2/n$ .) We shall show that  $S^2$  and the random vector  $(\hat{\beta}_0, \hat{\beta}_1)$  are independent. Since  $\hat{\beta}_0 = \bar{Y} - \bar{x}\hat{\beta}_1$ , we may rewrite  $S^2$  as follows:

$$\begin{aligned}S^2 &= \sum_{i=1}^n [Y_i - \bar{Y} - \hat{\beta}_1(x_i - \bar{x})]^2 \\ &= \sum_{i=1}^n (Y_i - \bar{Y})^2 - 2\hat{\beta}_1 \sum_{i=1}^n (x_i - \bar{x})(Y_i - \bar{Y}) + \hat{\beta}_1^2 s_x^2.\end{aligned}$$

It now follows from Eq. (11.1.1) that

$$S^2 = \sum_{i=1}^n Y_i^2 - n\bar{Y}^2 - s_x^2 \hat{\beta}_1^2.\tag{11.3.10}$$

Since  $\mathbf{Z} = \mathbf{A}\mathbf{Y}$ , where  $\mathbf{A}$  is an orthogonal matrix, we know from Theorem 8.3.4 that  $\sum_{i=1}^n Y_i^2 = \sum_{i=1}^n Z_i^2$ . By using this fact, we can now obtain the following relation from Eq. (11.3.4), (11.3.7), and (11.3.10):

$$S^2 = \sum_{i=1}^n Z_i^2 - Z_1^2 - Z_2^2 = \sum_{i=3}^n Z_i^2.$$

The random variables  $Z_1, \dots, Z_n$  are independent, and we have now shown that  $S^2$  is equal to the sum of the squares of only  $Z_3, \dots, Z_n$ . It follows, therefore, that  $S^2$  and the random vector  $(Z_1, Z_2)$  are independent. But  $\hat{\beta}_0$  and  $\hat{\beta}_1$  are functions of  $Z_1$  and  $Z_2$  only, as seen in Eq. (11.3.8). Hence,  $S^2$  and the random vector  $(\hat{\beta}_0, \hat{\beta}_1)$  are independent.

We shall now derive the distribution of  $S^2$ . For  $i = 3, \dots, n$ , we have  $Z_i = \sum_{j=1}^n a_{ij} Y_j$ . Hence,

$$\begin{aligned}
E(Z_i) &= \sum_{j=1}^n a_{ij} E(Y_j) = \sum_{j=1}^n a_{ij}(\beta_0 + \beta_1 x_j) \\
&= \sum_{j=1}^n a_{ij}[\beta_0 + \beta_1 \bar{x} + \beta_1(x_j - \bar{x})] \\
&= (\beta_0 + \beta_1 \bar{x}) \sum_{j=1}^n a_{ij} + \beta_1 \sum_{j=1}^n a_{ij}(x_j - \bar{x}).
\end{aligned} \tag{11.3.11}$$

Since the matrix  $\mathbf{A}$  is orthogonal, the sum of the products of the corresponding terms in any two different rows must be 0. In particular, for  $i = 3, \dots, n$ ,

$$\sum_{j=1}^n a_{ij} a_{1j} = 0 \quad \text{and} \quad \sum_{j=1}^n a_{ij} a_{2j} = 0.$$

It now follows from the expressions for  $a_{1j}$  and  $a_{2j}$  given in Eqs. (11.3.1) and (11.3.2) that for  $i = 3, \dots, n$ ,

$$\sum_{j=1}^n a_{ij} = 0 \quad \text{and} \quad \sum_{j=1}^n a_{ij}(x_j - \bar{x}) = 0.$$

When these values are substituted into Eq. (11.3.11), it is found that  $E(Z_i) = 0$  for  $i = 3, \dots, n$ .

We now know that the  $n - 2$  random variables  $Z_3, \dots, Z_n$  are independent, and that each has the normal distribution with mean 0 and variance  $\sigma^2$ . Since  $S^2 = \sum_{i=3}^n Z_i^2$ , it follows that the random variable  $S^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - 2$  degrees of freedom.

Finally, we know that  $\hat{\sigma}^2 = S^2/n$ , and hence  $\hat{\sigma}^2$  is independent of the estimators  $\hat{\beta}_0$  and  $\hat{\beta}_1$ , and the distribution of  $n\hat{\sigma}^2/\sigma^2$  is the  $\chi^2$  distribution with  $n - 2$  degrees of freedom. ■

### Tests of Hypotheses about the Regression Coefficients

It will be convenient, for the remainder of the discussion of simple linear regression, to let

$$\sigma' = \left( \frac{S^2}{n-2} \right)^{1/2}. \tag{11.3.12}$$

This random variable will appear in all of the test statistics and confidence intervals that we derive. It is analogous to the random variable with the same name that appears in Eqs. (8.4.3) and (8.4.5) and played a similar role in tests and confidence intervals for the mean of a single normal distribution.

We proved earlier that the joint distribution of  $(\hat{\beta}_0, \hat{\beta}_1)$  is bivariate normal. This implies that every linear combination  $c_0 \hat{\beta}_0 + c_1 \hat{\beta}_1$  has a normal distribution. We shall use this fact to simplify the discussion of inference about regression coefficients. We shall begin by deriving tests of hypotheses concerning a general linear combination  $c_0 \beta_0 + c_1 \beta_1$  of the regression parameters. Then, specific cases will be introduced by choosing special values for  $c_0$  and  $c_1$ . For example,  $c_0 = 1$  and  $c_1 = 0$  makes the linear combination  $\beta_0$ , while  $c_0 = 0$  and  $c_1 = 1$  leads to  $\beta_1$ .

**Tests of Hypotheses about a Linear Combination of  $\beta_0$  and  $\beta_1$**  Let  $c_0$ ,  $c_1$ , and  $c_*$  be specified numbers, where at least one of  $c_0$  and  $c_1$  is nonzero, and suppose that we are interested in testing the following hypotheses:

$$\begin{aligned} H_0: \quad c_0\beta_0 + c_1\beta_1 &= c_*, \\ H_1: \quad c_0\beta_0 + c_1\beta_1 &\neq c_*. \end{aligned} \quad (11.3.13)$$

We shall derive a test of these hypotheses based on the random variables  $c_0\hat{\beta}_0 + c_1\hat{\beta}_1$  and  $\sigma'$ .

**Theorem 11.3.3** For each  $0 < \alpha_0 < 1$ , a level  $\alpha_0$  test of the hypotheses (11.3.13) is to reject  $H_0$  if  $|U_{01}| \geq T_{n-2}^{-1}(1 - \alpha_0/2)$ , where

$$U_{01} = \left[ \frac{c_0^2}{n} + \frac{(c_0\bar{x} - c_1)^2}{s_x^2} \right]^{-1/2} \left( \frac{c_0\hat{\beta}_0 + c_1\hat{\beta}_1 - c_*}{\sigma'} \right), \quad (11.3.14)$$

and  $T_{n-2}^{-1}$  is the quantile function of the  $t$  distribution with  $n - 2$  degrees of freedom.

**Proof** In general, the mean of  $c_0\hat{\beta}_0 + c_1\hat{\beta}_1$  is  $c_0\beta_0 + c_1\beta_1$ , and its variance was found in Eq. (11.2.10). Therefore, when  $H_0$  is true, the following random variable  $W_{01}$  has the standard normal distribution:

$$W_{01} = \left[ \frac{c_0^2}{n} + \frac{(c_0\bar{x} - c_1)^2}{s_x^2} \right]^{-1/2} \left( \frac{c_0\hat{\beta}_0 + c_1\hat{\beta}_1 - c_*}{\sigma} \right).$$

Because the value of  $\sigma$  is unknown, a test of the hypotheses (11.3.13) cannot be based simply on the random variable  $W_{01}$ . However, the random variable  $S^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - 2$  degrees of freedom for all possible values of the parameters  $\beta_0$ ,  $\beta_1$ , and  $\sigma^2$ . Moreover, because  $(\hat{\beta}_0, \hat{\beta}_1)$  is independent of  $S^2$ , it follows that  $W_{01}$  and  $S^2$  are also independent. Hence, when the hypothesis  $H_0$  is true, the random variable

$$\frac{W_{01}}{\left[ \left( \frac{1}{n-2} \right) \left( \frac{S^2}{\sigma^2} \right) \right]^{1/2}} \quad (11.3.15)$$

has the  $t$  distribution with  $n - 2$  degrees of freedom. It is straightforward to show that the expression in (11.3.15) also equals  $U_{01}$  in Eq. (11.3.14), which is a function of the observable data alone. It follows that the test specified in the theorem is a level  $\alpha_0$  test of the hypotheses (11.3.13). ■

The test procedure in Theorem 11.3.3 is also the likelihood ratio test procedure for the hypotheses (11.3.13), but the proof will not be given here.

**Tests of One-Sided Hypotheses** The same derivation just finished can also be used to form tests of hypotheses such as

$$\begin{aligned} H_0: \quad c_0\beta_0 + c_1\beta_1 &\leq c_*, \\ H_1: \quad c_0\beta_0 + c_1\beta_1 &> c_*, \end{aligned} \quad (11.3.16)$$

or

$$\begin{aligned} H_0: \quad c_0\beta_0 + c_1\beta_1 &\geq c_*, \\ H_1: \quad c_0\beta_0 + c_1\beta_1 &< c_*. \end{aligned} \quad (11.3.17)$$

The proof of the following result is similar to the proof of Theorem 11.3.3 and will not be given here.

**Theorem 11.3.4** A level  $\alpha_0$  test of (11.3.16) is to reject  $H_0$  if  $U_{01} \geq T_{n-2}^{-1}(1 - \alpha_0)$ . A level  $\alpha_0$  test of (11.3.17) is to reject  $H_0$  if  $U_{01} \leq -T_{n-2}^{-1}(1 - \alpha_0)$ . ■

The only part of the proof of Theorem 11.3.4 that differs significantly from the corresponding part of Theorem 11.3.3 is the proof that the tests actually have level of significance  $\alpha_0$ . The proof of this is similar to the proof of Theorem 9.5.1 and is left to the reader in Exercise 23.

We shall next present examples of how to test several common hypotheses concerning  $\beta_0$  and  $\beta_1$  by making use of the fact that  $U_{01}$  in Eq. (11.3.14) has the  $t$  distribution with  $n - 2$  degrees of freedom. These examples will correspond to setting  $c_0$ ,  $c_1$ , and  $c_*$  equal to specific values.

**Tests of Hypotheses about  $\beta_0$**  Let  $\beta_0^*$  be a specified number ( $-\infty < \beta_0^* < \infty$ ), and suppose that it is desired to test the following hypotheses about the regression coefficient  $\beta_0$ :

$$\begin{aligned} H_0: \quad \beta_0 &= \beta_0^*, \\ H_1: \quad \beta_0 &\neq \beta_0^*. \end{aligned} \quad (11.3.18)$$

These hypotheses are the same as those in Eq. (11.3.13) if we make the substitutions  $c_0 = 1$ ,  $c_1 = 0$ , and  $c_* = \beta_0^*$ . If we substitute these values into the formula for  $U_{01}$  in Eq. (11.3.14), we obtain the following random variable,  $U_0$ ,

$$U_0 = \frac{\hat{\beta}_0 - \beta_0^*}{\sigma' \left[ \frac{1}{n} + \frac{\bar{x}^2}{s_x^2} \right]^{1/2}}, \quad (11.3.19)$$

which then has the  $t$  distribution with  $n - 2$  degrees of freedom if  $H_0$  is true.

Suppose that in a problem of simple linear regression, we are interested in testing the null hypothesis that the regression line  $y = \beta_0 + \beta_1 x$  passes through the origin against the alternative hypothesis that the line does not pass through the origin. These hypotheses can be stated in the following form:

$$\begin{aligned} H_0: \quad \beta_0 &= 0, \\ H_1: \quad \beta_0 &\neq 0. \end{aligned} \quad (11.3.20)$$

Here the hypothesized value  $\beta_0^*$  is 0.

Let  $u_0$  denote the value of  $U_0$  calculated from a given set of observed values  $(x_i, y_i)$  for  $i = 1, \dots, n$ . Then the tail area ( $p$ -value) corresponding to this value is the two-sided tail area

$$\Pr(U_0 \geq |u_0|) + \Pr(U_0 \leq -|u_0|).$$

For example, suppose that  $n = 20$  and the calculated value of  $U_0$  is 2.1. It is found from a table of the  $t$  distribution with 18 degrees of freedom that the corresponding tail area is 0.05. Hence, at each level of significance  $\alpha_0 < 0.05$ , the null hypothesis  $H_0$  would not be rejected. At every level of significance  $\alpha_0 \geq 0.05$ ,  $H_0$  would be rejected.

**Tests of Hypotheses about  $\beta_1$**  Let  $\beta_1^*$  be a specified number ( $-\infty < \beta_1^* < \infty$ ), and suppose that it is desired to test the following hypotheses about the regression

coefficient  $\beta_1$ :

$$\begin{aligned} H_0: \quad \beta_1 &= \beta_1^*, \\ H_1: \quad \beta_1 &\neq \beta_1^*. \end{aligned} \tag{11.3.21}$$

These hypotheses are the same as those in Eq. (11.3.13) if we make the substitutions  $c_0 = 0$ ,  $c_1 = 1$ , and  $c_* = \beta_1^*$ . If we substitute these values into the formula for  $U_{01}$  in Eq. (11.3.14), we obtain the following random variable,  $U_1$ ,

$$U_1 = s_x \frac{\hat{\beta}_1 - \beta_1^*}{\sigma'}, \tag{11.3.22}$$

which then has the  $t$  distribution with  $n - 2$  degrees of freedom if  $H_0$  is true.

Suppose that in a problem of simple linear regression we are interested in testing the hypothesis that the variable  $Y$  is actually unrelated to the variable  $X$ . Under Assumptions 11.2.1–11.2.5, this hypothesis is equivalent to the hypothesis that the regression function  $E(Y|x)$  is constant and not actually a function of  $x$ . Since it is assumed that the regression function has the form  $E(Y|x) = \beta_0 + \beta_1 x$ , this hypothesis is in turn equivalent to the hypothesis that  $\beta_1 = 0$ . Thus, the problem is one of testing the following hypotheses:

$$\begin{aligned} H_0: \quad \beta_1 &= 0, \\ H_1: \quad \beta_1 &\neq 0. \end{aligned}$$

Here the hypothesized value  $\beta_1^*$  is 0.

Let  $u_1$  denote the value of  $U_1$  calculated from a given set of observed values  $(x_i, y_i)$  for  $i = 1, \dots, n$ . Then the  $p$ -value corresponding to these data is

$$\Pr(U_1 \geq |u_1|) + \Pr(U_1 \leq -|u_1|).$$

### Example 11.3.2

**Gasoline Mileage.** Consider the two variables gasoline mileage and engine horsepower in Example 11.1.4. This time, let  $Y$  be 1 over gasoline mileage, that is, gallons per mile. Also, let  $X$  be engine horsepower. A plot of the observed  $(x_i, y_i)$  pairs is given in Fig. 11.8 together with the fitted least-squares regression line. Notice how much straighter the relationship is between the two variables in Fig. 11.8 than between the two variables in Fig. 11.6. The least-squares estimates for a simple linear regression of gallons per mile on engine horsepower are  $\hat{\beta}_0 = 0.01537$  and  $\hat{\beta}_1 = 1.396 \times 10^{-4}$ . Also,  $\sigma' = 7.181 \times 10^{-3}$ ,  $\bar{x} = 183.97$ , and  $s_x = 1036.9$ . Suppose that

**Figure 11.8** Plot of gallons per mile versus engine horsepower for 173 cars in Example 11.3.2. The least-squares regression line is drawn on the plot.

we wanted to test the null hypothesis  $H_0 : \beta_1 \geq 0$  against the alternative  $H_1 : \beta_1 < 0$ . The observed value of the statistic  $U_1$  in Eq. (11.3.22) is

$$u_1 = 1036.9 \frac{1.396 \times 10^{-4} - 0}{7.139 \times 10^{-3}} = 20.15,$$

which is larger than the  $1 - 10^{-16}$  quantile of the  $t$  distribution with 171 degrees of freedom. So, we would reject  $H_0$  at every level  $\alpha_0 \leq 10^{-16}$ .  $\blacktriangleleft$

**Tests of Hypotheses about the Mean of a Future Observation** Suppose that we are interested in testing the hypothesis that the regression line  $y = \beta_0 + \beta_1 x$  passes through a particular point  $(x^*, y^*)$ , where  $x^* \neq 0$ . In other words, suppose that we are interested in testing the following hypotheses:

$$H_0 : \beta_0 + \beta_1 x^* = y^*,$$

$$H_1 : \beta_0 + \beta_1 x^* \neq y^*.$$

These hypotheses have the same form as the hypotheses (11.3.13) with  $c_0 = 1$ ,  $c_1 = x^*$ , and  $c_* = y^*$ . Hence, they can be tested by carrying out a  $t$  test with  $n - 2$  degrees of freedom that is based on the statistic  $U_{01}$ .

**Example**  
**11.3.3**

**Pressure and the Boiling Point of Water.** In Example 11.3.1, the traveler was interested in testing the null hypothesis that  $H_0 : \beta_0 + 201.5\beta_1 = 24.5$  versus  $H_1 : \beta_0 + 201.5\beta_1 \neq 24.5$ . We shall make use of the statistic  $U_{01}$  in Eq. (11.3.14) with  $c_0 = 1$  and  $c_1 = 201.5$ . Based on the data in Table 11.5, we have already computed the least-squares estimates  $\hat{\beta}_0 = -81.06$  and  $\hat{\beta}_1 = 0.5229$ . We can also compute  $n = 17$ ,  $s_x^2 = 530.78$ ,  $\bar{x} = 202.95$ , and  $\sigma' = 0.2328$ . Then

$$U_{01} = \left[ \frac{1}{17} + \frac{(202.95 - 201.5)^2}{530.78} \right]^{1/2} \frac{-81.06 + 201.5 \times 0.5229 - 24.5}{0.2328} = -0.2204.$$

If  $H_0$  is true, then  $U_{0,1}$  has the  $t$  distribution with  $n - 2 = 15$  degrees of freedom. The  $p$ -value corresponding to the observed value  $-0.2204$  is 0.8285. The null hypothesis would be rejected at level  $\alpha_0$  only if  $\alpha_0 \geq 0.8285$ .  $\blacktriangleleft$

## Confidence Intervals

A confidence interval for  $\beta_0$ ,  $\beta_1$ , or any linear combination of the two can be obtained from the corresponding test procedure.

**Theorem**  
**11.3.5**

Let  $c_0$  and  $c_1$  be scalar constants that are not both 0. The open interval between the two random variables

$$c_0 \hat{\beta}_0 + c_1 \hat{\beta}_1 \pm \sigma' \left[ \frac{c_0^2}{n} + \frac{(c_0 \bar{x} - c_1)^2}{s_x^2} \right]^{1/2} T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{2} \right) \quad (11.3.23)$$

is a coefficient  $1 - \alpha_0$  confidence interval for  $c_0 \beta_0 + c_1 \beta_1$ .

**Proof** Consider the general hypotheses (11.3.13). Theorem 9.1.1 tells us that the set of all values of  $c_*$  for which the null hypothesis  $H_0$  would not be rejected at the level of significance  $\alpha_0$  forms a confidence interval for  $c_0 \beta_0 + c_1 \beta_1$  with confidence coefficient  $1 - \alpha_0$ . It is straightforward to check that  $c_*$  is between the two random variables in (11.3.23) if and only if  $|U_{01}| < T_{n-2}^{-1}(1 - \alpha_0/2)$ , which specifies when the level  $\alpha_0$  would not reject  $H_0$  according to Theorem 11.3.3.  $\blacksquare$

**Example 11.3.4** **Gasoline Mileage.** In Example 11.3.2, we rejected the null hypothesis that  $\beta_1 \leq 0$ , but we might wish to form an interval estimate of  $\beta_1$ . Apply Theorem 11.3.5 with  $c_0 = 0$  and  $c_1 = 1$ . The endpoints of a coefficient  $1 - \alpha_0$  confidence interval are then

$$\hat{\beta}_1 \pm \frac{\sigma'}{s_x} T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{2} \right).$$

For example, suppose that we desire a coefficient 0.8 confidence interval for  $\beta_1$ . We find  $T_{171}^{-1}(0.9) = 1.287$  using computer software (or we could have interpolated in the table in the back of the text). The remaining values needed to compute the endpoints are given in Example 11.3.2, and the observed interval is  $(1.307 \times 10^{-4}, 1.485 \times 10^{-4})$ .  $\blacktriangleleft$

Other special cases of Theorem 11.3.5 are when  $c_0 = 1$  and  $c_1 = 0$ , which provides a confidence interval for  $\beta_0$ , and when  $c_0 = 1$  and  $c_1 = x$ , which provides a confidence interval for the mean of  $Y$  when  $X = x$ . The second of these can also be described as the height  $\theta = \beta_0 + \beta_1 x$  of the regression line at a given point  $x$ . The corresponding confidence interval has the endpoints

$$\hat{\beta}_0 + \hat{\beta}_1 x \pm T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{2} \right) \sigma' \left[ \frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2} \right]^{1/2}. \quad (11.3.24)$$

**Prediction Intervals** On page 703, we discussed predicting a new  $Y$  value (independent of the observed data) when we knew the corresponding value of  $x$ . Suppose that we want an interval that should contain  $Y$  with some specified probability  $1 - \alpha_0$ . We can construct such an interval by considering the joint distribution of  $Y$ ,  $\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1 x$ , and  $S^2$ .

**Theorem 11.3.6** In the simple linear regression problem, let  $Y$  be a new observation with predictor  $x$  such that  $Y$  is independent of  $Y_1, \dots, Y_n$ . Let  $\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1 x$ . Then the probability that  $Y$  is between the following two random variables is  $1 - \alpha_0$ :

$$\hat{Y} \pm T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{2} \right) \sigma' \left[ 1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2} \right]^{1/2}. \quad (11.3.25)$$

**Proof** Since  $Y$  is independent of the observed data, we have that  $Y$ ,  $\hat{Y}$ , and  $S^2$  are all independent. Hence, the following two random variables are independent:

$$Z = \frac{Y - \hat{Y}}{\sigma' \sqrt{1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2}}}, \quad W = \frac{S^2}{\sigma'^2}.$$

Since  $Y$  and  $\hat{Y}$  are independent and normally distributed,  $Z$  has a normal distribution. Since  $E(Y) = E(\hat{Y})$ , the mean of  $Z$  is 0. It follows from Eq. (11.2.13) that the variance of  $Z$  is 1. It follows from Theorem 11.3.2 that  $W$  has the  $\chi^2$  distribution with  $n - 2$  degrees of freedom. It follows that  $Z/(W/[n - 2])^{1/2}$  has the  $t$  distribution with  $n - 2$  degrees of freedom. It is easy to see that  $Z/(W/[n - 2])^{1/2}$  is the same as

$$U_x = \frac{Y - \hat{Y}}{\sigma' \sqrt{1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2}}}. \quad (11.3.26)$$

It follows that  $\Pr(|U_x| < T_{n-2}^{-1}(1 - \alpha_0/2)) = 1 - \alpha_0$ . It is then straightforward to show that  $Y$  is between the two random variables in (11.3.25) if and only if  $|U_x| < T_{n-2}^{-1}(1 - \alpha_0/2)$ . ■

**Definition  
11.3.1**

**Prediction Interval.** The random interval whose endpoints are given by (11.3.25) is called a coefficient  $1 - \alpha_0$  prediction interval for  $Y$ .

Prior to observing the data, when  $\sigma'$ ,  $\hat{\beta}_0$ ,  $\hat{\beta}_1$ , and  $Y$  are all still random variables, the endpoints in (11.3.25) have the property that the probability is  $1 - \alpha_0$  that  $Y$  will be between the endpoints, and hence in the interval. After the data are observed, the interpretation of the interval whose endpoints are in (11.3.25) is similar to the interpretation of a confidence interval, but with the added complication that  $Y$  is still a random variable.

**Example  
11.3.5**

**Gasoline Mileage.** Suppose that we wish to predict the gasoline mileage for a car with a particular engine horsepower  $x$  in Example 11.3.2. In particular, let  $x = 100$ , and we shall use  $\alpha_0 = 0.1$  to form a prediction interval as above. Using the values computed in Example 11.3.2 and Eq. (11.3.25), we obtain the interval (0.01737, 0.04127) for predicting  $Y$  gallons per mile. Since  $Y$  is in this interval if and only if  $1/Y$  is between  $1/0.01737 = 57.56$  and  $1/0.04127 = 24.23$ , we can claim that the following interval is the observed value of a 90 percent prediction interval for miles per gallon: (24.23, 57.56). ◀

## The Analysis of Residuals

Whenever a statistical analysis is carried out, it is important to verify that the observed data appear to satisfy the assumptions on which the analysis is based. For example, in the statistical analysis of a problem of simple linear regression, we have assumed that the regression of  $Y$  on  $X$  is a linear function and that the observations  $Y_1, \dots, Y_n$  are independent. The M.L.E.'s of  $\beta_0$  and  $\beta_1$  and the tests of hypotheses about  $\beta_0$  and  $\beta_1$  were developed on the basis of these assumptions, but the data were not examined to find out whether or not these assumptions were reasonable.

One way to make a quick and informal check of these assumptions is to examine the discrepancies between the observed values  $y_1, \dots, y_n$  and the fitted regression line.

**Definition  
11.3.2**

**Residuals/Fitted Values.** For  $i = 1, \dots, n$ , the observed values of  $\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_i$  are called the *fitted values*. For  $i = 1, \dots, n$ , the observed values of  $e_i = y_i - \hat{y}_i$  are called the *residuals*.

Specifically, suppose that the  $n$  points  $(x_i, e_i)$ , for  $i = 1, \dots, n$  are plotted in the  $xe$ -plane. It must be true (see Exercise 4 at the end of Sec. 11.1) that  $\sum_{i=1}^n e_i = 0$  and  $\sum_{i=1}^n x_i e_i = 0$ . However, subject to these restrictions, the positive and negative residuals should be scattered randomly among the points  $(x_i, e_i)$ . If the positive residuals  $e_i$  tend to be concentrated at either the extreme values of  $x_i$  or the central values of  $x_i$ , then either the assumption that the regression of  $Y$  on  $X$  is a linear function or the assumption that the observations  $Y_1, \dots, Y_n$  are independent may be violated. In fact, if the plot of the points  $(x_i, e_i)$  exhibits any type of regular pattern, the assumptions may be violated.

**Example  
11.3.6**

**Pressure and the Boiling Point of Water.** The residuals from a least-squares fit to the data in Example 11.2.2 can be computed using the coefficients reported in Example 11.2.5:  $\hat{\beta}_0 = -81.06$  and  $\hat{\beta}_1 = 0.5229$ . Table 11.7 contains the original data together

**Table 11.7** Data from Table 11.5 together with fitted values, residuals from least-squares fit, and logarithm of pressure

$x_i$	$y_i$	$\hat{y}_i = -81.06 + 0.5229x_i$	$e_i = y_i - \hat{y}_i$	$\log(y_i)$
194.5	20.79	20.64	0.1512	3.034
194.3	20.79	20.53	0.2557	3.034
197.9	22.40	22.42	-0.0167	3.109
198.4	22.67	22.68	-0.0081	3.121
199.4	23.15	23.20	-0.0510	3.142
199.9	23.35	23.46	-0.1125	3.151
200.9	23.89	23.99	-0.0954	3.173
201.1	23.99	24.09	-0.0999	3.178
201.4	24.02	24.25	-0.2268	3.179
201.3	24.01	24.19	-0.1845	3.178
203.6	25.14	25.40	-0.2572	3.224
204.6	26.57	25.92	0.6499	3.280
209.5	28.49	28.48	0.0078	3.350
208.6	27.76	28.01	-0.2516	3.324
210.7	29.04	29.11	-0.0697	3.369
211.9	29.88	29.74	0.1428	3.397
212.2	30.06	29.89	0.1660	3.403

with the fitted values  $\hat{y}_i = -81.06 + 0.5229x_i$  and the residuals  $e_i = y_i - \hat{y}_i$  for all  $i$ . A plot of the residuals versus boiling point is shown in Fig. 11.9. This plot has two striking features. One is the exceptionally large positive residual corresponding to  $x_i = 204.6$  at the top of the plot. Observations with such large residuals are sometimes called *outliers*. Perhaps either the  $x_i$  or  $y_i$  value corresponding to this observation was recorded incorrectly or this observation was taken under conditions different from those of the other observations. Or perhaps that particular  $y_i$  value just happened to be very far from its mean. The other striking feature of the plot is that, aside from the outlier, the other residuals seem to form a U-shaped pattern. This sort of pattern suggests that the relationship between the two variables might be better described by a curve rather than a straight line.

Techniques for dealing with the two features that we noticed in Fig. 11.9 can be found in books devoted to regression methodology such as Belsley, Kuh, and Welsch (1980), Cook and Weisberg (1982), Draper and Smith (1998), and Weisberg (1985). One possible technique to deal with the curved look of the residual plot is to transform one or both of the two variables  $Y$  and  $X$  before performing the regression. Indeed, Forbes (1857) suspected that the logarithm of pressure would be linearly related to boiling point. Table 11.7 also contains the logarithms of pressure. If we perform a regression of the logarithm of pressure on the boiling point, we obtain the least-squares estimates  $\hat{\beta}_0 = -0.9709$  and  $\hat{\beta}_1 = 0.0206$ . The observed value of  $\sigma'$  is  $8.730 \times 10^{-3}$ . Residuals from this fit can be computed as  $\log(y_i) - (-0.9709 + 0.0206x_i)$ , and they are plotted in Fig. 11.10. The one large residual still appears in

**Figure 11.9** Plot of residuals versus boiling point for Example 11.3.6.

**Figure 11.10** Plot of residuals from regression of log-pressure versus boiling point for Example 11.3.6.

Fig. 11.10, but the curved shape of the remaining residuals has vanished. To see what effect that one observation has on the regression, we can fit the regression using only the other 16 observations. In this case, the estimated coefficients are  $\hat{\beta}_0 = -0.9518$  and  $\hat{\beta}_1 = 0.0205$  with  $\sigma' = 2.616 \times 10^{-3}$ . The coefficients don't change much, but the estimated standard deviation drops to less than one-third of its previous value. ◀

**Note: Both Models Cannot Be Correct in Example 11.3.6.** It cannot be the case that both the mean of pressure and the mean of the logarithm of pressure are linear functions of boiling point. When the residual plot in Fig. 11.9 revealed a curved shape, we began to suspect that the mean of pressure was *not* a linear function of boiling point. In this case, the probabilistic calculations performed in Examples 11.2.2, 11.2.5, and 11.3.3 become suspect as well.

**Note: What to Do with Outliers.** The data point with  $X = 204.6$  in Example 11.3.6 makes it difficult to interpret the results of the regression analysis. Forbes (1857) labels this point “Evidently a mistake.” Generally, when such data points appear in our data sets, we should try to verify whether they were collected under the same conditions as the remaining data. Sometimes the process by which the data are collected changes during the experiment. If the removal of the outlier makes a noticeable difference to the analysis, then that observation must be dealt with. If it is not possible to show that the observation should be removed based on how it was collected, it might be that the distribution of the  $Y_i$  values is different from a normal distribution. It might be that the distribution has higher probability of producing

extremely large deviations from the mean. In this case, one might have to resort to robust regression procedures similar to the robust procedures described in Sec. 10.7. Interested readers should consult Hampel et al. (1986) or Rousseeuw and Leroy (1987).

**Normal Quantile Plots** Another plot that is helpful in assessing the assumptions of the regression model is the *normal quantile plot*, sometimes called a normal scores plot or a normal Q-Q plot. Assume that the residuals are reasonable estimates of  $\varepsilon_i = Y_i - (\beta_0 + \beta_1 x_i)$ . Each  $\varepsilon_i$  has the normal distribution with mean 0 and variance  $\sigma^2$  according to the linear regression model. The normal quantile plot compares quantiles of a normal distribution with the ordered values of the residuals. We expect about 25 percent of the residuals to be below the 0.25 quantile of the normal distribution. We expect about 80 percent of the residuals to be below the 0.8 quantile of the normal distribution, and so forth. We can see how closely these expectations are met by plotting the ordered residuals against quantiles of the normal distribution.

Let  $r_1 \leq r_2 \leq \dots \leq r_n$  be the residuals ordered from smallest to largest. The points that we plot are  $(\Phi^{-1}(i/[n+1]), r_i)$  for  $i = 1, \dots, n$ , where  $\Phi^{-1}$  is the standard normal quantile function. The numbers  $\Phi^{-1}(i/[n+1])$  for  $i = 1, \dots, n$  are  $n$  quantiles of the standard normal distribution that divide the standard normal distribution into intervals of equal probability, including the intervals below the first quantile and above the last one. If the plotted points lie roughly along the line  $y = x$ , then roughly 25 percent of the residuals lie below the 0.25 quantile of the standard normal distribution, and roughly 80 percent of the residuals lie below the 0.8 quantile, and so on. If the points lie on a different line  $y = ax + b$ , then we could multiply the first coordinate of each point by  $a$  and add  $b$  to the first coordinate. This would make the new points lie on the line  $y = x$ , and the first coordinate of each point is now a quantile of the normal distribution with mean  $b$  and variance  $a^2$ . So roughly 25 percent of the residuals lie below the 0.25 quantile of the normal distribution with mean  $b$  and variance  $a^2$ , and so on. So, we examine the normal quantile plot to see how close the points are to lying on a straight line. We don't care which line it is, because we only care whether the data look like they come from some normal distribution. We fit the regression model to help decide which normal distribution.

**Example**  
**11.3.7**

**Pressure and the Boiling Point of Water.** As an illustration of the normal quantile plot, we deleted the troublesome observation (number 12) from the data set of Example 11.3.6 and fit the model in which the logarithm of pressure is regressed on the boiling point. The resulting normal quantile plot is shown in Fig. 11.11. The points in Fig. 11.11 lie roughly on a line, although it is not difficult to detect some curvature in the plot. It is usually the case that the extreme residuals (lowest and highest) do not line up well with the others, so one normally pays closest attention to the middle of the plot. Extreme observations that fall very far from the pattern of the others suggest a more serious problem. Outliers will typically show up in this way as well as in the other residual plots. ◀

If we know the order in which the observations were taken, there are some additional plots that can help reveal whether there is some dependence between the observations. We will introduce these plots when we discuss multiple regression later in this chapter. Readers desiring a deeper understanding of graphics associated with linear regression should read Cook and Weisberg (1994).

**Figure 11.11** Normal quantile plot for regression of log-pressure on boiling point with observation number 12 removed.

### Inference about Both $\beta_0$ and $\beta_1$ Simultaneously

**Tests of Hypotheses about Both  $\beta_0$  and  $\beta_1$**  Suppose next that  $\beta_0^*$  and  $\beta_1^*$  are given numbers and that we are interested in testing the following hypotheses about the values of  $\beta_0$  and  $\beta_1$ :

$$\begin{aligned} H_0: \quad & \beta_0 = \beta_0^* \quad \text{and} \quad \beta_1 = \beta_1^*, \\ H_1: \quad & \text{The hypothesis } H_0 \text{ is not true.} \end{aligned} \quad (11.3.27)$$

These hypotheses are not a special case of (11.3.13); hence, we shall not be able to test these hypotheses using  $U_{01}$  from Eq. (11.3.14). Instead, we shall derive the likelihood ratio test procedure for the hypotheses (11.3.27).

The likelihood function  $f_n(\mathbf{y}|\mathbf{x}, \beta_0, \beta_1, \sigma^2)$  is given by Eq. (11.2.2). We know from Sec. 11.2 that the likelihood function attains its maximum value when  $\beta_0$ ,  $\beta_1$ , and  $\sigma^2$  are equal to the M.L.E.'s  $\hat{\beta}_0$ ,  $\hat{\beta}_1$ , and  $\hat{\sigma}^2$ , as given by Eq. (11.1.1) and Eq. (11.2.3).

When the null hypothesis  $H_0$  is true, the values of  $\beta_0$  and  $\beta_1$  must be  $\beta_0^*$  and  $\beta_1^*$ , respectively. For these values of  $\beta_0$  and  $\beta_1$ , the maximum value of  $f_n(\mathbf{y}|\mathbf{x}, \beta_0^*, \beta_1^*, \sigma^2)$  over all the possible values of  $\sigma^2$  will be attained when  $\sigma^2$  has the following value  $\hat{\sigma}_0^2$ :

$$\hat{\sigma}_0^2 = \frac{1}{n} \sum_{i=1}^n (y_i - \beta_0^* - \beta_1^* x_i)^2.$$

Now consider the statistic

$$\Lambda(\mathbf{y}|\mathbf{x}) = \frac{\sup_{\sigma^2} f_n(\mathbf{y}|\mathbf{x}, \beta_0^*, \beta_1^*, \sigma^2)}{\sup_{\beta_0, \beta_1, \sigma^2} f_n(\mathbf{y}|\mathbf{x}, \beta_0, \beta_1, \sigma^2)}.$$

By using the results that have just been described, it can be shown that

$$\Lambda(\mathbf{y}|\mathbf{x}) = \left( \frac{\hat{\sigma}^2}{\hat{\sigma}_0^2} \right)^{n/2} = \left[ \frac{\sum_{i=1}^n (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i)^2}{\sum_{i=1}^n (y_i - \beta_0^* - \beta_1^* x_i)^2} \right]^{n/2}. \quad (11.3.28)$$

The denominator of the final expression in Eq. (11.3.28) can be rewritten as follows:

$$\begin{aligned} & \sum_{i=1}^n (y_i - \beta_0^* - \beta_1^* x_i)^2 \\ &= \sum_{i=1}^n [(y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i) + (\hat{\beta}_0 - \beta_0^*) + (\hat{\beta}_1 - \beta_1^*) x_i]^2. \end{aligned} \quad (11.3.29)$$

To simplify this expression further, let the statistic  $S^2$  be defined by Eq. (11.3.9), and let the statistic  $Q^2$  be defined as follows:

$$\begin{aligned} Q^2 &= n(\hat{\beta}_0 - \beta_0^*)^2 + \left( \sum_{i=1}^n x_i^2 \right) (\hat{\beta}_1 - \beta_1^*)^2 \\ &\quad + 2n\bar{x}(\hat{\beta}_0 - \beta_0^*)(\hat{\beta}_1 - \beta_1^*). \end{aligned} \quad (11.3.30)$$

We shall now expand the right side of Eq. (11.3.29) and use the following relations, which were established in Exercise 4 of Sec. 11.1:

$$\sum_{i=1}^n (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i) = 0 \quad \text{and} \quad \sum_{i=1}^n x_i (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i) = 0.$$

We then obtain the relation

$$\sum_{i=1}^n (y_i - \beta_0^* - \beta_1^* x_i)^2 = S^2 + Q^2.$$

It now follows from Eq. (11.3.28) that

$$\Lambda(\mathbf{y}|\mathbf{x}) = \left( \frac{S^2}{S^2 + Q^2} \right)^{n/2} = \left( 1 + \frac{Q^2}{S^2} \right)^{-n/2}. \quad (11.3.31)$$

The likelihood ratio test procedure specifies rejecting  $H_0$  when  $\Lambda(\mathbf{y}|\mathbf{x}) \leq k$ . It can be seen from Eq. (11.3.31) that this procedure is equivalent to rejecting  $H_0$  when  $Q^2/S^2 \geq k'$ , where  $k'$  is a suitable constant. To put this procedure in a more standard form, we shall let the statistic  $U^2$  be defined as follows:

$$U^2 = \frac{\frac{1}{2}Q^2}{\sigma^2}. \quad (11.3.32)$$

Then the likelihood ratio test procedure specifies rejecting  $H_0$  when  $U^2 \geq \gamma$ , where  $\gamma$  is a suitable constant.

We shall now determine the distribution of the statistic  $U^2$  when the hypothesis  $H_0$  is true. It can be shown (see Exercises 7 and 8) that when  $H_0$  is true, the random variable  $Q^2/\sigma^2$  has the  $\chi^2$  distribution with two degrees of freedom. Also, because the random variable  $S^2$  and the random vector  $(\hat{\beta}_0, \hat{\beta}_1)$  are independent, and because  $Q^2$  is a function of  $\hat{\beta}_0$  and  $\hat{\beta}_1$ , it follows that the random variables  $Q^2$  and  $S^2$  are independent. Finally, we know that  $S^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - 2$  degrees of freedom. Therefore, when  $H_0$  is true, the statistic  $U^2$  defined by Eq. (11.3.32) will have the  $F$  distribution with 2 and  $n - 2$  degrees of freedom. Since the null hypothesis  $H_0$  is rejected if  $U^2 \geq \gamma$ , the value of  $\gamma$  corresponding to a specified level of significance  $\alpha_0$  ( $0 < \alpha_0 < 1$ ) will be the  $1 - \alpha_0$  quantile of this  $F$  distribution, namely,  $F_{2, n-2}^{-1}(1 - \alpha_0)$ .

**Joint Confidence Set** Next, consider the problem of constructing a confidence set for the pair of unknown regression coefficients  $\beta_0$  and  $\beta_1$ . Such a confidence set can

be obtained from the statistic  $U^2$  defined by Eq. (11.3.32), which was used to test the hypotheses (11.3.27). Specifically, let  $F_{2,n-2}^{-1}(1 - \alpha_0)$  be the  $1 - \alpha_0$  quantile of the  $F$  distribution with 2 and  $n - 2$  degrees of freedom. Then the set of all pairs of values of  $\beta_0^*$  and  $\beta_1^*$  such that  $U^2 < F_{2,n-2}^{-1}(1 - \alpha_0)$  will form a confidence set for the pair  $(\beta_0, \beta_1)$  with confidence coefficient  $1 - \alpha_0$ . It can be shown (see Exercise 16) that this confidence set will contain all the points  $(\beta_0, \beta_1)$  inside a certain ellipse in the  $\beta_0\beta_1$ -plane. In other words, this confidence set will actually be a confidence ellipse.

The confidence ellipse that has just been derived for  $\beta_0$  and  $\beta_1$  can be used to construct a confidence set for the entire regression line  $y = \beta_0 + \beta_1 x$ . Corresponding to each point  $(\beta_0, \beta_1)$  inside the ellipse, we can draw a straight line  $y = \beta_0 + \beta_1 x$  in the  $xy$ -plane. The collection of all these straight lines corresponding to all points  $(\beta_0, \beta_1)$  inside the ellipse will be a confidence set with confidence coefficient  $1 - \alpha_0$  for the actual regression line. A rather lengthy and detailed analysis, which will not be presented here [see Scheffé (1959, section 3.5)], shows that the upper and lower limits of this confidence set are the curves defined by the following relations:

$$y = \hat{\beta}_0 + \hat{\beta}_1 x \pm [2F_{2,n-2}^{-1}(1 - \alpha_0)]^{1/2} \sigma' \left[ \frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2} \right]^{1/2}. \quad (11.3.33)$$

In other words, with confidence coefficient  $1 - \alpha_0$ , the actual regression line  $y = \beta_0 + \beta_1 x$  will lie between the curve obtained by using the plus sign in (11.3.33) and the curve obtained by using the minus sign in (11.3.33). The region between these curves is often called a *confidence band* or *confidence belt* for the regression line.

In similar fashion, the confidence ellipse can be used to construct simultaneous confidence intervals for every linear combination of  $\beta_0$  and  $\beta_1$ . The coefficient  $1 - \alpha_0$  interval for  $c_0\beta_0 + c_1\beta_1$  has the endpoints

$$c_0\hat{\beta}_0 + c_1\hat{\beta}_1 \pm \sigma' \left[ \frac{c_0^2}{n} + \frac{(c_0\bar{x} - c_1)^2}{s_x^2} \right]^{1/2} [2F_{2,n-2}^{-1}(1 - \alpha_0)]^{1/2}. \quad (11.3.34)$$

This differs from the individual confidence interval given in Eq. (11.3.23) solely in the replacement of the  $1 - \alpha_0/2$  quantile of the  $t_{n-2}$  distribution by the square root of 2 times the  $1 - \alpha_0$  quantile of the  $F_{2,n-2}$  distribution. The simultaneous intervals are wider than the individual intervals because they satisfy a more restrictive requirement. The probability (prior to observing the data) is  $1 - \alpha_0$  that all of the intervals of the form (11.3.34) simultaneously contain their corresponding parameters. Each interval of the form (11.3.23) contains its corresponding parameter with probability  $1 - \alpha_0$ , but the probability that two or more of them simultaneously contain their corresponding parameters is less than  $1 - \alpha_0$ .

**Alternative Tests and Confidence Sets** The hypotheses (11.3.27) are a special case of (9.1.26), and they can be tested by the same method outlined immediately after (9.1.26). The resulting test leads to an alternative confidence set for the pair  $(\beta_0, \beta_1)$ . The alternative level  $\alpha_0$  test of (11.3.27) merely combines the two level  $\alpha_0/2$  tests of (11.3.20) and (11.3.21). To be specific, the alternative level  $\alpha_0$  test  $\delta$  of (11.3.27) is to reject  $H_0$  if either

$$|U_0| \geq T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{4} \right) \text{ or } |U_1| \geq T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{4} \right) \text{ or both,} \quad (11.3.35)$$

where  $U_0$  and  $U_1$  are, respectively, the statistics in (11.3.19) and (11.3.22) that would be used for testing (11.3.20) and (11.3.21).

**Figure 11.12** Elliptical and rectangular joint coefficient 0.95 confidence sets for  $(\beta_0, \beta_1)$  in Example 11.3.8.

The corresponding joint confidence set for  $(\beta_0, \beta_1)$  is the set of all  $(\beta_0^*, \beta_1^*)$  pairs such that both  $|U_0|$  and  $|U_1|$  are strictly less than  $T_{n-2}^{-1}(1 - \alpha_0/4)$ . This alternative confidence set will be rectangular in shape rather than elliptical. This confidence rectangle also provides simultaneous confidence intervals for all linear combinations of the form  $c_0\beta_0 + c_1\beta_1$ . The formulas for the endpoints are not so pretty as (11.3.34). Let  $C$  be the joint confidence rectangle. Then the confidence interval for  $c_0\beta_0 + c_1\beta_1$  is the following:

$$\left( \inf_{(\beta_0^*, \beta_1^*) \in C} c_0\beta_0^* + c_1\beta_1^*, \sup_{(\beta_0^*, \beta_1^*) \in C} c_0\beta_0^* + c_1\beta_1^* \right). \quad (11.3.36)$$

The sup and inf will each occur at one of the four corners of the rectangle, so one need only compute four values of  $c_0\beta_0^* + c_1\beta_1^*$  to determine the interval. Some special cases are worked out in Exercise 24.

**Example  
11.3.8**

**Pressure and the Boiling Point of Water.** In Examples 11.2.1 and 11.2.2, we computed the least-squares estimates and the variances and covariance of the estimates. Figure 11.12 shows both the elliptical and the rectangular coefficient 0.95 joint confidence sets for the pair  $(\beta_0, \beta_1)$ . If all that we wanted were confidence intervals for the two parameters, we could extract those from both confidence sets. For the elliptical region, (11.3.34) gives the intervals  $(-1.0149, -0.8886)$  and  $(0.020207, 0.020830)$  for  $\beta_0$  and  $\beta_1$ , respectively. Notice that the endpoints of these intervals are, respectively, the minimum and maximum values of  $\beta_0$  and  $\beta_1$  in the elliptical joint confidence set in Fig. 11.12. Similarly, the joint confidence intervals from the rectangular joint confidence set are, respectively,  $(-1.0097, -0.8938)$  and  $(0.020233, 0.020804)$ , whose endpoints are also the minimum and maximum values of  $\beta_0$  and  $\beta_1$  in the rectangular joint confidence set in Fig. 11.12.

Finally, suppose that, in addition to confidence intervals for the two parameters  $\beta_0$  and  $\beta_1$ , we also want a confidence band for the regression function, namely, the mean log-pressure at all temperatures  $x$ . This mean is of the form  $c_0\beta_0 + c_1\beta_1$  with  $c_0 = 1$  and  $c_1 = x$ . The confidence bands are plotted in Fig. 11.13 based both on the elliptical and rectangular joint confidence sets. For example, at  $x = 201.5$ , we get the intervals  $(3.1809, 3.1846)$  and  $(3.0672, 3.2983)$  from the elliptical and rectangular sets, respectively.

**Figure 11.13** Coefficient 0.95 confidence bands for the regression function in Example 11.3.8. Bands are computed based both on the elliptical and on the rectangular joint confidence sets.

The joint confidence intervals for the two individual parameters are slightly shorter when computed from the rectangular confidence set compared to the elliptical set. But the confidence band for the regression function (Fig. 11.13) is much wider when computed from the rectangular set compared to the elliptical set. ◀

In Example 11.3.8, if one were interested solely in simultaneous confidence intervals for the three parameters  $\beta_0$ ,  $\beta_1$ , and  $\beta_0 + 201.5\beta_1$ , instead of the entire regression function, one could obtain shorter intervals from a generalization of the rectangular joint confidence set. The generalization is based on the Bonferroni inequality from Theorem 1.5.8.

**Theorem  
11.3.7**

Suppose that we are interested in forming simultaneous confidence intervals for several parameters  $\theta_1, \dots, \theta_n$ . For each  $i$ , let  $(A_i, B_i)$  be a coefficient  $1 - \alpha_i$  confidence interval for  $\theta_i$ . Then the probability that all  $n$  confidence intervals simultaneously cover their corresponding parameters is at least  $1 - \sum_{i=1}^n \alpha_i$ .

**Proof** For each  $i = 1, \dots, n$ , define the event  $E_i = \{A_i < \theta_i < B_i\}$ . Because  $(A_i, B_i)$  is a coefficient  $1 - \alpha_i$  confidence interval for  $\theta_i$ , we have  $\Pr(E_i^c) \leq \alpha_i$  for every  $i$ , and the probability that all  $n$  intervals simultaneously cover their corresponding parameters is  $\Pr(\bigcap_{i=1}^n E_i)$ . By the Bonferroni inequality, this last probability is at least  $1 - \sum_{i=1}^n \alpha_i$ . ■

Theorem 9.1.5 gives the corresponding result for a test of the joint hypotheses

$$H_0: \theta_i = \theta_i^* \text{ for all } i, \quad H_1: \text{not } H_0, \quad (11.3.37)$$

If we want simultaneous coefficient  $1 - \alpha_0$  confidence intervals for three parameters, let  $\alpha_i = \alpha_0/3$ .

**Example  
11.3.9**

**Pressure and the Boiling Point of Water.** Suppose that we are interested solely in simultaneous coefficient 0.95 confidence intervals for the three parameters  $\beta_0$ ,  $\beta_1$ , and  $\beta_0 + 201.5\beta_1$  in Example 11.3.8. Then we can use coefficient  $1 - 0.05/3 = 0.9833$  confidence intervals for each parameter. The necessary quantile of the  $t$  distribution is  $T_{14}^{-1}(0.9917) = 2.7178$ . The three intervals for  $\beta_0$ ,  $\beta_1$ , and  $\beta_0 + 201.5\beta_1$  are

$(-1.0146, -0.8889)$ ,  $(0.020296, 0.020828)$ , and  $(3.1809, 3.1845)$ , respectively. Notice that these are all shorter than the corresponding intervals based on the elliptical joint confidence set. The first two of these intervals are longer than the corresponding intervals from the rectangular joint confidence set in Example 11.3.8, but the third interval is much shorter than the corresponding interval based on that same rectangular set.  $\blacktriangleleft$

Finally, there is a way to construct a narrower confidence band for the entire regression function based on the Bonferroni inequality, but we leave the details to Exercise 25.

So, which confidence intervals should one use? Also, which test of (11.3.27) should one use? None of the tests that we have constructed are uniformly most powerful. Some are more powerful at some alternatives, while others are more powerful at other alternatives. The test corresponding to the rectangular joint confidence set is more powerful than the elliptical test if either  $\beta_0$  or  $\beta_1$  is a little larger or smaller than its hypothesized value while the other parameter is close to its hypothesized value. The elliptical test is more powerful than the rectangular test if both  $\beta_0$  and  $\beta_1$  are a little different from their hypothesized values, even if neither is far enough away to cause the rectangular test to reject. Without any specification of which alternatives are most important to detect, one might choose the elliptical test. On the other hand, if one's sole need is for a few confidence intervals and not a confidence band for the entire regression function, the intervals based on the Bonferroni inequality will generally be shorter. The different tests and confidence intervals differ solely by which quantiles are used in their construction. The larger the quantile, the longer the confidence interval. Table 11.8 gives the quantiles needed for the intervals based on the elliptical joint confidence set (which do *not* depend on how many intervals one constructs) and the quantiles needed for various numbers of intervals based on the Bonferroni inequality. One can see that the Bonferroni intervals will generally be shorter if one wants only three or fewer.

## Summary

For constants  $c_0$  and  $c_1$  that are not both 0, we saw that

$$\left[ \frac{c_0^2}{n} + \frac{(c_0\bar{x} - c_1)^2}{s_x^2} \right]^{-1/2} \frac{c_0\hat{\beta}_0 + c_1\hat{\beta}_1 - (c_0\beta_0 + c_1\beta_1)}{\sigma'} \quad (11.3.38)$$

has the  $t$  distribution with  $n - 2$  degrees of freedom under the assumptions of simple linear regression. We can use the random variable in (11.3.38) to test hypotheses about or to construct confidence intervals for  $\beta_0$ ,  $\beta_1$ , and linear combinations of the two. We also learned how to form a prediction interval for a future observation  $Y$  when the corresponding value for  $X$  is known.

Tests about both  $\beta_0$  and  $\beta_1$  simultaneously are based on the statistic  $U^2$  in Eq. (11.3.32), which has the  $F$  distribution with 2 and  $n - 2$  degrees of freedom when the null hypothesis  $H_0$  in Eq. (11.3.27) is true. A confidence band for the entire regression line  $y = \beta_0 + \beta_1x$  (a collection of confidence intervals, one for each  $x$ , such that all of the intervals simultaneously cover the true values of  $\beta_0 + \beta_1x$  with probability  $1 - \alpha_0$ ) is given by Eq. (11.3.33). The intervals in the confidence band are slightly wider than the individual confidence intervals with each separate  $x$ .

**Table 11.8** Comparison of the quantiles needed to compute  $k$  simultaneous joint confidence intervals based on the Bonferroni inequality and based on the elliptical joint confidence set

$\alpha_0$	$n$	$T_{n-2}^{-1}(1 - \alpha_0/[2k])$				
		$k = 1$	$k = 2$	$k = 3$	$k = 4$	$[2F_{2,n-2}^{-1}(1 - \alpha_0)]^{1/2}$
0.05	5	3.18	4.18	4.86	5.39	4.37
	10	2.31	2.75	3.02	3.21	2.99
	15	2.16	2.53	2.75	2.90	2.76
	20	2.10	2.45	2.64	2.77	2.67
	60	2.00	2.30	2.47	2.58	2.51
	120	1.98	2.27	2.43	2.54	2.48
	$\infty$	1.96	2.24	2.40	2.50	2.45
0.01	5	5.84	7.45	8.58	9.46	7.85
	10	3.36	3.83	4.12	4.33	4.16
	15	3.01	3.37	3.58	3.73	3.66
	20	2.88	3.20	3.38	3.51	3.47
	60	2.66	2.92	3.06	3.16	3.16
	120	2.62	2.86	3.00	3.09	3.10
	$\infty$	2.58	2.81	2.94	3.03	3.04

It is good practice to plot residuals from a regression against the predictor  $X$ . Such plots can reveal evidence of departures from the assumptions that underly the distribution theory developed in this section. In particular, one should look for patterns and unusual points in the plot of residuals. Plots of residuals against  $X$  help reveal departures from the assumed form of the mean of  $Y$ . Plots of sorted residuals against normal quantiles help reveal departures from the assumption that the distribution of each  $Y_i$  is normal.

## Exercises

1. Suppose that in a problem of simple linear regression, the 10 pairs of observed values of  $x_i$  and  $y_i$  given in Table 11.9 are obtained. Test the following hypotheses at the level of significance 0.05:

$$H_0: \beta_0 = 0.7,$$

$$H_1: \beta_0 \neq 0.7.$$

2. For the data presented in Table 11.9, test at the level of significance 0.05 the hypothesis that the regression line passes through the origin in the  $xy$ -plane.

3. For the data presented in Table 11.9, test at the level of significance 0.05 the hypothesis that the slope of the regression line is 1.

**Table 11.9** Data for Exercise 1

$i$	$x_i$	$y_i$	$i$	$x_i$	$y_i$
1	0.3	0.4	6	1.0	0.8
2	1.4	0.9	7	2.0	0.7
3	1.0	0.4	8	-1.0	-0.4
4	-0.3	-0.3	9	-0.7	-0.2
5	-0.2	0.3	10	0.7	0.7

4. For the data presented in Table 11.9, test at the level of significance 0.05 the hypothesis that the regression line is horizontal.

5. For the data presented in Table 11.9, test the following hypotheses at the level of significance 0.10:

$$\begin{aligned} H_0: \beta_1 &= 5\beta_0, \\ H_1: \beta_1 &\neq 5\beta_0. \end{aligned}$$

6. For the data presented in Table 11.9, test the hypothesis that when  $x = 1$ , the height of the regression line is  $y = 1$  at the level of significance 0.01.

7. In a problem of simple linear regression, let  $D = \hat{\beta}_0 + \hat{\beta}_1 \bar{x}$ . Show that the random variables  $\hat{\beta}_1$  and  $D$  are uncorrelated, and explain why  $\hat{\beta}_1$  and  $D$  must therefore be independent.

8. Let the random variable  $D$  be defined as in Exercise 7, and let the random variable  $Q^2$  be defined by Eq. (11.3.30).

a. Show that

$$\frac{Q^2}{\sigma^2} = \frac{(\hat{\beta}_1 - \beta_1^*)^2}{\text{Var}(\hat{\beta}_1)} + \frac{(D - \beta_0^* - \beta_1^* \bar{x})^2}{\text{Var}(D)}.$$

b. Explain why the random variable  $Q^2/\sigma^2$  will have the  $\chi^2$  distribution with two degrees of freedom when the hypothesis  $H_0$  in (11.3.27) is true.

9. For the data presented in Table 11.9, test the following hypotheses at the level of significance 0.05:

$$\begin{aligned} H_0: \beta_0 &= 0 \text{ and } \beta_1 = 1, \\ H_1: \text{At least one of the values } \beta_0 &= 0 \text{ and } \beta_1 = 1 \text{ is incorrect.} \end{aligned}$$

10. For the data presented in Table 11.9, construct a confidence interval for  $\beta_0$  with confidence coefficient 0.95.

11. For the data presented in Table 11.9, construct a confidence interval for  $\beta_1$  with confidence coefficient 0.95.

12. For the data presented in Table 11.9, construct a confidence interval for  $5\beta_0 - \beta_1 + 4$  with confidence coefficient 0.90.

13. For the data presented in Table 11.9, construct a confidence interval with confidence coefficient 0.99 for the height of the regression line at the point  $x = 1$ .

14. For the data presented in Table 11.9, construct a confidence interval with confidence coefficient 0.99 for the height of the regression line at the point  $x = 0.42$ .

15. Suppose that in a problem of simple linear regression, a confidence interval with confidence coefficient  $1 - \alpha_0$  ( $0 < \alpha_0 < 1$ ) is constructed for the height of the regression line at a given value of  $x$ . Show that the length of this confidence interval is shortest when  $x = \bar{x}$ .

16. Let the statistic  $U^2$  be as defined by Eq. (11.3.32), and let  $\gamma$  be fixed positive constant. Show that for all observed values  $(x_i, y_i)$ , for  $i = 1, \dots, n$ , the set of points  $(\beta_0^*, \beta_1^*)$  such that  $U^2 < \gamma$  is the interior of an ellipse in the  $\beta_0^* \beta_1^*$ -plane.

17. For the data presented in Table 11.9, construct a confidence ellipse for  $\beta_0$  and  $\beta_1$  with confidence coefficient 0.95.

18.

a. For the data presented in Table 11.9, sketch a confidence band in the  $xy$ -plane for the regression line with confidence coefficient 0.95.

b. On the same graph, sketch the curves which specify the limits at each point  $x$  of a confidence interval with confidence coefficient 0.95 for the value of the regression line at the point  $x$ .

19. Determine a value of  $c$  such that in a problem of simple linear regression, the statistic  $c \sum_{i=1}^n (Y_i - \hat{\beta}_0 - \hat{\beta}_2 x_i)^2$  will be an unbiased estimator of  $\sigma^2$ .

20. Suppose that a simple linear regression of miles per gallon ( $Y$ ) on car weight ( $X$ ) has been performed with  $n = 32$  observations. Suppose that the least-squares estimates are  $\hat{\beta}_0 = 68.17$  and  $\hat{\beta}_1 = -1.112$ , with  $\sigma' = 4.281$ . Other useful statistics are  $\bar{x} = 30.91$ , and  $\sum_{i=1}^n (x_i - \bar{x})^2 = 2054.8$ .

a. Suppose that we want to predict miles per gallon  $Y$  for a new observation with weight  $X = 24$ . What would be our prediction?

b. For the prediction in part (a), find a 95 percent prediction interval for the unobserved  $Y$  value.

21. Use the data in Table 11.6 on page 707. You should perform the least-squares regression requested in Exercise 18 in Sec. 11.2 before starting this exercise.

a. Plot the residuals from the least-squares regression against the 1970 price. Do you see a pattern?

b. Transform both prices to their natural logarithms and repeat the least-squares regression. Now plot the residuals against logarithm of 1970 price. Does this plot look any better than the one in part (a)?

22. Perform a least-squares regression of the logarithm of the 1980 fish price on the logarithm of the 1970 fish price, using the raw data in Table 11.6 on page 707.

a. Test the null hypothesis that the slope  $\beta_1$  is less than 2.0 at level  $\alpha_0 = 0.01$ .

b. Find a 90 percent confidence interval for the slope  $\beta_1$ .

c. Find a 90 percent prediction interval for the 1980 price of a species that cost 21.4 in 1970. (Note that 21.4 is the 1970 price, *not* the logarithm of the 1970 price.)

**23.** Prove that the first test in Theorem 11.3.4 does indeed have level  $\alpha_0$ . Hint: Use an argument similar to that used to prove part (ii) of Theorem 9.5.1.

**24.** Find explicit formulas (no sup or inf) for the endpoints of the interval in Eq. (11.3.36) for the following special cases:

- a.  $c_0 = 1$  and  $c_1 = x > 0$ .
- b.  $c_0 = 1$  and  $c_1 = x < 0$ .

Hint: In both cases the endpoints are of the form  $\hat{\beta}_0 + \hat{\beta}_1 x$  plus or minus linear functions of  $x$  that depend on the lengths of the sides of the rectangular joint confidence set.

**25.** In this problem, we will construct a narrower confidence band for a regression function using Theorem 11.3.7. Let  $\hat{\beta}_0$  and  $\hat{\beta}_1$  be the least-squares estimators, and let  $\sigma'$  be the estimator of  $\sigma$  used in this section. Let  $x_0 < x_1$  be two possible values of the predictor  $X$ .

- a. Find formulas for the simultaneous coefficient  $1 - \alpha_0$  confidence intervals for  $\beta_0 + \beta_1 x_0$  and  $\beta_0 + \beta_1 x_1$ .
- b. For each real number  $x$ , find the formula for the unique  $\alpha$  such that  $x = \alpha x_0 + (1 - \alpha)x_1$ . Call that value  $\alpha(x)$ .
- c. Call the intervals found in part (a)  $(A_0, B_0)$  and  $(A_1, B_1)$ , respectively. Define the event

$$C = \{A_0 < \beta_0 + \beta_1 x_0 < B_0 \text{ and } A_1 < \beta_0 + \beta_1 x_1 < B_1\}.$$

For each real  $x$ , define  $L(x)$  and  $U(x)$  to be, respectively, the smallest and largest of the following four numbers:

$$\begin{aligned} &\alpha(x)A_0 + [1 - \alpha(x)]A_1, \alpha(x)B_0 + [1 - \alpha(x)]A_1, \\ &\alpha(x)A_0 + [1 - \alpha(x)]B_1, \alpha(x)B_0 + [1 - \alpha(x)]B_1. \end{aligned}$$

If the event  $C$  occurs, prove that, for every real  $x$ ,  $L(x) < \beta_0 + \beta_1 x < U(x)$ .

## ★ 11.4 Bayesian Inference in Simple Linear Regression

In Sec. 8.6, we introduced an improper prior distribution for the mean  $\mu$  and precision  $\tau$  of a normal distribution. This prior simplified several calculations associated with the posterior distribution of the parameters. The prior also made some of the resulting inferences bear striking resemblance to inferences based on the sampling distributions of statistics. Something very similar occurs in the simple linear regression setting.

### Improper Priors for Regression Parameters

**Example**  
**11.4.1**

**Gasoline Mileage.** Once again, consider Example 11.3.2 on page 714. Suppose that we are interested in saying something about how far we think  $\beta_1$  is from 0 and how strongly we believe that. For example, suppose that we would like to be able to say how likely it is that  $|\beta_1|$  is at most  $c$  for arbitrary values of  $c$ . To do this requires us to compute a distribution for  $\beta_1$ . The posterior distribution of  $\beta_1$  given the observed data would serve this purpose. ◀

We shall continue to assume that we will observe pairs of variables  $(X_i, Y_i)$  for  $i = 1, \dots, n$ . We shall also assume that the conditional distribution of  $Y_1, \dots, Y_n$ , given  $X_1 = x_1, \dots, X_n = x_n$  and parameters  $\beta_0, \beta_1$ , and  $\sigma^2$ , is that the  $Y_i$  are independent with  $Y_i$  having the normal distribution with mean  $\beta_0 + \beta_1 x_i$  and variance  $\sigma^2$ . Let  $\tau = 1/\sigma^2$  be the precision, as we did in Sec. 8.6. If we let the parameters have an improper prior with “p.d.f.”  $\xi(\beta_0, \beta_1, \tau) = 1/\tau$ , then it is not difficult to find the posterior distribution of the parameters.

**Theorem**  
**11.4.1**

Suppose that  $Y_1, \dots, Y_n$  are independent given  $x_1, \dots, x_n$  and  $\beta_0, \beta_1$ , and  $\tau$ , with  $Y_i$  having the normal distribution with mean  $\beta_0 + \beta_1 x_i$  and precision  $\tau$ . Let the prior distribution be improper with “p.d.f.”  $\xi(\beta_0, \beta_1, \tau) = 1/\tau$ . Then the posterior distribution of  $\beta_0, \beta_1$ , and  $\tau$  is as follows. Conditional on  $\tau$ , the joint distribution of  $\beta_0$  and  $\beta_1$  is the bivariate normal distribution with correlation  $-n\bar{x}/(n \sum_{i=1}^n x_i^2)^{1/2}$

**Table 11.10** Posterior means and variances for simple linear regression with improper prior

Parameter	Mean	Variance
$\beta_0$	$\hat{\beta}_0$	$(\frac{1}{n} + \bar{x}^2/s_x^2)/\tau$
$\beta_1$	$\hat{\beta}_1$	$(s_x^2\tau)^{-1}$

**Table 11.11** Relation between Eq. (5.10.2) and Theorem 11.4.1

(5.10.2)	Theorem 11.4.1
$\rho$	$-n\bar{x}/(n \sum_{i=1}^n x_i^2)^{1/2}$
$\sigma_1^2$	$(\frac{1}{n} + \bar{x}^2/s_x^2)/\tau$
$\sigma_2^2$	$(s_x^2\tau)^{-1}$
$x_1$	$\beta_0$
$\mu_1$	$\hat{\beta}_0$
$x_2$	$\beta_1$
$\mu_2$	$\hat{\beta}_1$

and means and variances as given in Table 11.10. The posterior distribution of  $\tau$  is the gamma distribution with parameters  $(n - 2)/2$  and  $S^2/2$ , where  $S^2$  is defined in Eq. (11.3.9). The marginal posterior distribution of

$$\left[ \frac{c_0^2}{n} + \frac{(c_0\bar{x} - c_1)^2}{s_x^2} \right]^{-1/2} \frac{c_0\beta_0 + c_1\beta_1 - [c_0\hat{\beta}_0 + c_1\hat{\beta}_1]}{\sigma'} \quad (11.4.1)$$

is the  $t$  distribution with  $n - 2$  degrees of freedom if  $c_0$  and  $c_1$  are not both 0.

**Proof** The posterior p.d.f. is proportional to the product of the prior p.d.f. and the likelihood function. The likelihood is the conditional p.d.f. of the data  $\mathbf{Y} = (Y_1, \dots, Y_n)$  given the parameters (and  $\mathbf{x} = (x_1, \dots, x_n)$ ), namely,

$$f_n(\mathbf{y}|\beta_0, \beta_1, \tau, \mathbf{x}) = (\tau/[2\pi])^{n/2} \exp\left(-\frac{\tau}{2} \sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_i)^2\right). \quad (11.4.2)$$

To show that the posterior distribution is as stated in the theorem, it suffices to prove that  $1/\tau$  times (11.4.2) is proportional (as a function of  $\beta_0$ ,  $\beta_1$ , and  $\tau$ ) to the proposed posterior p.d.f.

The proposed posterior p.d.f. of  $\tau$  is proportional (as a function of  $\tau$ ) to

$$\tau^{(n-2)/2-1} e^{-S^2\tau/2}. \quad (11.4.3)$$

The proposed conditional posterior p.d.f. of  $(\beta_0, \beta_1)$  given  $\tau$  is the bivariate normal p.d.f. in Eq. (5.10.2) on page 338 with the substitutions in Table 11.11.

The key to simplifying the substitutions in Eq. (5.10.2) is to note that

$$1 - \rho^2 = \frac{s_x^2}{\sum_{i=1}^n x_i^2}, \quad \sigma_1^2 = \frac{\sum_{i=1}^n x_i^2}{ns_x^2 \tau}, \quad \text{and} \quad \frac{\rho}{\sigma_1 \sigma_2} = -\frac{\tau n \bar{x} s_x^2}{\sum_{i=1}^n x_i^2}.$$

The substitutions in Table 11.11 show that the proposed conditional posterior for  $(\beta_0, \beta_1)$  given  $\tau$  is proportional to

$$\tau \exp\left(-\frac{\tau}{2} \left[ n(\beta_0 - \hat{\beta}_0)^2 + 2n\bar{x}(\beta_0 - \hat{\beta}_0)(\beta_1 - \hat{\beta}_1) + \left(\sum_{i=1}^n x_i^2\right)(\beta_1 - \hat{\beta}_1)^2 \right]\right). \quad (11.4.4)$$

The product of (11.4.3) and (11.4.4) is the proposed joint posterior p.d.f., and it is proportional to

$$\begin{aligned} & \tau^{n/2-1} \exp\left(-\frac{\tau}{2} \left[ S^2 + n(\beta_0 - \hat{\beta}_0)^2 + 2n\bar{x}(\beta_0 - \hat{\beta}_0)(\beta_1 - \hat{\beta}_1) \right.\right. \\ & \quad \left.\left. + \left(\sum_{i=1}^n x_i^2\right)(\beta_1 - \hat{\beta}_1)^2 \right]\right). \end{aligned} \quad (11.4.5)$$

We shall now show that  $1/\tau$  times the right side of Eq. (11.4.2) is proportional to (11.4.5). The summation in the exponent of Eq. (11.4.2) is exactly the same as the summation in Eq. (11.3.29) if we remove the asterisks from (11.3.29). In Sec. 11.3, we rewrote (11.3.29) as

$$S^2 + n(\beta_0 - \hat{\beta}_0)^2 + \left(\sum_{i=1}^n x_i^2\right)(\beta_1 - \hat{\beta}_1)^2 + 2n\bar{x}(\beta_0 - \hat{\beta}_0)(\beta_1 - \hat{\beta}_1), \quad (11.4.6)$$

where the asterisks have been removed from (11.4.6). Notice that (11.4.6) is the same as the factor in the exponent of (11.4.5) that is multiplied by  $-\tau/2$ . Also, notice that  $1/\tau$  times the factor multiplying the exponential in (11.4.2) equals  $\tau^{n/2-1}$ . It follows that  $1/\tau$  times (11.4.2) is proportional to (11.4.5).

Finally, we prove that the random variable in (11.4.1) has the  $t$  distribution with  $n - 2$  degrees of freedom. Since  $(\beta_0, \beta_1)$  has a bivariate normal distribution conditional on  $\tau$ , it follows that  $c_0\beta_0 + c_1\beta_1$  has a normal distribution conditional on  $\tau$ . Its mean is  $c_0\hat{\beta}_0 + c_1\hat{\beta}_1$ . Its variance (given  $\tau$ ) is obtained from Eq. (5.10.9) and Table 11.10 (after some tedious algebra) as  $v/\tau$  where

$$v = \frac{c_0^2}{n} + c_0^2 \frac{\bar{x}^2}{s_x^2} + c_1^2 \frac{1}{s_x^2} - 2c_0c_1 \frac{\bar{x}}{s_x^2} = \frac{c_0^2}{n} + \frac{(c_0\bar{x} - c_1)^2}{s_x^2}.$$

Define the random variable

$$Z = \left(\frac{\tau}{v}\right)^{1/2} (c_0\beta_0 + c_1\beta_1 - [c_0\hat{\beta}_0 + c_1\hat{\beta}_1]),$$

and notice that  $Z$  has the standard normal distribution given  $\tau$  and hence is independent of  $\tau$ . The distribution of  $W = S^2\tau$  is the gamma distribution with parameters  $(n - 2)/2$  and  $1/2$ , which is also the  $\chi^2$  distribution with  $n - 2$  degrees of freedom. It follows from the definition of the  $t$  distribution that  $Z/(W/[n - 2])^{1/2}$  has the  $t$  distribution with  $n - 2$  degrees of freedom. Since  $\sigma'^2 = S^2/(n - 2)$ , it is straightforward to verify that  $Z/(W/[n - 2])^{1/2}$  is the same as the random variable in (11.4.1). ■

**Example  
11.4.2**

**Pressure and the Boiling Point of Water.** At the end of Example 11.3.6, we estimated the coefficients of the regression of log-pressure on the boiling point using only 16 of the 17 observations in Forbes' original data. We obtained  $\hat{\beta}_0 = -0.9518$  and  $\hat{\beta}_1 = 0.0205$  with  $\sigma' = 2.616 \times 10^{-3}$ . With one observation removed, we have  $n = 16$ ,  $\bar{x} = 202.85$ , and  $s_x^2 = 527.9$ . We can now apply Theorem 11.4.1 to make an inference based on the posterior distributions of the parameters. For example, suppose that we are interested in an interval estimate of  $\beta_1$ . Letting  $c_0 = 0$  and  $c_1 = 1$  in (11.4.1), we find that the posterior distribution of

$$\frac{s_x}{\sigma'}(\beta_1 - \hat{\beta}_1) = 449.2(\beta_1 - 0.0205) \quad (11.4.7)$$

is the  $t$  distribution with 14 degrees of freedom. If we want our interval to contain a portion of the posterior distribution with probability  $1 - \alpha_0$ , then we can note that the posterior probability is  $1 - \alpha_0$  that  $|449.2(\beta_1 - 0.0205)| \leq T_{14}^{-1}(1 - \alpha_0/2)$ . For example, if  $\alpha_0 = 0.1$ , then  $T_{14}^{-1}(1 - 0.1/2) = 1.761$ . The interval estimate is then  $0.0205 \pm 1.761/449.2 = (0.0166, 0.0244)$ .  $\blacktriangleleft$

The reader should note that the random variable in Eq. (11.4.7) is the same as  $U_1$  in Eq. (11.3.22) when  $\beta_1 = \beta_1^*$ . This implies that a coefficient  $1 - \alpha_0$  confidence interval for  $\beta_1$  will be the same as an interval containing posterior probability  $1 - \alpha_0$  when we use the improper prior in Theorem 11.4.1. Indeed, the random variable in (11.4.1) is the same as  $U_{01}$  in Eq. (11.3.14) for all  $c_0$  and  $c_1$  so long as  $c_0\beta_0 + c_1\beta_1 = c_*$ . This implies that coefficient  $1 - \alpha_0$  confidence intervals for all linear combinations of the regression parameters will also contain probability  $1 - \alpha_0$  of the posterior distribution when the improper prior in Theorem 11.4.1 is used. The reader can prove these claims in Exercises 1 and 2 in this section.

**Note: There is a Conjugate Family of Proper Prior Distributions.** The posterior distribution of the parameters given in Theorem 11.4.1 has the following form:  $\tau$  has a gamma distribution, and, conditional on  $\tau$ ,  $(\beta_0, \beta_1)$  has a bivariate normal distribution with variances and covariances that are multiples of  $1/\tau$ . The collection of distributions of the form just described is a conjugate family of prior distributions for the parameters of simple linear regression. Readers interested in the details of using such priors can consult a text like Broemeling (1985).

## Prediction Intervals

On page 716, we showed how to form intervals for predicting future observations. In the Bayesian framework, we can also form intervals for predicting future observations. Let  $Y$  be a future observation with corresponding predictor  $x$ . Then  $Z_1 = \tau^{1/2}(Y - \beta_0 - \beta_1x)$  has the standard normal distribution conditional on the parameters and the data; hence, it is independent of the parameters and the data. Let  $\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1x$  as we did on page 716. It can be shown that the conditional distribution of  $Z_2 = \tau^{1/2}(\beta_0 + \beta_1x - \hat{Y})$  given  $\tau$ , and the data is the normal distribution with mean 0 and variance

$$\frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2},$$

and hence it is independent of  $\tau$  and the data. (See Exercise 3.) Since  $Z_1$  is independent of all of the parameters, it is independent of  $Z_2$ , also. It follows that the conditional distribution of  $Z_1 + Z_2 = \tau^{1/2}(Y - \hat{Y})$ , given  $\tau$  and the data, is the normal

distribution with mean 0 and variance

$$1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2}.$$

As in the proof of Theorem 11.4.1,  $S^2\tau$  has the  $\chi^2$  distribution with  $n - 2$  degrees of freedom and is independent of  $Z_1 + Z_2$ . It follows from the definition of the  $t$  distribution that the random variable

$$U_x = \frac{Y - \hat{Y}}{\sigma' \left[ 1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2} \right]^{1/2}}$$

has the  $t$  distribution with  $n - 2$  degrees of freedom given the data. Hence, the conditional probability, given the data, is  $1 - \alpha_0$  that  $Y$  is in the interval with endpoints

$$\hat{Y} \pm T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{2} \right) \sigma' \left[ 1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2} \right]^{1/2}. \quad (11.4.8)$$

Notice that the  $U_x$  defined above is identical to the  $U_x$  defined in Eq. (11.3.26). Also, the interval (11.4.8) is the same as the one given in Eq. (11.3.25). The interpretation of the prediction interval based on the posterior distribution is somewhat simpler than the interpretation given after (11.3.25) because the probability is conditional on all of the known quantities (that is, the data). The probability only concerns the distribution of the unknown quantity  $Y$  conditional on the data.

**Example  
11.4.3**

**Pressure and the Boiling Point of Water.** Suppose that we are interested in predicting pressure when the boiling point of water is 208 degrees. We shall find an interval such that the posterior probability is 0.9 that the pressure will be in the interval. That is, we shall use Eq. (11.4.8) with  $\alpha_0 = 0.1$  and  $x = 208$ . We can find  $T_{14}(0.95) = 1.761$  from the table of the  $t$  distribution in this book. The rest of the necessary values are given in Example 11.4.2. In particular, with  $Y$  standing for log-pressure,  $\hat{Y} = -0.9518 + 0.0205 \times 208 = 3.3122$ , and

$$\begin{aligned} \sigma' \left[ 1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2} \right]^{1/2} &= 2.616 \times 10^{-3} \left[ 1 + \frac{1}{16} + \frac{(208 - 202.85)^2}{527.9} \right]^{1/2} \\ &= 2.759 \times 10^{-3}. \end{aligned}$$

So our interval for log-pressure has endpoints  $3.3122 \pm 1.761 \times 2.759 \times 10^{-3}$ , which are 3.307 and 3.317. The interval for pressure itself is then

$$(e^{3.307}, e^{3.317}) = (27.31, 27.58).$$

The reason that we can convert the interval for log-pressure into the interval for pressure so simply is that  $3.307 < Y < 3.317$  if and only if  $27.31 < e^Y < 27.58$ . So, the posterior probability of the first set of inequalities is the same as the posterior probability of the second set of inequalities.  $\blacktriangleleft$

### Tests of Hypotheses

On page 607, we began a discussion of tests based on the posterior distribution. If the cost of type I error is  $w_0$  and the cost of type II error is  $w_1$ , we found that the Bayes test was to reject the null hypothesis if the posterior probability of the null hypothesis is less than  $w_1/(w_0 + w_1)$ . Suppose that we use the improper prior and

that the null hypothesis is  $H_0 : c_0\beta_0 + c_1\beta_1 = c_*$ . Since the posterior distribution of  $c_0\beta_0 + c_1\beta_1$  is a continuous distribution, it is clear that the posterior probability of the null hypothesis is 0. For this reason, we shall begin by considering Bayes tests only for one-sided hypotheses. Suppose that the hypotheses of interest are

$$\begin{aligned} H_0 &: c_0\beta_0 + c_1\beta_1 \leq c_*, \\ H_1 &: c_0\beta_0 + c_1\beta_1 > c_*. \end{aligned} \quad (11.4.9)$$

The other direction can be handled in a similar fashion. Let  $\alpha_0 = w_1/(w_0 + w_1)$ . The posterior probability that the null hypothesis is true is the posterior probability that  $c_0\beta_0 + c_1\beta_1 \leq c_*$ . We have already derived the posterior distribution of  $c_0\beta_0 + c_1\beta_1$  in Theorem 11.4.1. So, we can compute

$$\begin{aligned} &\Pr(c_0\beta_0 + c_1\beta_1 \leq c_*) \\ &= \Pr\left(\left[\frac{c_0^2}{n} + \frac{(c_0\bar{x} - c_1)^2}{s_x^2}\right]^{-1/2} \frac{c_0\beta_0 + c_1\beta_1 - [c_0\hat{\beta}_0 + c_1\hat{\beta}_1]}{\sigma'}\right. \\ &\quad \left.\leq \left[\frac{c_0^2}{n} + \frac{(c_0\bar{x} - c_1)^2}{s_x^2}\right]^{-1/2} \frac{c_* - [c_0\hat{\beta}_0 + c_1\hat{\beta}_1]}{\sigma'}\right) \\ &= T_{n-2}\left(\left[\frac{c_0^2}{n} + \frac{(c_0\bar{x} - c_1)^2}{s_x^2}\right]^{-1/2} \frac{c_* - [c_0\hat{\beta}_0 + c_1\hat{\beta}_1]}{\sigma'}\right) \\ &= T_{n-2}(-U_{01}), \end{aligned}$$

where  $T_{n-2}$  denotes the c.d.f. of the  $t$  distribution with  $n - 2$  degrees of freedom and  $U_{01}$  is the random variable defined in Eq. (11.3.14). It is simple to see that  $T_{n-2}(-U_{01}) \leq \alpha_0$  if and only if  $U_{01} \geq T_{n-2}^{-1}(1 - \alpha_0)$ . Hence, the Bayes test of the hypotheses (11.4.9) is the same as the level  $\alpha_0$  test of these same hypotheses that was derived after Eq. (11.3.16). Hence, all of the one-sided tests that we learned how to perform in Sec. 11.3 are also Bayes tests when the improper prior is used.

On page 610, we began a discussion of how to deal with two-sided alternatives when the posterior distribution of the parameter was continuous. The same approach can be used in linear regression problems. We shall illustrate with an example.

#### Example 11.4.4

**Gasoline Mileage.** In Example 11.4.1, we wanted to make use of the posterior distribution of the slope parameter  $\beta_1$  from Example 11.3.2 in order to be able to say how likely we believe it is that  $\beta_1$  is close to 0. We can draw a plot of the posterior c.d.f. of  $|\beta_1|$  by making use of Theorem 11.4.1. The posterior distribution of  $s_x(\beta_1 - \hat{\beta}_1)/\sigma'$  is the  $t$  distribution with  $n - 2$  degrees of freedom. In Example 11.3.2, we computed  $s_x = 1036.9$ ,  $\sigma' = 7.181 \times 10^{-3}$ ,  $\hat{\beta}_1 = 1.396 \times 10^{-4}$ , and  $n = 173$ . It follows that, for all positive  $c$ ,

$$\begin{aligned} \Pr(|\beta_1| \leq c) &= \Pr(-c \leq \beta_1 \leq c) = T_{171}\left(\frac{1036.9}{7.181 \times 10^{-3}}(c - 1.396 \times 10^{-4})\right) \\ &\quad - T_{171}\left(\frac{1036.9}{7.181 \times 10^{-3}}(-c - 1.396 \times 10^{-4})\right), \end{aligned}$$

where  $T_{171}$  is the c.d.f. of the  $t$  distribution with 171 degrees of freedom. Figure 11.14 contains a plot of the posterior c.d.f. of  $|\beta_1|$ . We can see that the probability is essentially 1 that  $|\beta_1| < 1.6 \times 10^{-4}$ , but it is also essentially 1 that  $|\beta_1| > 1.2 \times 10^{-4}$ . These numbers may look small. However, remember that  $\beta_1$  must get multiplied by

**Figure 11.14** Plot of posterior c.d.f. of  $|\beta_1|$  in Example 11.4.4.

horsepower, which is typically a number in the 50–300 range. So, even if  $\beta_1$  is as small as  $1.2 \times 10^{-4}$ , the difference between gallons per mile at 100 and 200 horsepower will be 0.012, which is a sizeable difference in gallons per mile. We can also translate this result into miles per gallon. Suppose that  $\beta_1 = 1.2 \times 10^{-4}$ , and suppose that  $\beta_0$  equals its conditional mean given that  $\beta_1 = 1.2 \times 10^{-4}$ . This conditional mean can be computed using the method of Exercise 7, and it equals 0.01897. Then the miles per gallon for a 200 horsepower car is 23.27, and the miles per gallon for a 100 horsepower car is 32.23.  $\blacktriangleleft$

### Summary

We have used improper prior distributions for the parameters of the simple linear regression model, and we have found the posterior distributions of the parameters after observing  $n$  data points. The posterior distributions of the intercept and slope parameters are  $t$  distributions with  $n - 2$  degrees of freedom that have been shifted and rescaled. These posterior distributions show striking similarities to the sampling distributions of the least-squares estimators. Indeed, posterior probability intervals for the parameters are exactly the same as confidence intervals, prediction intervals for future observations are the same as those based on the sampling distributions, and level  $\alpha_0$  tests of one-sided null and alternative hypotheses reject the null hypotheses when the posterior probability of the null hypothesis is less than  $\alpha_0$ . The only significant lack of connection between posterior calculations and those based on sampling distributions is the testing of hypotheses in which the alternative is two-sided.

## Exercises

- Assume the usual conditions for simple linear regression. Assume that we use the improper prior discussed in this section. Let  $(a, b)$  be the observed value of a coefficient  $1 - \alpha_0$  confidence interval for  $\beta_1$  constructed as in Sec. 11.3. Prove that the posterior probability is  $1 - \alpha_0$  that  $a < \beta_1 < b$ .
- Assume the usual conditions for simple linear regression. Assume that we use the improper prior discussed in this section. Let  $(a, b)$  be the observed value of a coefficient  $1 - \alpha_0$  confidence interval for  $c_0\beta_0 + c_1\beta_1$  con-

structed as in Sec. 11.3. Prove that the posterior probability is  $1 - \alpha_0$  that  $a < c_0\beta_0 + c_1\beta_1 < b$ .

- Assume a simple linear regression model with the improper prior. Show that, conditional on  $\tau$ , the posterior distribution of  $\tau^{1/2}(\beta_0 + \beta_1 x - \hat{Y})$  is the normal distribution with mean 0 and variance

$$\frac{1}{n} + \frac{(x - \bar{x})^2}{s_x^2}.$$

4. We wish to fit a simple linear regression model to the data in Table 11.9 on page 727. Use an improper prior distribution.
- Find the posterior distribution of the parameters.
  - Find a bounded interval that contains 90 percent of the posterior distribution of  $\beta_1$ .
  - Find the probability that  $\beta_0$  is between 0 and 2.
5. Use the data in Table 11.9, and suppose that we wish to fit a simple linear regression model to the data. Use the improper prior.
- Find the posterior distribution of the slope parameter  $\beta_1$ .
  - Find the posterior distribution of  $\beta_0 + \beta_1$ , the mean of a future observation  $Y$  corresponding to  $x = 1$ .
6. Use the data in Table 11.6 on page 707. Assume that we wish to fit a simple linear regression model for predicting logarithm of 1980 price from logarithm of 1970 price.
- Find the posterior distribution of the slope parameter  $\beta_1$ .
  - Find the posterior probability that  $\beta_1 \leq 2$ .
  - Find a 95 percent prediction interval for the 1980 price of a species that cost 21.4 in 1970.
7. In a simple linear regression problem with the usual improper prior, prove that the conditional mean of  $\beta_0$  given  $\beta_1$  is  $\hat{\beta}_0 - \bar{x}(\beta_1 - \hat{\beta}_1)$ . Hint: Use the fact that  $(\beta_0, \beta_1)$  has a bivariate normal distribution as described in Theorem 11.4.1, and then use Eq. (5.10.6) to find the conditional mean.

## 11.5 The General Linear Model and Multiple Regression

The simple linear regression model can be extended to allow the mean of  $Y$  to be a function of several predictor variables. Much of the resulting distribution theory, is very similar to the simple regression case.

### The General Linear Model

**Example  
11.5.1**

Unemployment in the 1950s. The data in Table 11.12 provide the unemployment rates during the 10 years from 1950 to 1959 together with an index of industrial production from the Federal Reserve Board. It might make sense to think that unemployment is related to industrial production. Other factors also play a role, and those other factors most likely changed over the course of the decade. As a surrogate for these other factors, some function of the year could be included as a predictor. Figure 11.15 shows plots of unemployment against each of the two predictor variables. It is not clear from the plots precisely how unemployment varies with the two predictors, but there appear to be some relationships. In this section, we shall show how to fit a regression model with more than one predictor to these and other data. ▶

In this section, we shall study regression problems in which the observations  $Y_1, \dots, Y_n$  satisfy assumptions like Assumptions 11.2.1–11.2.5 that were made in Sections 11.2 and 11.3. In particular, we shall again assume that each observation  $Y_i$  has a normal distribution, that the observations  $Y_1, \dots, Y_n$  are independent, and that the observations  $Y_1, \dots, Y_n$  have the same variance  $\sigma^2$ . Instead of a single predictor being associated with each  $Y_i$ , we assume that a  $p$ -dimensional vector  $\mathbf{z}_i = (z_{i0}, \dots, z_{ip-1})$  is associated with each  $Y_i$ . The assumptions that we make can now be restated in this framework.

**Assumption  
11.5.1**

Predictor is known. Either the vectors  $\mathbf{z}_1, \dots, \mathbf{z}_n$  are known ahead of time, or they are the observed values of random vectors  $\mathbf{Z}_1, \dots, \mathbf{Z}_n$  on whose values we condition before computing the joint distribution of  $(Y_1, \dots, Y_n)$ .

**Table 11.12** Unemployment data for Example 11.5.1

Unemployment	Index of production	Year
3.1	113	1950
1.9	123	1951
1.7	127	1952
1.6	138	1953
3.2	130	1954
2.7	146	1955
2.6	151	1956
2.9	152	1957
4.7	141	1958
3.8	159	1959

**Figure 11.15** Plots of unemployment against the two predictor variables for Example 11.5.1.

**Assumption 11.5.2** **Normality.** For  $i = 1, \dots, n$ , the conditional distribution of  $Y_i$  given the vectors  $z_1, \dots, z_n$  is a normal distribution.

**Assumption 11.5.3** **Linear Mean.** There is a vector of parameters  $\beta = (\beta_0, \dots, \beta_{p-1})$  such that the conditional mean of  $Y_i$  given the values  $z_1, \dots, z_n$  has the form

$$z_{i0}\beta_0 + z_{i1}\beta_1 + \dots + z_{ip-1}\beta_{p-1}, \quad (11.5.1)$$

for  $i = 1, \dots, n$ .

**Assumption 11.5.4** **Common Variance.** There is a parameter  $\sigma^2$  such that the conditional variance of  $Y_i$  given the values  $z_1, \dots, z_n$  is  $\sigma^2$  for  $i = 1, \dots, n$ .

**Assumption 11.5.5** **Independence.** The random variables  $Y_1, \dots, Y_n$  are independent given the observed  $z_1, \dots, z_n$ .

The generalization that we introduce here is that the mean of each observation  $Y_i$  is a linear combination of  $p$  unknown parameters  $\beta_0, \dots, \beta_{p-1}$  as in (11.5.1). Each value  $z_{ij}$  either may be fixed by the experimenter before the experiment is started or may be observed in the experiment along with the value of  $Y_i$ . In the latter case, Eq. (11.5.1) gives the conditional mean of  $Y_i$  given the observed  $z_{ij}$  values.

**Definition 11.5.1** General Linear Model. The statistical model in which the observations  $Y_1, \dots, Y_n$  satisfy Assumptions 11.5.1–11.5.5 is called the *general linear model*.

In Definition 11.5.1, the term *linear* refers to the fact that the expectation of each observation  $Y_i$  is a linear function of the unknown parameters  $\beta_0, \dots, \beta_{p-1}$ .

Many different types of regression problems are examples of general linear models. For example, in a problem of simple linear regression,  $E(Y_i) = \beta_0 + \beta_1 x_i$  for  $i = 1, \dots, n$ . This expectation can be represented in the form given in Eq. (11.5.1), with  $p = 2$ , by letting  $z_{i0} = 1$  and  $z_{i1} = x_i$  for  $i = 1, \dots, n$ . Similarly, if the regression of  $Y$  on  $X$  is a polynomial of degree  $k$ , then, for  $i = 1, \dots, n$ ,

$$E(Y_i) = \beta_0 + \beta_1 x_i + \dots + \beta_k x_i^k. \quad (11.5.2)$$

In this case,  $p = k + 1$  and  $E(Y_i)$  can be represented in the form given in Eq. (11.5.1) by letting  $z_{ij} = x_i^j$  for  $j = 0, \dots, k$ .

As a final example, consider a problem in which the regression of  $Y$  on  $k$  variables  $X_1, \dots, X_k$  is a function like that given in Eq. (11.2.1). A problem of this type is called a problem of *multiple linear regression* because we are considering the regression of  $Y$  on  $k$  variables  $X_1, \dots, X_k$ , rather than on just a single variable  $X$ , and we are assuming also that this regression is a linear function of the parameters  $\beta_0, \dots, \beta_k$ . In a problem of multiple linear regression, we obtain  $n$  vectors of observations  $(x_{i1}, \dots, x_{ik}, Y_i)$ , for  $i = 1, \dots, n$ . Here  $x_{ij}$  is the observed value of the variable  $X_j$  for the  $i$ th observation. Then  $E(Y_i)$  is given by the relation

$$E(Y_i) = \beta_0 + \beta_1 x_{i1} + \dots + \beta_k x_{ik}. \quad (11.5.3)$$

This expectation can also be represented in the form given in Eq. (11.5.1), with  $p = k + 1$ , by letting  $z_{i0} = 1$  and  $z_{ij} = x_{ij}$  for  $j = 1, \dots, k$ .

**Example 11.5.2**

Unemployment in the 1950s. In Example 11.5.1, we can let  $Y$  stand for the unemployment rate, while  $X_1$  stands for the index of production and  $X_2$  stands for the year.

Our discussion has indicated that the general linear model is general enough to include problems of simple and multiple linear regression, problems in which the regression function is a polynomial, problems in which the regression function has the form given in Eq. (11.1.16), and many other problems.

Some books devoted to regression and other linear models are Cook and Weisberg (1999), Draper and Smith (1998), Graybill and Iyer (1994), and Weisberg (1985).

## Maximum Likelihood Estimators

We shall now describe a procedure for determining the M.L.E.'s of  $\beta_0, \dots, \beta_{p-1}$  in the general linear model. Since  $E(Y_i)$  is given by Eq. (11.5.1) for  $i = 1, \dots, n$ , the likelihood function after observing values  $y_1, \dots, y_n$  will have the following form:

$$\frac{1}{(2\pi\sigma^2)^{n/2}} \exp\left[-\frac{1}{2\sigma^2} \sum_{i=1}^n (y_i - z_{i0}\beta_0 - \dots - z_{ip-1}\beta_{p-1})^2\right]. \quad (11.5.4)$$

Since the M.L.E.'s are the values that maximize the likelihood function (11.5.4), it can be seen that the estimates  $\hat{\beta}_0, \dots, \hat{\beta}_{p-1}$  will be the values of  $\beta_0, \dots, \beta_{p-1}$  for which the following sum of squares  $Q$  is minimized:

$$Q = \sum_{i=1}^n (y_i - z_{i0}\beta_0 - \dots - z_{ip-1}\beta_{p-1})^2. \quad (11.5.5)$$

Since  $Q$  is the sum of the squares of the deviations of the observed values from the linear function given in Eq. (11.5.1), it follows that the M.L.E.'s  $\hat{\beta}_0, \dots, \hat{\beta}_{p-1}$  will be the same as the least-squares estimates.

To determine the values of  $\hat{\beta}_0, \dots, \hat{\beta}_{p-1}$ , we can calculate the  $p$  partial derivatives  $\partial Q / \partial \beta_j$  for  $j = 0, \dots, p-1$  and can set each of these derivatives equal to 0. The resulting  $p$  equations, which are called the *normal equations*, will form a set of  $p$  linear equations in  $\beta_0, \dots, \beta_{p-1}$ . We shall assume that the  $p \times p$  matrix formed by the coefficients of  $\beta_0, \dots, \beta_{p-1}$  in the normal equations is nonsingular. Then these equations will have a unique solution  $\hat{\beta}_0, \dots, \hat{\beta}_{p-1}$ , and  $\hat{\beta}_0, \dots, \hat{\beta}_{p-1}$  will be both the M.L.E.'s and the least-squares estimates of  $\beta_0, \dots, \beta_{p-1}$ .

For a problem of polynomial regression in which  $E(Y_i)$  is given by Eq. (11.5.2), the normal equations were presented as the relations (11.1.8). For a problem of multiple linear regression in which  $E(Y_i)$  is given by Eq. (11.5.3), the normal equations were presented as the relations (11.1.13).

If we substitute  $\hat{\beta}_i$  for  $\beta_i$  for  $i = 0, \dots, p-1$  in the formula for  $Q$  in Eq. (11.5.5), we obtain

$$S^2 = \sum_{i=1}^n (Y_i - z_{i0}\hat{\beta}_0 - \dots - z_{ip-1}\hat{\beta}_{p-1})^2. \quad (11.5.6)$$

Eq. (11.5.6) is the natural generalization of Eq. (11.3.9) to the multiple regression case. It can be shown using the same method outlined in the proof of Theorem 11.2.1 that the M.L.E. of  $\sigma^2$  in the general linear model is

$$\hat{\sigma}^2 = \frac{S^2}{n}. \quad (11.5.7)$$

The details are left to Exercise 1 at the end of this section. In analogy to Eq. (11.3.12), we define the useful quantity

$$\sigma' = \left( \frac{S^2}{n-p} \right)^{1/2}. \quad (11.5.8)$$

This makes  $\sigma'^2$  an unbiased estimator of  $\sigma^2$ . (See Exercise 2.)

### Explicit Form of the Estimators

In order to derive the explicit form and the properties of the estimators  $\hat{\beta}_0, \dots, \hat{\beta}_{p-1}$ , it is convenient to use the notation and techniques of vectors and matrices. We shall let the  $n \times p$  matrix  $\mathbf{Z}$  be defined as follows:

$$\mathbf{Z} = \begin{bmatrix} z_{10} & \cdots & z_{1p-1} \\ z_{20} & \cdots & z_{2p-1} \\ \vdots & \ddots & \vdots \\ z_{n0} & \cdots & z_{np-1} \end{bmatrix}. \quad (11.5.9)$$

This matrix  $\mathbf{Z}$  distinguishes one regression problem from another, because the entries in  $\mathbf{Z}$  determine the particular linear combinations of the unknown parameters  $\beta_0, \dots, \beta_{p-1}$  that are relevant in a given problem.

**Definition 11.5.2** Design Matrix. The matrix  $\mathbf{Z}$  in Eq. (11.5.9) for a general linear model is called the *design matrix* of the model.

The name “design matrix” comes from the case in which the  $z_{ij}$  are chosen by the experimenter to achieve a well-designed experiment. It should be kept in mind, however, that some or all of the entries in  $\mathbf{Z}$  may be simply the observed values of certain variables, and may not actually be controlled by the experimenter.

We shall also let  $\mathbf{y}$  be the  $n \times 1$  vector of observed values of  $Y_1, \dots, Y_n$ ,  $\boldsymbol{\beta}$  be the  $p \times 1$  vector of parameters, and  $\hat{\boldsymbol{\beta}}$  be the  $p \times 1$  vector of estimates. These vectors may be represented as follows:

$$\mathbf{y} = \begin{bmatrix} y_1 \\ \vdots \\ y_n \end{bmatrix}, \quad \boldsymbol{\beta} = \begin{bmatrix} \beta_0 \\ \vdots \\ \beta_{p-1} \end{bmatrix}, \quad \text{and} \quad \hat{\boldsymbol{\beta}} = \begin{bmatrix} \hat{\beta}_0 \\ \vdots \\ \hat{\beta}_{p-1} \end{bmatrix}.$$

The transpose of a vector or matrix  $\mathbf{v}$  will be denoted by  $\mathbf{v}'$ .

**Theorem 11.5.1** General Linear Model Estimators. The least squares estimator (and M.L.E.) of  $\boldsymbol{\beta}$  is

$$\hat{\boldsymbol{\beta}} = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y}. \quad (11.5.10)$$

**Proof** The sum of squares  $Q$  given in Eq. (11.5.5) can be written in the following form:

$$Q = (\mathbf{y} - \mathbf{Z}\boldsymbol{\beta})'(\mathbf{y} - \mathbf{Z}\boldsymbol{\beta}).$$

Since  $Q$  is a quadratic function of the coordinates of  $\boldsymbol{\beta}$ , it is straightforward to take the partial derivatives of  $Q$  with respect to these coordinates and set them equal to 0. For example, the partial derivative with respect to  $\beta_0$  is

$$\frac{\partial Q}{\partial \beta_0} = -2 \sum_{i=1}^n z_{i0}y_i + 2 \sum_{j=0}^{p-1} \beta_j \sum_{i=1}^n z_{i0}z_{ij}. \quad (11.5.11)$$

Each of the other partial derivatives produces an equation similar to (11.5.11). Set the right-hand sides of each of these  $p$  equations to 0, and arranged them into the following matrix equation:

$$\mathbf{Z}'\mathbf{Z}\boldsymbol{\beta} = \mathbf{Z}'\mathbf{y}. \quad (11.5.12)$$

Because it is assumed that the  $p \times p$  matrix  $\mathbf{Z}'\mathbf{Z}$  is nonsingular, the vector of estimates  $\hat{\boldsymbol{\beta}}$  will be the unique solution of Eq. (11.5.12). In order for  $\mathbf{Z}'\mathbf{Z}$  to be nonsingular, the number of observations  $n$  must be at least  $p$ , and there must be at least  $p$  linearly independent rows in the matrix  $\mathbf{Z}$ . When this assumption is satisfied, it follows from Eq. (11.5.12) that  $\hat{\boldsymbol{\beta}} = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{y}$ . Thus, if we replace the vector  $\mathbf{y}$  of observed values by the vector  $\mathbf{Y}$  of random variables, the form for the vector of estimators  $\hat{\boldsymbol{\beta}}$  will be (11.5.10). ■

Virtually every statistical computer package will calculate least-squares estimates for a multiple linear regression. Even some handheld calculators will perform multiple linear regression. The matrix  $(\mathbf{Z}'\mathbf{Z})^{-1}$  is useful for more than just computing  $\hat{\boldsymbol{\beta}}$  in

Eq. (11.5.10), as we shall see later in this section. Not every piece of regression software makes it easy to access this matrix.

It follows from Eq. (11.5.10) that each of the estimators  $\hat{\beta}_0, \dots, \hat{\beta}_{p-1}$  will be a linear combination of the coordinates  $Y_1, \dots, Y_n$  of the vector  $\mathbf{Y}$ . Since each of these coordinates has a normal distribution and they are independent, it follows that each estimator  $\hat{\beta}_j$  will also have a normal distribution. Indeed, the entire vector  $\hat{\beta}$  has a joint normal distribution (called a *multivariate normal distribution*), which is a generalization of the bivariate normal distribution to more than two coordinates. We shall not discuss the multivariate normal distribution in detail in this text, but we shall merely point out one feature that it has in common with the bivariate normal distribution: If a vector  $\hat{\beta}$  has a multivariate normal distribution, then every linear combination of the coordinates of  $\hat{\beta}$  has a normal distribution. Indeed, every collection of linear combinations of the coordinates of  $\hat{\beta}$  has a multivariate normal distribution.

**Example  
11.5.3**

Unemployment in the 1950s. The matrix  $\mathbf{Z}$  in Example 11.5.1 has three columns. The first column is the number 1 ten times. The second column is the second column of Table 11.12. In order to avoid some numerical problems, we shall let the third column of  $\mathbf{Z}$  be the third column of Table 11.12 minus 1949. The vector  $\mathbf{y}$  is the first column of Table 11.12. We can then compute the matrix  $(\mathbf{Z}'\mathbf{Z})^{-1}$  and the vector  $\mathbf{Z}'\mathbf{y}$ :

$$(\mathbf{Z}'\mathbf{Z})^{-1} = \begin{pmatrix} 38.35 & -0.3323 & 1.383 \\ -0.3323 & 2.915 \times 10^{-3} & -0.01272 \\ 1.383 & -0.01272 & 0.06762 \end{pmatrix} \quad \mathbf{Z}'\mathbf{y} = \begin{pmatrix} 28.2 \\ 3931 \\ 172.3 \end{pmatrix}.$$

We can then use Eq. (11.5.10) to compute

$$\hat{\beta} = \begin{pmatrix} 13.45 \\ -0.1033 \\ 0.6594 \end{pmatrix}.$$

We shall examine the residuals later in this section. ◀

### Mean Vector and Covariance Matrix

We shall now derive the means, variances, and covariances of  $\hat{\beta}_0, \dots, \hat{\beta}_{p-1}$ . Suppose that  $\mathbf{Y}$  is an  $n$ -dimensional random vector with coordinates  $Y_1, \dots, Y_n$ . Thus,

$$\mathbf{Y} = \begin{bmatrix} Y_1 \\ \vdots \\ Y_n \end{bmatrix}. \quad (11.5.13)$$

The expectation  $E(\mathbf{Y})$  of this random vector is defined to be the  $n$ -dimensional vector whose coordinates are the expectations of the individual coordinates of  $\mathbf{Y}$ . Hence,

$$E(\mathbf{Y}) = \begin{bmatrix} E(Y_1) \\ \vdots \\ E(Y_n) \end{bmatrix}.$$

**Definition  
11.5.3**

**Mean Vector/Covariance Matrix.** If  $\mathbf{Y}$  is a random vector, then the vector  $E(\mathbf{Y})$  is called the *mean vector* of  $\mathbf{Y}$ . The *covariance matrix* of  $\mathbf{Y}$  is defined to be the  $n \times n$  matrix such that, for  $i = 1, \dots, n$  and  $j = 1, \dots, n$ , the element in the  $i$ th row and  $j$ th column is  $\text{Cov}(Y_i, Y_j)$ . We shall let  $\text{Cov}(\mathbf{Y})$  denote this covariance matrix.

For example, if  $\text{Cov}(Y_i, Y_j) = \sigma_{ij}$  for all  $i$  and  $j$ , then

$$\text{Cov}(\mathbf{Y}) = \begin{bmatrix} \sigma_{11} & \cdots & \sigma_{1n} \\ \vdots & \ddots & \vdots \\ \sigma_{n1} & \cdots & \sigma_{nn} \end{bmatrix}.$$

For  $i = 1, \dots, n$ ,  $\text{Var}(Y_i) = \text{Cov}(Y_i, Y_i) = \sigma_{ii}$ . Therefore, the  $n$  diagonal elements of the matrix  $\text{Cov}(\mathbf{Y})$  are the variances of  $Y_1, \dots, Y_n$ . Furthermore, since  $\text{Cov}(Y_i, Y_j) = \text{Cov}(Y_j, Y_i)$ , then  $\sigma_{ij} = \sigma_{ji}$ . Therefore, the matrix  $\text{Cov}(\mathbf{Y})$  must be symmetric.

The mean vector and the covariance matrix of the random vector  $\mathbf{Y}$  in the general linear model can easily be determined. It follows from Eq. (11.5.1) that

$$E(\mathbf{Y}) = \mathbf{Z}\boldsymbol{\beta}. \quad (11.5.14)$$

Also, the coordinates  $Y_1, \dots, Y_n$  of  $\mathbf{Y}$  are independent, and the variance of each of these coordinates is  $\sigma^2$ . Therefore,

$$\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}, \quad (11.5.15)$$

where  $\mathbf{I}$  is the  $n \times n$  identity matrix.

The following result helps us find the mean vector and covariance matrix of  $\hat{\boldsymbol{\beta}}$ .

**Theorem  
11.5.2**

Suppose that  $\mathbf{Y}$  is an  $n$ -dimensional random vector as specified by Eq. (11.5.13), for which the mean vector  $E(\mathbf{Y})$  and the covariance matrix  $\text{Cov}(\mathbf{Y})$  exist. Suppose also that  $\mathbf{A}$  is a  $p \times n$  matrix whose elements are constants, and that  $\mathbf{W}$  is a  $p$ -dimensional random vector defined by the relation  $\mathbf{W} = \mathbf{AY}$ . Then  $E(\mathbf{W}) = \mathbf{AE}(\mathbf{Y})$  and  $\text{Cov}(\mathbf{W}) = \mathbf{A} \text{Cov}(\mathbf{Y}) \mathbf{A}'$ .

**Proof** Let the elements of matrix  $\mathbf{A}$  be denoted as follows:

$$\mathbf{A} = \begin{bmatrix} a_{01} & \cdots & a_{0n} \\ \vdots & \ddots & \vdots \\ a_{p-11} & \cdots & a_{p-1n} \end{bmatrix}.$$

Then the  $i$ th coordinate of the vector  $E(\mathbf{W})$  is

$$E(W_i) = E\left(\sum_{j=1}^n a_{ij} Y_j\right) = \sum_{j=1}^n a_{ij} E(Y_j). \quad (11.5.16)$$

It can be seen that the final summation in Eq. (11.5.16) is the  $i$ th coordinate of the vector  $\mathbf{AE}(\mathbf{Y})$ . Hence,  $E(\mathbf{W}) = \mathbf{AE}(\mathbf{Y})$ .

Next, for  $i = 0, \dots, p - 1$  and  $j = 0, \dots, p - 1$ , the element in the  $i$ th row and  $j$ th column of the  $p \times p$  matrix  $\text{Cov}(\mathbf{W})$  is

$$\text{Cov}(W_i, W_j) = \text{Cov}\left(\sum_{r=1}^n a_{ir} Y_r, \sum_{s=1}^n a_{js} Y_s\right).$$

Therefore, by Exercise 8 of Sec. 4.6,

$$\text{Cov}(W_i, W_j) = \sum_{r=1}^n \sum_{s=1}^n a_{ir} a_{js} \text{Cov}(Y_r, Y_s). \quad (11.5.17)$$

Using the formula for matrix multiplication, one finds that the right side of Eq. (11.5.17) is the element in the  $i$ th row and  $j$ th column of the  $p \times p$  matrix  $\mathbf{A} \operatorname{Cov}(\mathbf{Y})\mathbf{A}'$ . Hence,  $\operatorname{Cov}(\mathbf{W}) = \mathbf{A} \operatorname{Cov}(\mathbf{Y})\mathbf{A}'$ . ■

The means, the variances, and the covariances of the estimators  $\hat{\beta}_0, \dots, \hat{\beta}_{p-1}$  can be obtained by applying Theorem 11.5.2.

**Theorem  
11.5.3**

In the general linear model,  $E(\hat{\beta}) = \beta$ , and  $\operatorname{Cov}(\hat{\beta}) = \sigma^2(\mathbf{Z}'\mathbf{Z})^{-1}$ .

**Proof** Eq. (11.5.10) says that  $\hat{\beta}$  can be represented in the form  $\hat{\beta} = \mathbf{AY}$ , where  $\mathbf{A} = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$ . Therefore, it follows from Theorem 11.5.2 and Eq. (11.5.14) that

$$E(\hat{\beta}) = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'E(\mathbf{Y}) = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Z}\beta = \beta.$$

Also, it follows from Theorem 11.5.2 and Eq. (11.5.15) that

$$\begin{aligned}\operatorname{Cov}(\hat{\beta}) &= (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\operatorname{Cov}(\mathbf{Y})\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \\ &= (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'(\sigma^2\mathbf{I})\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \\ &= \sigma^2(\mathbf{Z}'\mathbf{Z})^{-1}.\end{aligned}$$

Thus,  $E(\hat{\beta}_j) = \beta_j$  for  $j = 0, \dots, p - 1$ , and for  $j = 0, \dots, p - 1$ ,  $\operatorname{Var}(\hat{\beta}_j)$  equals  $\sigma^2$  times the  $j$ th diagonal entry of the matrix  $(\mathbf{Z}'\mathbf{Z})^{-1}$ . Also, for  $i \neq j$ ,  $\operatorname{Cov}(\hat{\beta}_i, \hat{\beta}_j)$  will be equal to  $\sigma^2$  times the entry in the  $i$ th row and  $j$ th column of the matrix  $(\mathbf{Z}'\mathbf{Z})^{-1}$ .

**Example  
11.5.4**

**Dishwasher Shipments.** The United States Department of Commerce collects data on factory shipments of durable goods as well as other economic indicators. Table 11.13 contains the numbers of factory shipments of dishwashers (in thousands) and private residential investment in billions of 1972 dollars for the years 1960 through 1985. Figure 11.16 shows plots of dishwasher shipments against year and private residential investment. Let  $Y$  stand for dishwasher shipments. We could fit a model in which the mean of  $Y$  is given by Eq. (11.5.3) with  $k = 2$ . The matrix  $\mathbf{Z}$  would have three columns and 26 rows. The first column would be all the number 1. The second column would have time, expressed as the year minus 1960 for numerical stability. The third column would have private residential investment. We can then compute

$$(\mathbf{Z}'\mathbf{Z})^{-1} = \begin{pmatrix} 1.152 & 0.01279 & -0.02660 \\ 0.01279 & 0.001136 & -0.0005636 \\ -0.02660 & -0.0005636 & 0.0007026 \end{pmatrix}.$$

The correlation between  $\hat{\beta}_1$  and  $\hat{\beta}_2$  can be computed as

$$\rho = \frac{\operatorname{Cov}(\hat{\beta}_1, \hat{\beta}_2)}{(\operatorname{Var}(\hat{\beta}_1)\operatorname{Var}(\hat{\beta}_2))^{1/2}} = \frac{-0.0005636\sigma^2}{(0.001136\sigma^2 \times 0.0007026\sigma^2)^{1/2}} = -0.6309.$$

Notice that the correlation does not depend on the unknown value of  $\sigma^2$ , but only on the design matrix. Also notice that the correlation is negative and sizeable. If one of the coefficients is overestimated, the other one will tend to be underestimated. ◀

**Table 11.13** Dishwasher shipments and residential investment from 1960–1985

Year	Dishwasher shipments (thousands)	Private residential investment (billions of 1972 dollars)
1960	555	34.2
1961	620	34.3
1962	720	37.7
1963	880	42.5
1964	1050	43.1
1965	1290	42.7
1966	1528	38.2
1967	1586	37.1
1968	1960	43.1
1969	2118	43.6
1970	2116	41.0
1971	2477	53.7
1972	3199	63.8
1973	3702	62.3
1974	3320	48.2
1975	2702	42.2
1976	3140	51.2
1977	3356	60.7
1978	3558	62.4
1979	3488	59.1
1980	2738	47.1
1981	2484	44.7
1982	2170	37.8
1983	3092	52.7
1984	3491	60.3
1985	3536	61.4

### The Joint Distribution of the Estimators

Let the random variable  $S^2$  be defined as in Eq. (11.5.6). The sum of squares  $S^2$  can also be represented in the following form:

$$S^2 = (\mathbf{Y} - \mathbf{Z}\hat{\boldsymbol{\beta}})'(\mathbf{Y} - \mathbf{Z}\hat{\boldsymbol{\beta}}). \quad (11.5.18)$$

The method in the proof of Theorem 11.3.2 can be extended by making use of methods that are beyond the scope of this book in order to prove the following two facts. First,  $S^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - p$  degrees of freedom. Second,  $S^2$  and the random vector  $\hat{\boldsymbol{\beta}}$  are independent.

From Eq. (11.5.7), we see that  $\hat{\sigma}^2 = S^2/n$ . Hence, the random variable  $n\hat{\sigma}^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - p$  degrees of freedom, and the estimators  $\hat{\sigma}^2$  and  $\hat{\boldsymbol{\beta}}$  are independent.

The following result summarizes what we have proven and stated without proof concerning the joint distribution of  $\hat{\boldsymbol{\beta}}$  and  $\hat{\sigma}^2$ .

**Corollary 11.5.1** Let the entries in the symmetric  $p \times p$  matrix  $(\mathbf{Z}'\mathbf{Z})^{-1}$  be denoted as follows:

$$(\mathbf{Z}'\mathbf{Z})^{-1} = \begin{bmatrix} \zeta_{00} & \cdots & \zeta_{0p-1} \\ \vdots & \ddots & \vdots \\ \zeta_{p-10} & \cdots & \zeta_{p-1p-1} \end{bmatrix}. \quad (11.5.19)$$

For  $j = 0, \dots, p - 1$ , the estimator  $\hat{\beta}_j$  has the normal distribution with mean  $\beta_j$  and variance  $\zeta_{jj}\sigma^2$ . Furthermore, for  $i \neq j$ , we have  $\text{Cov}(\hat{\beta}_i, \hat{\beta}_j) = \zeta_{ij}\sigma^2$ . Also, the entire vector  $\hat{\boldsymbol{\beta}}$  has a multivariate normal distribution. Finally,  $\hat{\sigma}^2$  is independent of  $\hat{\boldsymbol{\beta}}$  and  $n\hat{\sigma}^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - p$  degrees of freedom. ■

Note that  $\hat{\boldsymbol{\beta}}$  is also independent of  $\sigma^2$  from Eq. (11.5.8).

### Testing Hypotheses

Suppose that it is desired to test the hypothesis that one of the regression coefficients  $\beta_j$  has a particular value  $\beta_j^*$ . In other words, suppose that the following hypotheses are to be tested:

$$\begin{aligned} H_0: \quad \beta_j &= \beta_j^*, \\ H_1: \quad \beta_j &\neq \beta_j^*. \end{aligned} \quad (11.5.20)$$

Since  $\text{Var}(\hat{\beta}_j) = \zeta_{jj}\sigma^2$ , it follows that when  $H_0$  is true, the following random variable  $W_j$  will have the standard normal distribution:

$$W_j = \frac{(\hat{\beta}_j - \beta_j^*)}{\zeta_{jj}^{1/2}\sigma}.$$

Furthermore, since the random variable  $S^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - p$  degrees of freedom, and since  $S^2$  and  $\hat{\boldsymbol{\beta}}$  are independent, it follows that when  $H_0$  is true, the following random variable  $U_j$  will have the  $t$  distribution with  $n - p$  degrees

of freedom:

$$U_j = \frac{W_j}{\left[ \frac{1}{n-p} \left( \frac{s^2}{\sigma^2} \right) \right]^{1/2}} = \frac{(\hat{\beta}_j - \beta_j^*)}{(\zeta_{jj})^{1/2} \sigma'}. \quad (11.5.21)$$

The level  $\alpha_0$  test of the hypotheses (11.5.20) specifies that the null hypothesis  $H_0$  should be rejected if  $|U_j| \geq T_{n-p}^{-1}(1 - \alpha_0/2)$ , where  $T_{n-p}^{-1}$  is the quantile function of the  $t$  distribution with  $n - p$  degrees of freedom. Furthermore, if  $u$  is the value of  $U_j$  observed in a given problem, the corresponding  $p$ -value is

$$\Pr(U_j \geq |u|) + \Pr(U_j \leq -|u|). \quad (11.5.22)$$

Tests for one-sided hypotheses can be derived in a similar fashion.

**Example  
11.5.5**

**Dishwasher Shipments.** In Example 11.5.4, the least-squares estimates for the model are  $\hat{\beta}_0 = -1314$ ,  $\hat{\beta}_1 = 66.91$ , and  $\hat{\beta}_2 = 58.86$ . The observed value of  $\sigma'$  is 352.9. Now suppose that we are interested in testing the hypotheses

$$\begin{aligned} H_0: \quad & \beta_1 = 0, \\ H_1: \quad & \beta_1 \neq 0, \end{aligned}$$

where  $\beta_1$  is the coefficient of time in the multiple linear regression model. Using the matrix  $(\mathbf{Z}'\mathbf{Z})^{-1}$  found in Example 11.5.4, we can calculate

$$U_1 = \frac{66.91 - 0}{(0.001136)^{1/2} \times 352.9} = 5.625.$$

The degrees of freedom are  $26 - 3 = 23$ , and 5.625 is larger than every quantile listed in the table of the  $t$  distribution in this book. Using a computer program, we find that the  $p$ -value is about  $1 \times 10^{-5}$ .  $\blacktriangleleft$

**Example  
11.5.6**

**Unemployment in the 1950s.** In Example 11.5.3, we regressed unemployment on a Federal Reserve Board index of production and time. The least-squares estimates are  $\hat{\beta}_0 = 13.45$ ,  $\hat{\beta}_1 = -0.1033$ , and  $\hat{\beta}_2 = 0.6594$ . The observed value of  $\sigma'$  is 0.4011. Now suppose that we wish to test the hypotheses

$$\begin{aligned} H_0: \quad & \beta_2 \leq 0.4, \\ H_1: \quad & \beta_2 > 0.4. \end{aligned}$$

To test these hypotheses, we reject  $H_0$  if  $U_2$  is too large. We calculate  $U_2$  using the matrix  $(\mathbf{Z}'\mathbf{Z})^{-1}$  computed in Example 11.5.3:

$$U_2 = \frac{0.6594 - 0.4}{(0.06762)^{1/2} \times 0.4011} = 2.487.$$

The degrees of freedom are  $10 - 3 = 7$ , and 2.487 falls between the 0.975 and 0.99 quantiles of the  $t$  distribution with seven degrees of freedom. The  $p$ -value is actually 0.0209, so we would reject  $H_0$  at every level  $\alpha_0 \geq 0.0209$ .  $\blacktriangleleft$

Problems of testing hypotheses that specify the values of two coefficients  $\beta_i$  and  $\beta_j$  are discussed in Exercises 17 to 21 at the end of this section. Problems of testing hypotheses about linear combinations of  $\beta_0, \dots, \beta_{p-1}$  are the subject of Exercise 26.

Some computer programs make it easy to test hypotheses about individual  $\beta_j$ 's. Indeed, most software automatically supplies the value of the test statistic  $U_j$  for

testing the following hypotheses for each  $j$  ( $j = 0, \dots, k$ ):

$$\begin{aligned} H_0: \quad \beta_j &= 0, \\ H_1: \quad \beta_j &\neq 0. \end{aligned} \tag{11.5.23}$$

Some programs also compute the corresponding  $p$ -values that are found from the expression (11.5.22).

**Power of the Test** If the null hypothesis in (11.5.20) is false, then the statistic  $U_j$  has the noncentral  $t$  distribution with  $n - p$  degrees of freedom and noncentrality parameter  $\psi = (\beta_j - \beta_j^*)/(\zeta_{jj}^{1/2}\sigma)$ . Plots such as those in Figures 9.12 and 9.14 or computer programs can be used to calculate the power of the  $t$  test for specific parameter values.

## Prediction

Let  $\mathbf{z}' = (z_0, \dots, z_{p-1})$  be a vector of predictors for a future observation  $Y$ . We wish to predict  $Y$  using  $\hat{Y} = \mathbf{z}'\hat{\boldsymbol{\beta}}$ , and we want to know the M.S.E. We shall assume that  $Y$  is independent of the observed data. This makes  $Y$  and  $\hat{Y}$  independent. We can write

$$\hat{Y} = \mathbf{z}'\hat{\boldsymbol{\beta}} = \mathbf{z}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y},$$

so that  $\hat{Y}$  is a linear combination of the original data  $\mathbf{Y}$ . Since the coordinates of  $\mathbf{Y}$  are independent normal random variables, Theorem 11.3.1 tells us that  $\hat{Y}$  has a normal distribution. The mean of  $\hat{Y}$  is easily seen to be

$$E(\hat{Y}) = \mathbf{z}'E(\hat{\boldsymbol{\beta}}) = \mathbf{z}'\boldsymbol{\beta}.$$

The variance of  $\hat{Y}$  is obtained from Theorem 11.5.2:

$$\begin{aligned} \text{Var}(\hat{Y}) &= \mathbf{z}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}' \text{Cov}(\mathbf{Y})\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{z} \\ &= \mathbf{z}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{z}\sigma^2. \end{aligned}$$

Since  $Y$  has the normal distribution with mean  $\mathbf{z}'\boldsymbol{\beta}$  and variance  $\sigma^2$  and is independent of  $\hat{Y}$ , it follows that  $Y - \hat{Y}$  has the normal distribution with mean 0 and variance

$$\text{Var}(Y - \hat{Y}) = \text{Var}(\hat{Y}) + \text{Var}(Y) = \sigma^2[1 + \mathbf{z}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{z}]. \tag{11.5.24}$$

Since  $Y - \hat{Y}$  has mean 0, Eq. (11.5.24) is also the M.S.E. for using  $\hat{Y}$  to predict  $Y$ .

We can also form a prediction interval for  $Y$  just as we did in (11.3.25). As we did there, define

$$Z = \frac{Y - \hat{Y}}{\sigma[1 + \mathbf{z}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{z}]^{1/2}}, \quad W = \frac{S^2}{\sigma^2}.$$

Then  $Z$  has the standard normal distribution independent of  $W$ , which has the  $\chi^2$  distribution with  $n - p$  degrees of freedom. Hence,

$$\frac{Z}{(W/[n - p])^{1/2}} = \frac{Y - \hat{Y}}{\sigma[1 + \mathbf{z}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{z}]^{1/2}}$$

has the  $t$  distribution with  $n - p$  degrees of freedom. It follows that the interval with

the following endpoints has probability  $1 - \alpha_0$  of containing  $Y$ , prior to observing the data:

$$\hat{Y} \pm T_{n-p}^{-1} \left( 1 - \frac{\alpha_0}{2} \right) \sigma' [1 + \mathbf{z}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{z}]^{1/2}. \quad (11.5.25)$$

**Example  
11.5.7**

**Predicting Dishwasher Shipments.** In Example 11.5.4, the least-squares estimates for the model are  $\hat{\beta}_0 = -1314$ ,  $\hat{\beta}_1 = 66.91$ , and  $\hat{\beta}_2 = 58.86$ . The observed value of  $\sigma'$  is 352.9. Now suppose that we are interested in predicting dishwasher shipments for 1986. We happen to know that in 1986 private residential investment was 67.2 billion. In order to predict dishwasher shipments for 1986, we first form the vector of predictors  $\mathbf{z}' = (1, 26, 67.2)$ . Then we compute  $\hat{Y} = \mathbf{z}'\hat{\beta} = 4381$  and

$$\sigma'[1 + \mathbf{z}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{z}]^{1/2} = 352.9[1 + 0.2136]^{1/2} = 388.8.$$

We can now compute a prediction interval for 1986 dishwasher shipments. For example, with  $\alpha_0 = 0.1$ , we get a 90 percent prediction interval using  $T_{23}^{-1}(0.95) = 1.714$ ,

$$(4381 - 1.714 \times 388.8, 4381 + 1.714 \times 388.8) = (3715, 5047).$$

This is quite a wide range due to the large value of  $\sigma'$ . The actual value for dishwasher sales in 1986 was 3915, which is quite far from  $\hat{Y}$ , but still within the interval. ◀

## Multiple $R^2$

In a problem of multiple linear regression, we are typically interested in determining how well the variables  $X_1, \dots, X_k$  explain the observed variation in the random variable  $Y$ . The variation among the  $n$  observed values  $y_1, \dots, y_n$  of  $Y$  can be measured by the value of  $\sum_{i=1}^n (y_i - \bar{y})^2$ , which is the sum of the squares of the deviations of  $y_1, \dots, y_n$  from the average  $\bar{y}$ . Similarly, after the regression of  $Y$  on  $X_1, \dots, X_k$  has been fitted from the data, the variation among the  $n$  observed values of  $Y$  that is still present can be measured by the sum of the squares of the deviations of  $y_1, \dots, y_n$  from the fitted regression. This sum of squares will be equal to the value of  $S^2$  in Eq. (11.5.6) calculated from the observed values, i.e.,  $S^2 = \sum_{i=1}^n (y_i - \hat{y}_i)^2$ , where  $\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_{i1} + \dots + \hat{\beta}_k x_{ik}$ .

It now follows that the proportion of the variation among the observed values  $y_1, \dots, y_n$  that remains unexplained by the fitted regression is

$$\frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2}.$$

In turn, the proportion of the variation among the observed values  $y_1, \dots, y_n$  that is explained by the fitted regression is given by the following value  $R^2$ :

$$R^2 = 1 - \frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2}. \quad (11.5.26)$$

**Example  
11.5.8**

**Unemployment in the 1950s.** For the data in Example 11.5.1, we can compute  $\bar{y}_{10} = 2.82$ , and then  $\sum_{i=1}^{10} (y_i - \bar{y}_{10})^2 = 8.376$ . The value of  $S^2$  is  $(10 - 3) \times \sigma'^2 = 1.126$ , so  $R^2 = 1 - 1.126/8.376 = 0.8656$ . ◀

The value of  $R^2$  must lie in the interval  $0 \leq R^2 \leq 1$ . When  $R^2 = 0$ , the least-squares estimates have the values  $\hat{\beta}_0 = \bar{y}$  and  $\hat{\beta}_1 = \dots = \hat{\beta}_k = 0$ . In this case, the fitted regression function is just the constant function  $y = \bar{y}$ . When  $R^2$  is close to 1, the

variation of the observed values of  $Y$  around the fitted regression function is much smaller than their variation around  $\bar{y}$ .

## Analysis of Residuals

In Sec. 11.3, we described some plots for assessing whether or not the assumptions of the simple linear regression model seem to be met. These same plots, together with some others, are also useful in the general linear model. Recall that, in general, the residuals are the values

$$e_i = y_i - \hat{y}_i = y_i - z_{i0}\hat{\beta}_0 - \cdots - z_{ip-1}\hat{\beta}_{p-1}.$$

**Example  
11.5.9**

**Unemployment in the 1950s.** In this example,  $p = 3$  with  $z_{i0} = 1$  for all  $i$ . We have plotted the residuals against the two predictor variables in the top row of Fig. 11.17 to begin looking for violations of the assumptions. The residual from the first year (1950) is very high, and the remaining residuals appear to lie near a line with positive slope in each plot. This suggests that the first observation does not follow the same pattern as the others. We also performed the regression without the 1950 data point. The residual plots using the new least-squares estimates fit from the 1951–1959 data are in the bottom row of Fig. 11.17. The residuals for 1951–1959 no longer lie on a sloped line. Also, Fig. 11.18 shows normal quantile plots both before and after deleting the 1950 observation. The right plot is much straighter. Of course, such a graphical analysis does not show that the 1950 observation should be deleted. We should check to see if something might have occurred in 1950 that would make a drastic change to the relationship between unemployment and time (such as the start of the war in Korea.)  $\blacktriangleleft$

Another plot that is useful in multiple regression cases is a plot of residuals against fitted values,  $\hat{y}_i$  for  $i = 1, \dots, n$ . (See Exercise 27 to see why this plot is not used in simple linear regression.) This plot helps to reveal dependence between the mean and variance of  $Y$ . (Recall that  $\hat{y}_i$  is an estimate of the mean of  $Y_i$ .) If the residuals are more spread out at one end or the other of this plot, it suggests that the variance of  $Y$  changes as the mean changes, which violates the assumption that all observations have the same variance. The left plot in Fig. 11.19 is a plot of residuals

**Figure 11.17** Plots of residuals against the two predictor variables for Example 11.5.9. Top row: using all data for 1950–1959. Bottom row: using only 1951–1959 data.

**Figure 11.18** Normal quantile plots of residuals for Example 11.5.9. The left plot is from the regression using all 10 observations. The right plot uses only 1951–1959.

**Figure 11.19** Residual plots for Example 11.5.9. Left: plot of residuals against fitted values. Right: plot of pairs of consecutive residuals. Both plots use 1951–1959 data only.

against fitted values for the unemployment data. It appears that the residuals corresponding to low fitted values are more spread out than those corresponding to high fitted values. Methods for responding to such features in a residual plot can be found in texts on regression methodology such as Draper and Smith (1998) and Cook and Weisberg (1999).

If the time of each measurement is available, as in Examples 11.5.1 and 11.5.4, it makes sense to plot residuals against time to see if there is any time dependence not captured by the model. Since time was one of the predictors in each of these examples, we will plot residuals against time when we plot residuals against the predictors. In addition to plotting the residuals against time, we can also plot the nearby residuals against each other to see if small ones tend to occur together and/or if large ones tend to occur together. Let  $v_1, \dots, v_n$  be the residuals ordered by time. We can plot the  $n - 1$  points  $(v_1, v_2), (v_2, v_3), \dots, (v_{n-1}, v_n)$ . If these plotted points follow a pattern, it suggests that there is dependence between observations that are close together in time, called *serial dependence*. This would violate the assumption that the observations are independent. The right plot in Fig. 11.19 is the plot of consecutive pairs of residuals for the unemployment data. The points in this plot cluster in opposite corners, suggesting serial dependence, although the small sample size makes it difficult to be certain.

#### Example 11.5.10

**Dishwasher Shipments.** Consider, again, the data from Example 11.5.4. Plots of residuals against the two predictors, in the top row of Fig. 11.20, reveal a serious problem. There is a curve in the plot of residuals against the year. The residuals are highest in the middle years and lower in the early and late years. This suggests that perhaps the relationship between shipments and time is not linear. The plot of pairs of consecu-

**Figure 11.20** Residual plots for Example 11.5.10. Top row: residuals against predictors. Lower left: residuals against fitted values. Lower right: pairs of successive residuals.

**Figure 11.21** Residual plots for regression of dishwasher shipments on a quadratic function of time. Left: plot of residuals against time. Right: plot of pairs of consecutive residuals.

tive residuals also suggests some time dependence. This could be a result of the same problem that caused the curve in the plot of residuals against time, or it could indicate that successive observations are dependent. It is possible that deviations from the overall trend in dishwasher sales might persist for more than one year. For example, a boom or bust in sales one year might carry over to part of the next year. The normal quantile plot (not shown) is fairly straight.

In order to try to determine whether there is serial dependence or a nonlinear relationship (or both) in these data, we fit another model in which the mean of  $Y$  is a linear function of private residential investment but a quadratic function of time. That is, let  $X_1$  stand for the year (minus 1960), let  $X_2$  stand for private residential investment, and let  $X_3 = X_1^2$ . Then

$$E(Y) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_1^2.$$

The least-squares estimates from this model are  $\hat{\beta}_0 = -1445$ ,  $\hat{\beta}_1 = 206.1$ ,  $\hat{\beta}_2 = 48.5$ , and  $\hat{\beta}_3 = -5.23$ . The observed value of  $\sigma'$  is 235.7. The plots of residuals against time and of consecutive pairs of residuals are in Fig. 11.21. The plot of residuals against time is better than before, but the pairs of consecutive residuals still lie close to a line. This suggests that we need to take serial dependence into account. One book that describes methods for dealing with serial dependence (commonly called *time series analysis*) is Box, Jenkins, and Reinsel (1994).  $\blacktriangleleft$

## Summary

In the general linear model, we assume that the mean of each observation  $Y_i$  can be expressed as  $z_{i0}\beta_0 + \dots + z_{ip-1}\beta_{p-1}$ , where  $\beta_0, \dots, \beta_{p-1}$  are unknown parameters and  $z_{i0}, \dots, z_{ip-1}$  are the observed values of predictors. These predictors can be control variables, other variables that are measured along with  $Y_i$ , or functions of such variables. Least-squares estimators of the parameters are denoted  $\hat{\beta}_0, \dots, \hat{\beta}_{p-1}$ , and they can be calculated according to Eq. (11.5.10) or by using a computer. The variance of each  $Y_i$  is assumed to be the same value  $\sigma^2$ . Every linear combination of the least-squares estimators has a normal distribution and is independent of the unbiased estimator  $\sigma'^2$  of  $\sigma^2$  given in Eq. (11.5.8).

For testing hypotheses about a single  $\beta_j$ , the statistic  $U_j$  in Eq. (11.5.21) has the  $t$  distribution with  $n - p$  degrees of freedom given that the null hypothesis is true. For predicting a future  $Y$  value, we can form prediction intervals using the endpoints given by (11.5.25). We should always plot the residuals  $y_i - \hat{y}_i$  against the predictors, fitted values  $\hat{y}_i$ , and time (if available) to check on the assumptions of the linear regression model. Patterns in these plots can suggest violations of the assumption about the form of the mean of  $Y_i$  and/or the constant variance assumption. We should also make a normal quantile plot. Deviations from a straight line in this plot suggest that the  $Y_i$  values might not have a normal distribution, although violations of the assumptions about the mean and variance can also cause patterns in this plot. If observation time is available, we should also plot pairs of consecutive residuals to look for serial dependence.

## Exercises

**1.** Show that the M.L.E. of  $\sigma^2$  in the general linear model is given by Eq. (11.5.7).

**2.** Prove that  $\sigma'^2$ , defined in Eq. (11.5.8), is an unbiased estimator of  $\sigma^2$ . You may assume that  $S^2/\sigma^2$  has a  $\chi^2$  distribution with  $n - p$  degrees of freedom.

**3.** Consider a regression problem in which, for each value  $x$  of a certain variable  $X$ , the random variable  $Y$  has the normal distribution with mean  $\beta x$  and variance  $\sigma^2$ , where the values of  $\beta$  and  $\sigma^2$  are unknown. Suppose that  $n$  independent pairs of observations  $(x_i, Y_i)$  are obtained. Show that the M.L.E. of  $\beta$  is

$$\hat{\beta} = \frac{\sum_{i=1}^n x_i Y_i}{\sum_{i=1}^n x_i^2}.$$

**4.** For the conditions of Exercise 3, show that  $E(\hat{\beta}) = \beta$  and  $\text{Var}(\hat{\beta}) = \sigma^2 / (\sum_{i=1}^n x_i^2)$ .

**5.** Suppose that when a small amount  $x$  of an insulin preparation is injected into a rabbit, the percentage decrease  $Y$  in blood sugar has the normal distribution with mean  $\beta x$  and variance  $\sigma^2$ , where the values of  $\beta$  and  $\sigma^2$  are unknown. Suppose that when independent observations are made on 10 different rabbits, the observed values of  $x_i$  and  $Y_i$  for  $i = 1, \dots, 10$  are as given in Table 11.14.

Determine the values of the M.L.E.'s  $\hat{\beta}$  and  $\hat{\sigma}^2$ , and the value of  $\text{Var}(\hat{\beta})$ .

**Table 11.14** Data for Exercise 5

$i$	$x_i$	$y_i$	$i$	$x_i$	$y_i$
1	0.6	8	6	2.2	19
2	1.0	3	7	2.8	9
3	1.7	5	8	3.5	14
4	1.7	11	9	3.5	22
5	2.2	10	10	4.2	22

**6.** For the conditions of Exercise 5 and the data in Table 11.14, carry out a test of the following hypotheses:

$$H_0: \beta = 10,$$

$$H_1: \beta \neq 10.$$

**7.** Consider a regression problem in which a patient's reaction  $Y$  to a new drug  $B$  is to be related to his reaction  $X$  to a standard drug  $A$ . Suppose that for each value  $x$  of  $X$ , the regression function is a polynomial of the form  $E(Y) = \beta_0 + \beta_1 x + \beta_2 x^2$ . Suppose also that 10 pairs of observed values are as shown in Table 11.1 on page 690. Under the standard assumptions of the general linear model, determine the values of the M.L.E.'s  $\hat{\beta}_0, \hat{\beta}_1, \hat{\beta}_2$ , and  $\hat{\sigma}^2$ .

**8.** For the conditions of Exercise 7 and the data in Table 11.1, determine the values of  $\text{Var}(\hat{\beta}_0)$ ,  $\text{Var}(\hat{\beta}_1)$ ,  $\text{Var}(\hat{\beta}_2)$ ,  $\text{Cov}(\hat{\beta}_0, \hat{\beta}_1)$ ,  $\text{Cov}(\hat{\beta}_0, \hat{\beta}_2)$ , and  $\text{Cov}(\hat{\beta}_1, \hat{\beta}_2)$ .

**9.** For the conditions of Exercise 7 and the data in Table 11.1, carry out a test of the following hypotheses:

$$\begin{aligned} H_0: \quad & \beta_2 = 0, \\ H_1: \quad & \beta_2 \neq 0. \end{aligned}$$

**10.** For the conditions of Exercise 7 and the data in Table 11.1, carry out a test of the following hypotheses:

$$\begin{aligned} H_0: \quad & \beta_1 = 4, \\ H_1: \quad & \beta_1 \neq 4. \end{aligned}$$

**11.** For the conditions of Exercise 7 and the data given in Table 11.1, determine the value of  $R^2$ , as defined by Eq. (11.5.26).

**12.** Consider a problem of multiple linear regression in which a patient's reaction  $Y$  to a new drug  $B$  is to be related to her reaction  $X_1$  to a standard drug  $A$  and her heart rate  $X_2$ . Suppose that, for all values  $X_1 = x_1$  and  $X_2 = x_2$ , the regression function has the form  $E(Y) = \beta_0 + \beta_1 x_1 + \beta_2 x_2$ , and the values of 10 sets of observations  $(x_{i1}, x_{i2}, Y_i)$  are given in Table 11.2 on page 696. Under the standard assumptions of multiple linear regression, determine the values of the M.L.E.'s  $\hat{\beta}_0$ ,  $\hat{\beta}_1$ ,  $\hat{\beta}_2$ , and  $\hat{\sigma}^2$ .

**13.** For the conditions of Exercise 12 and the data in Table 11.2, determine the values of  $\text{Var}(\hat{\beta}_0)$ ,  $\text{Var}(\hat{\beta}_1)$ ,  $\text{Var}(\hat{\beta}_2)$ ,  $\text{Cov}(\hat{\beta}_0, \hat{\beta}_1)$ ,  $\text{Cov}(\hat{\beta}_0, \hat{\beta}_2)$ , and  $\text{Cov}(\hat{\beta}_1, \hat{\beta}_2)$ .

**14.** For the conditions of Exercise 12 and the data in Table 11.2, carry out a test of the following hypotheses:

$$\begin{aligned} H_0: \quad & \beta_1 = 0, \\ H_1: \quad & \beta_1 \neq 0. \end{aligned}$$

**15.** For the conditions of Exercise 12 and the data in Table 11.2, carry out a test of the following hypotheses:

$$\begin{aligned} H_0: \quad & \beta_2 = -1, \\ H_1: \quad & \beta_2 \neq -1. \end{aligned}$$

**16.** For the conditions of Exercise 12 and the data in Table 11.2, determine the value of  $R^2$ , as defined by Eq. (11.5.26).

**17.** Consider the general linear model in which the observations  $Y_1, \dots, Y_n$  are independent and have normal distributions with the same variance  $\sigma^2$  and in which  $E(Y_i)$  is given by Eq. (11.5.1). Let the matrix  $(\mathbf{Z}'\mathbf{Z})^{-1}$  be defined by Eq. (11.5.19). For all values of  $i$  and  $j$  such that  $i \neq j$ , let the random variable  $A_{ij}$  be defined as follows:

$$A_{ij} = \hat{\beta}_i - \frac{\zeta_{ij}}{\zeta_{jj}} \hat{\beta}_j.$$

Show that  $\text{Cov}(\hat{\beta}_j, A_{ij}) = 0$ , and explain why  $\hat{\beta}_j$  and  $A_{ij}$  are therefore independent.

**18.** For the conditions of Exercise 17, show that  $\text{Var}(A_{ij}) = [\zeta_{ii} - (\zeta_{ij}^2/\zeta_{jj})]\sigma^2$ . Also show that the following random variable  $W^2$  has the  $\chi^2$  distribution with two degrees of freedom:

$$W^2 = \frac{\zeta_{jj}(\hat{\beta}_i - \beta_i)^2 + \zeta_{ii}(\hat{\beta}_j - \beta_j)^2 - 2\zeta_{ij}(\hat{\beta}_i - \beta_i)(\hat{\beta}_j - \beta_j)}{(\zeta_{ii}\zeta_{jj} - \zeta_{ij}^2)\sigma^2}.$$

*Hint:* Show that

$$W^2 = \frac{(\hat{\beta}_j - \beta_j)^2}{\zeta_{jj}\sigma^2} + \frac{[A_{ij} - E(A_{ij})]^2}{\text{Var}(A_{ij})}.$$

**19.** Consider again the conditions of Exercises 17 and 18, and let the random variable  $\sigma'$  be as defined by Eq. (11.5.8).

- a. Show that the random variable  $\sigma^2 W^2 / (2\sigma'^2)$  has the  $F$  distribution with two and  $n - p$  degrees of freedom.
- b. For every two given numbers  $\beta_i^*$  and  $\beta_j^*$ , describe how to carry out a test of the following hypotheses:

$$\begin{aligned} H_0: \quad & \beta_i = \beta_i^* \text{ and } \beta_j = \beta_j^*, \\ H_1: \quad & \text{The hypothesis } H_0 \text{ is not true.} \end{aligned}$$

**20.** For the conditions of Exercise 7 and the data in Table 11.1, carry out a test of the following hypotheses:

$$\begin{aligned} H_0: \quad & \beta_1 = \beta_2 = 0, \\ H_1: \quad & \text{The hypothesis } H_0 \text{ is not true.} \end{aligned}$$

**21.** For the conditions of Exercise 12 and the data in Table 11.2, carry out a test of the following hypotheses:

$$\begin{aligned} H_0: \quad & \beta_1 = 1 \text{ and } \beta_2 = 0, \\ H_1: \quad & \text{The hypothesis } H_0 \text{ is not true.} \end{aligned}$$

**22.** Consider a problem of simple linear regression as described in Sec. 11.2, and let  $R^2$  be defined by Eq. (11.5.26) of this section. Show that

$$R^2 = \frac{[\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})]^2}{[\sum_{i=1}^n (x_i - \bar{x})^2][\sum_{i=1}^n (y_i - \bar{y})^2]}.$$

**23.** Suppose that  $\mathbf{X}$  and  $\mathbf{Y}$  are  $n$ -dimensional random vectors for which the mean vectors  $E(\mathbf{X})$  and  $E(\mathbf{Y})$  exist. Show that  $E(\mathbf{X} + \mathbf{Y}) = E(\mathbf{X}) + E(\mathbf{Y})$ .

**24.** Suppose that  $\mathbf{X}$  and  $\mathbf{Y}$  are independent  $n$ -dimensional random vectors for which the covariance matrices  $\text{Cov}(\mathbf{X})$  and  $\text{Cov}(\mathbf{Y})$  exist. Show that  $\text{Cov}(\mathbf{X} + \mathbf{Y}) = \text{Cov}(\mathbf{X}) + \text{Cov}(\mathbf{Y})$ .

- 25.** Suppose that  $\mathbf{Y}$  is a three-dimensional random vector with coordinates  $Y_1$ ,  $Y_2$ , and  $Y_3$ , and suppose that the covariance matrix of  $\mathbf{Y}$  is as follows:

$$\text{Cov}(\mathbf{Y}) = \begin{bmatrix} 9 & -3 & 0 \\ -3 & 4 & 0 \\ 0 & 0 & 5 \end{bmatrix}.$$

Determine the value of  $\text{Var}(3Y_1 + Y_2 - 2Y_3 + 8)$ .

- 26.** In a general linear model setting with  $p$  predictors, we wish to test the following hypotheses:

$$\begin{aligned} H_0: \quad & \sum_{j=0}^{p-1} c_j \beta_j = c_* , \\ H_1: \quad & \sum_{j=0}^{p-1} c_j \beta_j \neq c_* . \end{aligned} \tag{11.5.27}$$

- a. Show that  $\sum_{j=0}^{p-1} c_j \hat{\beta}_j$  has a normal distribution and find its mean and variance. (You may wish to use Theorems 11.3.1 and 11.5.2.)
- b. Let  $\mathbf{c}' = (c_0, \dots, c_{p-1})$ . If  $H_0$  is true, show that

$$U = \frac{\sum_{j=0}^{p-1} c_j \hat{\beta}_j - c_*}{\sigma' (\mathbf{c}' (\mathbf{Z}' \mathbf{Z})^{-1} \mathbf{c})^{1/2}}$$

- has the  $t$  distribution with  $n - p$  degrees of freedom.
- c. Explain how to test the hypotheses in (11.5.27) at level of significance  $\alpha_0$ .

- 27.** In a simple linear regression problem, the plot of residuals against fitted values would look the same as the plot of residuals against the predictor  $X$  (or a mirror image of it), except for the labeling of the horizontal axis. Explain why this is true.

- 28.** Consider a multiple linear regression problem with design matrix  $\mathbf{Z}$  and observations  $\mathbf{Y}$ . Let  $\mathbf{Z}_1$  be the matrix remaining when at least one column is removed from  $\mathbf{Z}$ . Then  $\mathbf{Z}_1$  is the design matrix for a linear regression problem with fewer predictors and the same data  $\mathbf{Y}$ . Prove that the value of  $R^2$  calculated in the problem using design matrix  $\mathbf{Z}$  is at least as large as the value of  $R^2$  calculated in the problem using design matrix  $\mathbf{Z}_1$ .

- 29.** Calculate the value of  $R^2$  for the dishwasher shipment data (Example 11.5.4) using the model in which the mean of  $Y_i$  is a linear function of both year and private residential investment.

- 30.** Consider again the conditions of Exercise 26. Suppose that the null hypothesis in (11.5.27) is false. Find the distribution of the statistic  $U$  defined in that exercise.

## 11.6 Analysis of Variance

In Sec. 9.6, we studied methods for comparing the means of two normal distributions. In this section, we shall consider experiments in which we need to compare the means of two or more normal distributions. The theory behind the methods developed here is based entirely on results from the general linear model in Sec. 11.5.

### The One-Way Layout

#### Example

##### 11.6.1

**Calories in Hot Dogs.** Moore and McCabe (1999) describe data gathered by *Consumer Reports* (June 1986, pp. 364–67). The data comprise (among other things) calorie contents from 63 brands of hot dogs. (See Table 11.15.) The hot dogs come in four varieties: beef, “meat” (don’t ask), poultry, and “specialty.” (Specialty hot dogs include stuffing such as cheese or chili.) It is interesting to know whether, and to what extent, the different varieties differ in their calorie contents. Data structures of the sort in this example, consisting of several groups of similar random variables, are the subject of this section. ◀

In this section and in the remainder of this chapter, we shall study a topic known as the *analysis of variance*, abbreviated ANOVA. Problems of ANOVA are actually problems of multiple regression in which the design matrix  $\mathbf{Z}$  has a very special form. In other words, the study of ANOVA can be placed within the framework of the general linear model (Definition 11.5.1), if we continue to make

**Table 11.15** Calorie counts in four types of hot dogs for Example 11.6.2

Type	Calorie Count
Beef	186, 181, 176, 149, 184, 190, 158, 139, 175, 148, 152, 111, 141, 153, 190, 157, 131, 149, 135, 132
Meat	173, 191, 182, 190, 172, 147, 146, 139, 175, 136, 179, 153, 107, 195, 135, 140, 138
Poultry	129, 132, 102, 106, 94, 102, 87, 99, 107, 113, 135, 142, 86, 143, 152, 146, 144
Specialty	155, 170, 114, 191, 162, 146, 140, 187, 180

the basic assumptions for such a model: The observations that are obtained are independent and normally distributed; all these observations have the same variance  $\sigma^2$ ; and the mean of each observation can be represented as a linear combination of certain unknown parameters. The theory and methodology of ANOVA were mainly developed by R. A. Fisher during the 1920s.

We shall begin our study of ANOVA by considering a problem known as the *one-way layout*. In this problem, it is assumed that random samples from  $p$  different normal distributions are available, each of these distributions has the same variance  $\sigma^2$ , and the means of the  $p$  distributions are to be compared on the basis of the observed values in the samples. This problem was considered for two populations ( $p = 2$ ) in Sec. 9.6, and the results to be presented here for an arbitrary value of  $p$  will generalize those presented in Sec. 9.6. Specifically, we shall now make the following assumption: For  $i = 1, \dots, p$ , the random variables  $Y_{i1}, \dots, Y_{in_i}$  form a random sample of  $n_i$  observations from the normal distribution with mean  $\mu_i$  and variance  $\sigma^2$ , and the values of  $\mu_1, \dots, \mu_p$  and  $\sigma^2$  are unknown.

In this problem, the sample sizes  $n_1, \dots, n_p$  are not necessarily the same. We shall let  $n = \sum_{i=1}^p n_i$  denote the total number of observations in the  $p$  samples, and we shall assume that all  $n$  observations are independent.

**Example****11.6.2**

**Calories in Hot Dogs.** In Example 11.6.1, the sample sizes are  $n_1 = 20$  (beef),  $n_2 = 17$  (meat),  $n_3 = 17$  (poultry), and  $n_4 = 9$  (specialty). In this case, we let  $\mu_1$  stand for the mean calorie count for brands of beef hot dogs, while  $\mu_2, \mu_3$ , and  $\mu_4$  will stand for the mean calorie count for brands of meat, poultry, and specialty hot dogs, respectively. All calorie counts are assumed to be independent normal random variables with variance  $\sigma^2$ . These data will be analyzed after we develop the ANOVA methodology. 

It follows from the assumptions we have just made that for  $j = 1, \dots, n_i$  and  $i = 1, \dots, p$ , we have  $E(Y_{ij}) = \mu_i$  and  $\text{Var}(Y_{ij}) = \sigma^2$ . Since the expectation  $E(Y_{ij})$  of each observation is equal to one of the  $p$  parameters  $\mu_1, \dots, \mu_p$ , it is obvious that each of these expectations can be regarded as a linear combination of  $\mu_1, \dots, \mu_p$ . Furthermore, we can regard the  $n$  observations  $Y_{ij}$  as the elements of a single long

$n$ -dimensional vector  $\mathbf{Y}$ , which can be written as follows:

$$\mathbf{Y} = \begin{bmatrix} Y_{11} \\ \vdots \\ Y_{1n_1} \\ \vdots \\ Y_{p1} \\ \vdots \\ Y_{pn_p} \end{bmatrix}. \quad (11.6.1)$$

This one-way layout therefore satisfies the conditions of the general linear model. In order to make the one-way layout look exactly like the general linear model, we could define parameters  $\beta_i = \mu_{i+1}$  for  $i = 0, \dots, p - 1$ . Then the  $n \times p$  design matrix,  $\mathbf{Z}$ , has one column for each population. The column corresponding to population 1 has  $n_1$  1's followed by  $n_2 + \dots + n_p$  0's. The column corresponding to population 2 has  $n_1$  0's followed by  $n_2$  1's followed by  $n_3 + \dots + n_p$  0's, and so on. For example, using the hot dog data in Example 11.6.2, the  $\mathbf{Z}$  matrix would be

$$\mathbf{Z} = \left[ \begin{array}{cccc} 1 & 0 & 0 & 0 \\ \vdots & & & \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ \vdots & & & \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ \vdots & & & \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ \vdots & & & \\ 0 & 0 & 0 & 1 \end{array} \right] \quad \begin{array}{l} \left. \right\} 20 \text{ rows} \\ \left. \right\} 17 \text{ rows} \\ \left. \right\} 17 \text{ rows} \\ \left. \right\} 9 \text{ rows} \end{array} \quad (11.6.2)$$

We shall not use the general linear model notation any further in the development of ANOVA, because the parameters  $\mu_1, \dots, \mu_p$  are more natural.

For  $i = 1, \dots, p$ , we shall let  $\bar{Y}_{i+}$  denote the sample mean of the  $n_i$  observations in the  $i$ th sample. Thus,

$$\bar{Y}_{i+} = \frac{1}{n_i} \sum_{j=1}^{n_i} Y_{ij}. \quad (11.6.3)$$

Similar logic to that used in the proof of Theorem 11.2.1 can be used to show that  $\bar{Y}_{i+}$  is the M.L.E., or least-squares estimator, of  $\mu_i$  for  $i = 1, \dots, p$ . Also, the M.L.E. of  $\sigma^2$  is

$$\hat{\sigma}^2 = \frac{1}{n} \sum_{i=1}^p \sum_{j=1}^{n_i} (Y_{ij} - \bar{Y}_{i+})^2. \quad (11.6.4)$$

The details are left to Exercise 1.

## Partitioning a Sum of Squares

**Example**  
**11.6.3**

**Calories in Hot Dogs.** In Examples 11.6.1 and 11.6.2, we notice that the calorie counts within each type differ quite a bit from each other. We need to be able to quantify both the variation within type and the variation between types if we are going to try to address the question of whether or not different types of hot dogs have the same calorie counts.  $\blacktriangleleft$

In a one-way layout, we are often interested in testing the hypothesis that the  $p$  distributions from which the samples were drawn are actually the same; that is, we desire to test the following hypotheses:

$$\begin{aligned} H_0: \quad & \mu_1 = \cdots = \mu_p, \\ H_1: \quad & \text{The hypothesis } H_0 \text{ is not true.} \end{aligned} \quad (11.6.5)$$

For instance, in Example 11.6.2, the null hypothesis  $H_0$  in (11.6.5) would be that the mean calorie counts for all four types of hot dogs are the same, but it would not specify what the common value is. The alternative hypothesis  $H_1$  would be that at least two of the means differ, but it would not specify which means differ nor would it specify by how much the means differ.

Before we develop an appropriate test procedure, we shall carry out some preparatory algebraic manipulations. First, define

$$\bar{Y}_{++} = \frac{1}{n} \sum_{i=1}^p \sum_{j=1}^{n_i} Y_{ij} = \frac{1}{n} \sum_{i=1}^p n_i \bar{Y}_{i+},$$

which is the overall average of all  $n$  observations. We shall partition the sum of squares

$$S_{\text{Tot}}^2 = \sum_{i=1}^p \sum_{j=1}^{n_i} (Y_{ij} - \bar{Y}_{++})^2 \quad (11.6.6)$$

into two smaller sums of squares, each of which will be associated with a certain type of variation among the  $n$  observations. Note that  $S_{\text{Tot}}^2/n$  would be the M.L.E. of  $\sigma^2$  if we believed that all of the observations came from a single normal distribution rather than from  $p$  different normal distributions. This means that we can interpret  $S_{\text{Tot}}^2$  as an overall measure of variation between the  $n$  observations. One of the smaller sums of squares into which we shall partition  $S_{\text{Tot}}^2$  will measure the variation between the  $p$  different samples, and the other sum of squares will measure the variation between the observations within each of the samples. The test of the hypotheses (11.6.5) that we shall develop will be based on the ratio of these two measures of variation. For this reason, the name *analysis of variance* has been used to describe this problem and other related problems.

**Theorem**  
**11.6.1**

**Partitioning the Sum of Squares.** Let  $S_{\text{Tot}}^2$  be as defined in Eq. (11.6.6). Then

$$S_{\text{Tot}}^2 = S_{\text{Resid}}^2 + S_{\text{Betw}}^2, \quad (11.6.7)$$

where

$$S_{\text{Resid}}^2 = \sum_{i=1}^p \sum_{j=1}^{n_i} (Y_{ij} - \bar{Y}_{i+})^2, \quad \text{and} \quad S_{\text{Betw}}^2 = \sum_{i=1}^p n_i (\bar{Y}_{i+} - \bar{Y}_{++})^2.$$

Furthermore,  $S_{\text{Resid}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - p$  degrees of freedom and is independent of  $S_{\text{Betw}}^2$ .

**Table 11.16** General form of ANOVA table for one-way layout

Source of variation	Degrees of freedom	Sum of squares	Mean square
Between samples	$p - 1$	$S_{\text{Betw}}^2$	$S_{\text{Betw}}^2/(p - 1)$
Residuals	$n - p$	$S_{\text{Resid}}^2$	$S_{\text{Resid}}^2/(n - p)$
Total	$n - 1$	$S_{\text{Tot}}^2$	

**Proof** If we consider only the  $n_i$  observations in sample  $i$ , then the sum of squares for those values can be written as follows:

$$\sum_{j=1}^{n_i} (Y_{ij} - \bar{Y}_{++})^2 = \sum_{j=1}^{n_i} (Y_{ij} - \bar{Y}_{i+})^2 + n_i(\bar{Y}_{i+} - \bar{Y}_{++})^2. \quad (11.6.8)$$

It follows from Theorem 8.3.1 that the sum forming the first term on the right side of Eq. (11.6.8), when divided by  $\sigma^2$ , has the  $\chi^2$  distribution with  $n_i - 1$  degrees of freedom and that it is independent of  $\bar{Y}_{i+}$ . Since  $\bar{Y}_{++}$  is a function of  $\bar{Y}_{1+}, \dots, \bar{Y}_{p+}$ , all of which are independent of the first term on the right side of Eq. (11.6.8), it follows that the two terms on the right side of Eq. (11.6.8) are independent.

If we now sum each of the terms in Eq. (11.6.8) over the values of  $i$ , we obtain Eq. (11.6.7). Since all the observations in the  $p$  samples are independent, the two terms on the right side of Eq. (11.6.7) are independent. Also,  $S_{\text{Resid}}^2/\sigma^2$  is the sum of  $p$  independent random variables, with the  $i$ th one having the  $\chi^2$  distribution with  $n_i - 1$  degrees of freedom. Hence,  $S_{\text{Resid}}^2/\sigma^2$  will itself have the  $\chi^2$  distribution with  $\sum_{i=1}^p (n_i - 1) = n - p$  degrees of freedom. ■

As we noted earlier,  $S_{\text{Tot}}^2$  can be regarded as the total variation of the observations around their overall mean. Similarly,  $S_{\text{Resid}}^2$  can be regarded as the total variation of the observations around their particular sample means, or the total residual variation within the samples. Also,  $S_{\text{Betw}}^2$  can be regarded as the total variation of the sample means around the overall mean, or the variation between the sample means. Thus, the total variation  $S_{\text{Tot}}^2$  has been partitioned into two independent components,  $S_{\text{Resid}}^2$  and  $S_{\text{Betw}}^2$ , which represent different types of variations. This partitioning is often summarized in a table, which is called the ANOVA table for the one-way layout and is presented here as Table 11.16.

The numbers in the “Mean square” column of Table 11.16 are just the sums of squares divided by the degrees of freedom. They are used for testing the hypotheses (11.6.5). The degrees of freedom in the “Between samples” and “Total” rows will turn out to be degrees of freedom for random variables with  $\chi^2$  distributions if the null hypothesis in (11.6.5) is true. We shall see why this is true after we develop an appropriate test of the hypotheses (11.6.5).

**Note: The Residual Mean Square Is the Same as the Unbiased Estimator of  $\sigma^2$  in the Regression Setting.** We began this section by expressing the one-way layout as a multiple linear regression problem with data vector  $\mathbf{Y}$  and design matrix  $\mathbf{Z}$ . Compare the M.L.E. of  $\sigma^2, \hat{\sigma}^2$  in Eq. (11.6.4), to the residual mean square in Table 11.16 to see that the two differ only in the constant in the denominator. The M.L.E. is  $S_{\text{Resid}}^2/n$ ,

**Table 11.17** ANOVA table for Example 11.6.4

Source of variation	Degrees of freedom	Sum of squares	Mean square
Between samples	3	19,454	6485
Residuals	59	32,995	559.2
Total	62	52,449	

while the residual mean square is  $S_{\text{Resid}}^2/(n - p)$ . Recall that this last ratio was called  $\sigma^2$  in Sec. 11.5, and is an unbiased estimator of  $\sigma^2$ . (Prove this last fact in Exercise 8.)

**Example  
11.6.4**

Calories in Hot Dogs. The four sample averages in Example 11.6.2 are

$$\bar{Y}_{1+} = 156.85, \quad \bar{Y}_{2+} = 158.71, \quad \bar{Y}_{3+} = 118.76, \quad \bar{Y}_{4+} = 160.56.$$

The overall average is  $\bar{Y}_{++} = 147.60$ . We can now form the ANOVA table in Table 11.17. We shall test the hypotheses (11.6.5) after we develop an appropriate test statistic.  $\blacktriangleleft$

### Testing Hypotheses

In order to test the hypotheses (11.6.5), we need a test statistic that will tend to be larger if  $H_1$  is true than it is if  $H_0$  is true. We also need to know the distribution of the test statistic when  $H_0$  is true.

**Theorem  
11.6.2**

Suppose that  $H_0$  in (11.6.5) is true. Then

$$U^2 = \frac{S_{\text{Betw}}^2/(p-1)}{S_{\text{Resid}}^2/(n-p)} \tag{11.6.9}$$

has the  $F$  distribution with  $p - 1$  and  $n - p$  degrees of freedom.

**Proof** If all  $p$  samples of observations have the same mean, it can be shown (see Exercise 2) that  $S_{\text{Betw}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $p - 1$  degrees of freedom. We have already seen that  $S_{\text{Betw}}^2$  is independent of  $S_{\text{Resid}}^2$ , and  $S_{\text{Resid}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - p$  degrees of freedom. It therefore follows that when  $H_0$  is true,  $U^2$  has the distribution stated in the theorem.  $\blacksquare$

When the null hypothesis  $H_0$  is not true, so that at least two of the  $\mu_i$  values are different, then the expectation of the numerator of  $U^2$  will be larger than it would be if  $H_0$  were true. (See Exercise 11.) The distribution of the denominator of  $U^2$  remains the same regardless of whether or not  $H_0$  is true. A sensible level  $\alpha_0$  test of the hypotheses (11.6.5) would then be to reject  $H_0$  if  $U^2 \geq F_{p-1, n-p}^{-1}(1 - \alpha_0)$ , where  $F_{p-1, n-p}^{-1}$  is the quantile function for the  $F$  distribution with  $p - 1$  and  $n - p$  degrees of freedom. A partial table of  $F$  distribution quantiles is given in the back of this book. It can be shown that this test is also the level  $\alpha_0$  likelihood ratio test procedure. (See Exercise 12.)

**Example  
11.6.5**

**Calories in Hot Dogs.** Suppose that we desire to test the null hypothesis that all four types of hot dogs have the same mean calorie count against the alternative hypothesis that at least two types have different means. The statistic  $U^2$  in Eq. (11.6.9) has the  $F$  distribution with 3 and 59 degrees of freedom if the null hypothesis is true. The observed value of  $U^2$  is the ratio of the between samples mean square to the residual mean square from Table 11.17, namely,  $6485/559.2 = 11.60$ . The  $p$ -value corresponding to this value is  $4.5 \times 10^{-6}$ , so the null hypothesis would be rejected at most standard levels.  $\blacktriangleleft$

**Power of the Test** If the null hypothesis in (11.6.5) is false, then the statistic  $U^2$  in Eq. (11.6.9) has a distribution known as noncentral  $F$ . For more details on the power function, consult a more advanced text such as Scheffé (1959, chapter 2). We shall not discuss the power of ANOVA tests any further.

### Analysis of Residuals

Since the one-way layout is a special case of the general linear model, we make the assumptions of the general linear model when we perform the one-way ANOVA calculations. We should also compute residuals and plot them to see if the assumptions appear reasonable. The residuals are the values  $e_{ij} = Y_{ij} - \bar{Y}_{i+}$ , for  $j = 1, \dots, n_i$  and  $i = 1, \dots, p$ .

**Example  
11.6.6**

**Calories in Hot Dogs.** Figure 11.22 contains a plot of residuals against the categorical variable “hot dog type.” Figure 11.23 contains the plot of residuals against normal quantiles. The points in the normal quantile plot are labeled by the hot dog type. Several disturbing features appear in these plots. First, there are three residuals with large negative values. Second, each of the first three samples appears to contain two distinct subsets, one with low residuals and one with high residuals. There is a gap between the two subsets in each sample. This suggests that there is another variable that we haven’t discussed yet but which distinguishes these two subgroups. If we go back to the reported data (in the original *Consumer Reports* article), we find that the weight of each package and the number of hot dogs per package are also reported. The ratio of these two numbers is the weight of an average hot dog. Figure 11.24 contains a plot of residuals against average hot dog weight. Notice that most of the large residuals come from the larger (heavier) hot dogs and the smaller residuals tend to come from the smaller (lighter) hot dogs. Perhaps a better analysis would have set  $Y$  equal to calories per ounce rather than calories per hot dog.  $\blacktriangleleft$

**Figure 11.22** Plot of residuals against hot dog type.

**Figure 11.23** Plot of residuals against normal quantiles. The points are labeled by the hot dog type.

**Figure 11.24** Plot of residuals against average hot dog weight. The points are labeled by the hot dog type.

## Summary

The one-way layout can be considered as a general linear model, and we can use the methods of Sec. 11.5 to fit the model. However, the hypotheses of most interest in the one-way layout are (11.6.5). These hypotheses concern more than one linear combination of the regression coefficients, and they are not a special case of the hypotheses that we learned how to test in Sec. 11.5. To test these new hypotheses, we developed the analysis of variance (ANOVA) and the ANOVA table. The test statistic is  $U^2$  in Eq. (11.6.9), which has the  $F$  distribution with  $p - 1$  and  $n - p$  degrees of freedom if  $H_0$  is true. The level  $\alpha_0$  test of  $H_0$  is to reject  $H_0$  if  $U^2$  is greater than the  $1 - \alpha_0$  quantile of the appropriate  $F$  distribution.

## Exercises

- In a one-way layout, show that  $\bar{Y}_{i+}$  is the least-squares estimator of  $\mu_i$  by showing that the  $i$ th coordinate of the vector  $(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y}$  is  $\bar{Y}_{i+}$  for  $i = 1, \dots, p$ .
- Assume that  $H_0$  in (11.6.5) is true; that is, all observations have the same mean  $\mu$ . Prove that  $S_{\text{Betw}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $p - 1$  degrees of freedom. Hint: Let

$$\mathbf{X} = \begin{pmatrix} n_1^{1/2}(\bar{Y}_{1+} - \mu)/\sigma \\ \vdots \\ n_p^{1/2}(\bar{Y}_{p+} - \mu)/\sigma \end{pmatrix},$$

then use the same method that was used in Sec. 8.3 to find the distribution of the sample variance. You may use the following fact without proving it:

Let  $\mathbf{u} = ((n_1/n)^{1/2}, \dots, (n_p/n)^{1/2})$ . Then there exists an orthogonal matrix  $\mathbf{A}$  whose first row is  $\mathbf{u}$ .

3. Show that

$$\sum_{i=1}^p n_i (\bar{Y}_{i+} - \bar{Y}_{++})^2 = \sum_{i=1}^p n_i \bar{Y}_{i+}^2 - n \bar{Y}_{++}^2.$$

4. Specimens of milk from a number of dairies in three different districts were analyzed, and the concentration of the radioactive isotope strontium-90 was measured in each specimen. Suppose that specimens were obtained from four dairies in the first district, from six dairies in the second district, and from three dairies in the third district, and that the results measured in picocuries per liter were as follows:

- District 1: 6.4, 5.8, 6.5, 7.7,
- District 2: 7.1, 9.9, 11.2, 10.5, 6.5, 8.8,
- District 3: 9.5, 9.0, 12.1.

- a. Assuming that the variance of the concentration of strontium-90 is the same for the dairies in all three districts, determine the M.L.E. of the mean concentration in each of the districts and the M.L.E. of the common variance.
- b. Test the hypothesis that the three districts have identical concentrations of strontium-90.

5. A random sample of 10 students was selected from the senior class at each of four large high schools, and the score of each of these 40 students on a certain mathematics examination was observed. Suppose that for the 10 students from each school, the sample mean and the sample variance of the scores were as shown in Table 11.18. Test the hypothesis that the senior classes at all four high schools would perform equally well on this examination. Discuss carefully the assumptions that you are making in carrying out this test.

**Table 11.18** Data for Exercise 5

School	Sample mean	Sample variance
1	105.7	30.3
2	102.0	54.4
3	93.5	25.0
4	110.8	36.4

6. Suppose that a random sample of size  $n$  is taken from the normal distribution with mean  $\mu$  and variance  $\sigma^2$ . Before the sample is observed, the random variables are divided into  $p$  groups of sizes  $n_1, \dots, n_p$ , where  $n_i \geq 2$  for  $i = 1, \dots, p$  and  $\sum_{i=1}^p n_i = n$ . For  $i = 1, \dots, p$ , let  $Q_i$  denote the sum of the squares of the deviations of the  $n_i$  observations in the  $i$ th group from the sample mean of those  $n_i$  observations. Find the distribution of the sum  $Q_1 + \dots + Q_p$  and the distribution of the ratio  $Q_1/Q_p$ .

7. Verify that the  $t$  test presented in Sec. 9.6 for comparing the means of two normal distributions is the same as the test presented in this section for the one-way layout with  $p = 2$  by verifying that if  $U$  is defined by Eq. (9.6.3), then  $U^2$  is equal to the expression given in Eq. (11.6.9).

8. Show that in a one-way layout the following statistic is an unbiased estimator of  $\sigma^2$ :

$$\frac{1}{n-p} \sum_{i=1}^p \sum_{j=1}^{n_i} (Y_{ij} - \bar{Y}_{i+})^2.$$

9. In a one-way layout, show that for all values of  $i, i'$ , and  $j$ , where  $j = 1, \dots, n_i, i = 1, \dots, p$ , and  $i' = 1, \dots, p$ , the following three random variables  $W_1, W_2$ , and  $W_3$  are uncorrelated with each other:

$$W_1 = Y_{ij} - \bar{Y}_{i+}, \quad W_2 = \bar{Y}_{i'+} - \bar{Y}_{++}, \quad W_3 = \bar{Y}_{++}.$$

10. In 1973, the President of Texaco, Inc., made a statement to a U.S. Senate subcommittee concerned with air and water pollution. The committee was concerned with, among other things, the noise levels associated with automobile filters. He cited the data in Table 11.19 from a study that included vehicles of three different sizes.

**Table 11.19** Data for Exercise 10

Vehicle size	Noise values
Small	810, 820, 820, 835, 835, 835
Medium	840, 840, 840, 845, 855, 850
Large	785, 790, 785, 760, 760, 770

- a. Construct the ANOVA table for these data.
- b. Compute the  $p$ -value for the null hypothesis that all three sizes of vehicles produce the same level of noise on average.

11. Assume that the null hypothesis  $H_0$  in (11.6.5) is false. Prove that the expected value of  $S_{\text{Betw}}^2$  is  $(p-1)\sigma^2 + \sum_{i=1}^p n_i(\mu_i - \bar{\mu})^2$ , where  $\bar{\mu} = \frac{1}{n} \sum_{i=1}^p n_i \mu_i$ .

12. Prove that the level  $\alpha_0$  likelihood ratio test of hypotheses (11.6.5) in the one-way layout is to reject  $H_0$  if  $U^2 > F_{p-1, n-p}^{-1}(1-\alpha_0)$ . Hint: First, partition  $\sum_{j=1}^{n_i} (y_{ij} - \mu_i)^2$  in a manner similar to Eq. (11.6.8). Then, replace  $\bar{Y}_{++}$  by a constant, say,  $\mu$ , in the formula for  $S_{\text{Tot}}^2$ , and partition the result in a manner similar to Eq. (11.6.7). There will be one extra term.

13. Suppose that the null hypothesis in (11.6.5) is true. Prove that  $S_{\text{Tot}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $n-1$  degrees of freedom.

**14.** A popular alternative parameterization of the one-way layout is the following. Let  $\mu = \frac{1}{n} \sum_{i=1}^p n_i \mu_i$ , and define  $\alpha_i = \mu_i - \mu$ . This makes  $E(Y_{ij}) = \mu + \alpha_i$ .

- a. Prove that  $\sum_{i=1}^p n_i \alpha_i = 0$ .
- b. Prove that the M.L.E. of  $\alpha_i$  is  $\bar{Y}_{i+} - \bar{Y}_{++}$ .

- c. Prove that the null hypothesis  $H_0$  in (11.6.5) is equivalent to  $\alpha_1 = \dots = \alpha_p = 0$ .
- d. Prove that the mean of  $S_{\text{Betw}}^2$  is  $(p-1)\sigma^2 + \sum_{i=1}^p n_i \alpha_i^2$ .

## ★ 11.7 The Two-Way Layout

In Sec. 11.6, we learned how to analyze several samples that differed in some characteristic. For example, we analyzed data collected from hot dogs that differed by the type of meat from which they were made. Suppose that, in addition to differing by the type of meat, the hot dogs had also differed by being labeled either “low fat” or not. This would have given us two different characteristics to form the basis for comparisons. In this section, we shall study how to analyze data consisting of observations that differ on two characteristics.

### The Two-Way Layout with One Observation in Each Cell

**Example  
11.7.1**

**Radioactive Isotope in Milk.** Suppose that in an experiment to measure the concentration of a certain radioactive isotope in milk, specimens of milk are obtained from four different dairies, and the concentration of the isotope in each specimen is measured by three different methods. If we let  $Y_{ij}$  denote the measurement that is made for the specimen from the  $i$ th dairy by using the  $j$ th method, for  $i = 1, 2, 3, 4$  and  $j = 1, 2, 3$ , then in this example there will be a total of 12 measurements. There are two main questions of interest in this example. The first is whether the concentration of the isotope is the same in the milk of all four dairies. The second question is whether the three different methods produce concentration measurements that appear to differ. ◀

A problem of the type in Example 11.7.1, in which the value of the random variable being observed is affected by two factors, is called a *two-way layout*. In the general two-way layout, there are two factors, which we shall call  $A$  and  $B$ . We shall assume that there are  $I$  possible different values, or different *levels*, of factor  $A$ , and that there are  $J$  possible different values, or different *levels*, of factor  $B$ . For  $i = 1, \dots, I$  and  $j = 1, \dots, J$ , an observation  $Y_{ij}$  of the variable being studied is obtained when factor  $A$  has the value  $i$  and factor  $B$  has the value  $j$ . If the  $IJ$  observations are arranged in a matrix as in Table 11.20, then  $Y_{ij}$  is the observation in the  $(i, j)$  cell of the matrix.

We shall continue to make the assumptions of the general linear model for the two-way layout. Thus, we shall assume that all the observations  $Y_{ij}$  are independent, each observation has a normal distribution, and all the observations have the same variance  $\sigma^2$ . In this section, we specialize the assumption about the mean  $E(Y_{ij})$  as follows: We shall assume not only that  $E(Y_{ij})$  depends on the values  $i$  and  $j$  of the two factors, but also that there exist numbers  $\theta_1, \dots, \theta_I$  and  $\psi_1, \dots, \psi_J$  such that

$$E(Y_{ij}) = \theta_i + \psi_j \quad \text{for } i = 1, \dots, I \quad \text{and } j = 1, \dots, J. \quad (11.7.1)$$

Thus, Eq. (11.7.1) states that the value of  $E(Y_{ij})$  is the sum of the following two effects: an effect  $\theta_i$  due to factor  $A$  having the value  $i$ , and an effect  $\psi_j$  due to factor  $B$

		Factor B				
		Factor A	1	2	...	J
1			$Y_{11}$	$Y_{12}$	...	$Y_{1J}$
2			$Y_{21}$	$Y_{22}$		$Y_{2J}$
:						
$I$			$Y_{I1}$	$Y_{I2}$		$Y_{IJ}$

having the value  $j$ . For this reason, the assumption that  $E(Y_{ij})$  has the form given in Eq. (11.7.1) is called an *assumption of additivity* of the effects of the factors.

The meaning of the assumption of additivity can be clarified by the following example. Consider the sale of  $I$  different magazines at  $J$  different newsstands. Suppose that a particular newsstand sells on the average 30 more copies per week of magazine 1 than of magazine 2. Then by the assumption of additivity, it must also be true that each of the other  $J - 1$  newsstands sells on the average 30 more copies per week of magazine 1 than of magazine 2. Similarly, suppose that the sales of a particular magazine are on the average 50 more copies per week at newsstand 1 than at newsstand 2. Then by the assumption of additivity, it must also be true that the sales of each of the other  $I - 1$  magazines are on the average 50 more copies per week at newsstand 1 than at newsstand 2. The assumption of additivity is a very restrictive assumption because it does not allow for the possibility that a particular magazine may sell unusually well at some particular newsstand. In Sec. 11.8, we shall consider models in which we do not make the assumption of additivity.

Even though we assume in the general two-way layout that the effects of the factors  $A$  and  $B$  are additive, the numbers  $\theta_i$  and  $\psi_j$  that satisfy Eq. (11.7.1) are not uniquely defined. We can add an arbitrary constant  $c$  to each of the numbers  $\theta_1, \dots, \theta_I$  and subtract the same constant  $c$  from each of the numbers  $\psi_1, \dots, \psi_J$  without changing the value of  $E(Y_{ij})$  for any of the  $IJ$  observations. Hence, it does not make sense to try to estimate the value of  $\theta_i$  or  $\psi_j$  from the given observations, since neither  $\theta_i$  nor  $\psi_j$  is uniquely defined. In order to avoid this difficulty, we shall express  $E(Y_{ij})$  in terms of different parameters. The following assumption is equivalent to the assumption of additivity.

We shall assume that there exist numbers  $\mu, \alpha_1, \dots, \alpha_I$ , and  $\beta_1, \dots, \beta_J$  such that

$$\sum_{i=1}^I \alpha_i = 0 \quad \text{and} \quad \sum_{j=1}^J \beta_j = 0, \quad (11.7.2)$$

and

$$E(Y_{ij}) = \mu + \alpha_i + \beta_j \quad \text{for } i = 1, \dots, I \text{ and } j = 1, \dots, J. \quad (11.7.3)$$

There is an advantage in expressing  $E(Y_{ij})$  in this way. If the values of  $E(Y_{ij})$  for  $i = 1, \dots, I$  and  $j = 1, \dots, J$  are a set of numbers that satisfy Eq. (11.7.1) for *some* set of values of  $\theta_1, \dots, \theta_I$  and  $\psi_1, \dots, \psi_J$ , then there exists a *unique* set of values of  $\mu, \alpha_1, \dots, \alpha_I$ , and  $\beta_1, \dots, \beta_J$  that satisfy Eqs. (11.7.2) and (11.7.3) (see Exercise 3).

The parameter  $\mu$  is called the *overall mean*, or the *grand mean*, since it follows from Eqs. (11.7.2) and (11.7.3) that

$$\mu = \frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J E(Y_{ij}). \quad (11.7.4)$$

The parameters  $\alpha_1, \dots, \alpha_I$  are called the *effects of factor A*, and the parameters  $\beta_1, \dots, \beta_J$  are called the *effects of factor B*.

It follows from Eq. (11.7.2) that  $\alpha_I = -\sum_{i=1}^{I-1} \alpha_i$  and  $\beta_J = -\sum_{j=1}^{J-1} \beta_j$ . Hence, each expectation  $E(Y_{ij})$  in Eq. (11.7.3) can be expressed as a particular linear combination of the  $I + J - 1$  parameters  $\mu, \alpha_1, \dots, \alpha_{I-1}$ , and  $\beta_1, \dots, \beta_{J-1}$ . Therefore, if we regard the  $IJ$  observations as elements of a single long  $IJ$ -dimensional vector, then the two-way layout satisfies the conditions of the general linear model. In a practical problem, however, it is not convenient to actually replace  $\alpha_I$  and  $\beta_J$  with their expressions in terms of the other  $\alpha_i$ 's and  $\beta_j$ 's, because this replacement would destroy the symmetry that is present in the experiment among the different levels of each factor.

### Estimating the Parameters

The following result is straightforward, but tedious, to prove.

**Theorem** Define

**11.7.1**

$$\begin{aligned}\bar{Y}_{i+} &= \frac{1}{J} \sum_{j=1}^J Y_{ij} \quad \text{for } i = 1, \dots, I, \\ \bar{Y}_{+j} &= \frac{1}{I} \sum_{i=1}^I Y_{ij} \quad \text{for } j = 1, \dots, J, \\ \bar{Y}_{++} &= \frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J Y_{ij} = \frac{1}{I} \sum_{i=1}^I \bar{Y}_{i+} = \frac{1}{J} \sum_{j=1}^J \bar{Y}_{+j}.\end{aligned}\quad (11.7.5)$$

Then the M.L.E.'s (and least-squares estimators) of  $\mu, \alpha_1, \dots, \alpha_I$ , and  $\beta_1, \dots, \beta_J$  are as follows:

$$\begin{aligned}\hat{\mu} &= \bar{Y}_{++}, \\ \hat{\alpha}_i &= \bar{Y}_{i+} - \bar{Y}_{++} \quad \text{for } i = 1, \dots, I, \\ \hat{\beta}_j &= \bar{Y}_{+j} - \bar{Y}_{++} \quad \text{for } j = 1, \dots, J.\end{aligned}\quad (11.7.6)$$

The M.L.E. of  $\sigma^2$  will be

$$\hat{\sigma}^2 = \frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \hat{\mu} - \hat{\alpha}_i - \hat{\beta}_j)^2 = \frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \hat{Y}_{ij})^2. \quad \blacksquare$$

It is easily verified (see Exercise 6) that  $\sum_{i=1}^I \hat{\alpha}_i = \sum_{j=1}^J \hat{\beta}_j = 0$ ;  $E(\hat{\mu}) = \mu$ ;  $E(\hat{\alpha}_i) = \alpha_i$  for  $i = 1, \dots, I$ ; and  $E(\hat{\beta}_j) = \beta_j$  for  $j = 1, \dots, J$ . Because  $E(Y_{ij}) = \mu + \alpha_i + \beta_j$ , the M.L.E. of  $E(Y_{ij})$  is

$$\hat{Y}_{ij} = \bar{Y}_{i+} + \bar{Y}_{+j} - \bar{Y}_{++} = \hat{\mu} + \hat{\alpha}_i + \hat{\beta}_j,$$

which is also called the *fitted value* for  $Y_{ij}$ .

**Example**  
**11.7.2**

Radioactive Isotope in Milk. Consider again Example 11.7.1. Suppose that the concentrations of the radioactive isotope measured in picocuries per liter by three different methods in specimens of milk from four dairies are as shown in Table 11.21. From

**Table 11.21** Data for Example 11.7.2

Dairy	Method		
	1	2	3
1	6.4	3.2	6.9
2	8.5	7.8	10.1
3	9.3	6.0	9.6
4	8.8	5.6	8.4

**Table 11.22** Fitted values for observations in Example 11.7.2

Dairy	Method		
	1	2	3
1	6.2	3.6	6.7
2	9.5	6.9	10.0
3	9.0	6.4	9.5
4	8.3	5.7	8.8

Table 11.21, the row averages are  $\bar{Y}_{1+} = 5.5$ ,  $\bar{Y}_{2+} = 8.8$ ,  $\bar{Y}_{3+} = 8.3$ , and  $\bar{Y}_{4+} = 7.6$ ; the column averages are  $\bar{Y}_{+1} = 8.25$ ,  $\bar{Y}_{+2} = 5.65$ , and  $\bar{Y}_{+3} = 8.75$ ; and the average of all the observations is  $\bar{Y}_{++} = 7.55$ . Hence, by Eq. (11.7.6), the values of the M.L.E.'s are  $\hat{\mu} = 7.55$ ,  $\hat{\alpha}_1 = -2.05$ ,  $\hat{\alpha}_2 = 1.25$ ,  $\hat{\alpha}_3 = 0.75$ ,  $\hat{\alpha}_4 = 0.05$ ,  $\hat{\beta}_1 = 0.70$ ,  $\hat{\beta}_2 = -1.90$ , and  $\hat{\beta}_3 = 1.20$ .

The fitted values  $\hat{Y}_{ij}$  for all of the observations are given in Table 11.22. By comparing the observed values in Table 11.21 with the fitted values in Table 11.22, we see that the differences between corresponding terms are generally small. These small differences indicate that the model used in the two-way layout, which assumes the additivity of the effects of the two factors, provides a good fit for the observed values. Finally, it is found from Tables 11.21 and 11.22 that

$$\sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \hat{Y}_{ij})^2 = 2.74.$$

Hence, by Theorem 11.7.1,  $\hat{\sigma}^2 = 2.74/12 = 0.228$ . ◀

### Partitioning the Sum of Squares

We shall partition the total sum of squares in much the same way that we did in Sec. 11.6. Begin with

$$S_{\text{Tot}}^2 = \sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \bar{Y}_{++})^2. \quad (11.7.7)$$

We shall now partition the sum of squares  $S_{\text{Tot}}^2$  into three smaller sums of squares. Each of these smaller sums of squares will be associated with a certain type of variation among the observations  $Y_{ij}$ . Each of them (divided by  $\sigma^2$ ) will have a  $\chi^2$  distribution if certain null hypotheses are true, and they will be mutually independent whether or not the null hypotheses are true. Therefore, just as in the one-way layout, we can construct tests of certain null hypotheses based on an analysis of variance, that is, on an analysis of these different types of variation.

**Theorem 11.7.2** **Partitioning the Sum of Squares.** Let  $S_{\text{Tot}}^2$  be as defined in Eq. (11.7.7). Then

$$S_{\text{Tot}}^2 = S_{\text{Resid}}^2 + S_A^2 + S_B^2, \quad (11.7.8)$$

where

$$\begin{aligned} S_{\text{Resid}}^2 &= \sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++})^2, \\ S_A^2 &= J \sum_{i=1}^I (\bar{Y}_{i+} - \bar{Y}_{++})^2, \\ S_B^2 &= I \sum_{j=1}^J (\bar{Y}_{+j} - \bar{Y}_{++})^2. \end{aligned}$$

Furthermore,  $S_{\text{Resid}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $(I-1)(J-1)$  degrees of freedom, and the three component sums of squares are mutually independent.

**Proof** We shall begin by rewriting  $S_{\text{Tot}}^2$  as follows:

$$S_{\text{Tot}}^2 = \sum_{i=1}^I \sum_{j=1}^J [(Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++}) + (\bar{Y}_{i+} - \bar{Y}_{++}) + (\bar{Y}_{+j} - \bar{Y}_{++})]^2. \quad (11.7.9)$$

By expanding the right side of Eq. (11.7.9), we obtain (see Exercise 8) Eq. (11.7.8).

It can be shown that the random variables  $S_{\text{Resid}}^2$ ,  $S_A^2$ , and  $S_B^2$  are independent. (See Exercise 9 for a related result.) Furthermore, it can be shown that  $S_{\text{Resid}}^2$  has the  $\chi^2$  distribution with  $IJ - (I + J - 1) = (I-1)(J-1)$  degrees of freedom. ■

It is easy to see that  $S_A^2$  measures the variation of the sample means for the different levels of factor  $A$  around the overall sample mean. Similarly,  $S_B^2$  measures the variation of the sample means for the different levels of factor  $B$  around the overall sample mean. By using relations (11.7.6), we can rewrite  $S_{\text{Resid}}^2$  as

$$S_{\text{Resid}}^2 = \sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \hat{\mu} - \hat{\alpha}_i - \hat{\beta}_j)^2 = \sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \hat{Y}_{ij})^2.$$

This makes it clear that  $S_{\text{Resid}}^2$  measures the residual variation, that is, the variation between the observations not explained by the model. The partitioning is summarized in Table 11.23, which is the ANOVA table for the two-way layout. As in the case of the one-way layout, the degrees of freedom will turn out to be degrees of freedom for various  $\chi^2$  random variables when certain null hypotheses are true.

**Table 11.23** General ANOVA table for two-way layout

Source of variation	Degrees of freedom	Sum of squares	Mean square
Factor A	$I - 1$	$S_A^2$	$S_A^2/(I - 1)$
Factor B	$J - 1$	$S_B^2$	$S_B^2/(J - 1)$
Residuals	$(I - 1)(J - 1)$	$S_{\text{Resid}}^2$	$S_{\text{Resid}}^2/[(I - 1)(J - 1)]$
Total	$IJ - 1$	$S_{\text{Tot}}^2$	

**Table 11.24** ANOVA table Example 11.7.3

Source of variation	Degrees of freedom	Sum of squares	Mean square
Dairy	3	18.99	6.33
Method	2	22.16	11.08
Residuals	6	2.74	0.4567
Total	11	43.89	

**Example  
11.7.3**

Radioactive Isotope in Milk. Using the estimates calculated in Example 11.7.2, we can compute the ANOVA table in Table 11.24. After we develop appropriate test statistics, we can use Table 11.24 to test hypotheses about the effects of the two factors.

## Testing Hypotheses

**Example  
11.7.4**

Radioactive Isotope in Milk. Consider again the situation described in Example 11.7.2 involving four dairies and three measurement methods. We might be interested in testing that, for each of the three methods of measurement, the distributions of concentration of isotope do not differ from one dairy to the next. If we regard the dairy as factor  $A$  and the measurement method as factor  $B$ , then the hypothesis that  $\alpha_i = 0$  for  $i = 1, \dots, I$  means that for each method of measurement, the concentration of the isotope has the same distribution for all four dairies. In other words, there are no differences among the dairies. Alternatively, we might be interested in testing the hypothesis that, for each dairy, the three methods of measurement all produce the same distribution of concentration of isotope. For this case, the hypothesis that  $\beta_j = 0$  for  $j = 1, \dots, J$  means that for each dairy, the three methods of measurement yield the same distribution for the concentration of the isotope. However, this hypothesis does not state that regardless of which of the three different methods is applied to a particular specimen of milk, the same value would be obtained. Because of the inherent variability of the measurements, the hypothesis states only that the values yielded by the three methods have the same normal distribution.

In a problem involving a two-way layout, we are often interested in testing the hypothesis that one or both of the factors has no effect on the distribution of the observations. In other words, we are often interested either in testing the hypothesis that all of the effects  $\alpha_1, \dots, \alpha_I$  of factor  $A$  are equal to 0 or in testing the hypothesis that all of the effects  $\beta_1, \dots, \beta_J$  of factor  $B$  are equal to 0 or in testing that all of the  $\alpha_i$  and  $\beta_j$  are 0. For the remainder of the discussion of testing hypotheses, it will be useful to define

$$\sigma' = \left( \frac{S_{\text{Resid}}^2}{(I-1)(J-1)} \right)^{1/2}. \quad (11.7.10)$$

**Theorem 11.7.3** Consider the following hypotheses:

$$\begin{aligned} H_0: \quad \alpha_i &= 0 \quad \text{for } i = 1, \dots, I, \\ H_1: \quad &\text{The hypothesis } H_0 \text{ is not true.} \end{aligned} \quad (11.7.11)$$

If  $H_0$  is true, then the following random variable has the  $F$  distribution with  $I-1$  and  $(I-1)(J-1)$  degrees of freedom:

$$U_A^2 = \frac{S_A^2}{(I-1)\sigma'^2}. \quad (11.7.12)$$

Similarly, suppose next that the following hypotheses are to be tested:

$$\begin{aligned} H_0: \quad \beta_j &= 0 \quad \text{for } j = 1, \dots, J, \\ H_1: \quad &\text{The hypothesis } H_0 \text{ is not true.} \end{aligned} \quad (11.7.13)$$

When the null hypothesis  $H_0$  is true, the following statistic has the  $F$  distribution with  $J-1$  and  $(I-1)(J-1)$  degrees of freedom:

$$U_B^2 = \frac{S_B^2}{(J-1)\sigma'^2}. \quad (11.7.14)$$

Finally, suppose that the following hypotheses are to be tested:

$$\begin{aligned} H_0: \quad \alpha_i &= 0 \text{ for } i = 1, \dots, I, \quad \text{and} \quad \beta_j = 0 \text{ for } j = 1, \dots, J, \\ H_1: \quad &\text{The hypothesis } H_0 \text{ is not true.} \end{aligned} \quad (11.7.15)$$

When the null hypothesis  $H_0$  is true, the following statistic has the  $F$  distribution with  $I+J-2$  and  $(I-1)(J-1)$  degrees of freedom:

$$U_{A+B}^2 = \frac{S_A^2 + S_B^2}{(I+J-2)\sigma'^2}. \quad (11.7.16)$$

For each case above, a level  $\alpha_0$  test of the hypotheses is to reject  $H_0$  if the corresponding statistic ( $U_A^2$ ,  $U_B^2$ , or  $U_{A+B}^2$ ) is at least as large as the  $1 - \alpha_0$  quantile of the corresponding  $F$  distribution.

**Proof** We shall prove the claim for hypotheses (11.7.11). The proof for hypotheses (11.7.13) is virtually identical. The proof for hypotheses (11.7.15) is similar and is left for Exercise 16. Since  $\sum_{j=1}^J \beta_j = 0$ , we conclude that  $\bar{Y}_{i+}$  has the normal distribution with mean  $\mu$  and variance  $\sigma^2/J$  for each  $i = 1, \dots, I$ . Since the  $\bar{Y}_{i+}$  are independent and  $\bar{Y}_{++}$  is the average of  $\bar{Y}_{1+}, \dots, \bar{Y}_{I+}$ , Theorem 8.3.1 says that the following

random variable has the  $\chi^2$  distribution with  $I - 1$  degrees of freedom:

$$\frac{J}{\sigma^2} \sum_{i=1}^I (\bar{Y}_{i+} - \bar{Y}_{++})^2 = \frac{S_A^2}{\sigma^2}.$$

Since  $S_{\text{Resid}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $(I - 1)(J - 1)$  degrees of freedom, we now conclude that

$$\frac{S_A^2/(I - 1)}{S_{\text{Resid}}^2/[(I - 1)(J - 1)]} \quad (11.7.17)$$

has the  $F$  distribution with  $I - 1$  and  $(I - 1)(J - 1)$  degrees of freedom. It is easy to see that the random variable in (11.7.17) is the same as  $U_A^2$  defined in Eq. (11.7.12).

Let  $F_{I-1, (I-1)(J-1)}^{-1}(1 - \alpha_0)$  denote the  $1 - \alpha_0$  quantile of the  $F$  distribution with  $I - 1$  and  $(I - 1)(J - 1)$  degrees of freedom. Let  $\delta$  be the test that rejects  $H_0$  if  $U_A^2 \geq F_{I-1, (I-1)(J-1)}^{-1}(1 - \alpha_0)$ , and let  $\pi(\theta|\delta)$  be its power function for each parameter vector  $\theta$ . Since  $U_A^2$  has the stated  $F$  distribution for all parameter vectors  $\theta$  that are consistent with  $H_0$ , it follows that for each such  $\theta$ ,  $\pi(\theta|\delta) = \alpha_0$ , and  $\delta$  is a level  $\alpha_0$  test.  $\blacksquare$

Notice that  $U_A^2$  in Theorem 11.7.3 is the ratio of the factor  $A$  mean square to the residuals mean square in Table 11.23. When the null hypothesis  $H_0$  in (11.7.12) is not true, the value of  $\alpha_i = E(\bar{Y}_{i+} - \bar{Y}_{++})$  is not 0 for at least one value of  $i$ . Hence, the expectation of the numerator of  $U_A^2$  will be larger than it would be when  $H_0$  is true. (See Exercise 1.) The distribution of the denominator of  $U_A^2$  remains the same regardless of whether  $H_0$  is true. It can also be shown that the test in Theorem 11.7.3 is also the level  $\alpha_0$  likelihood ratio test procedure for the hypotheses (11.7.11).

### Example 11.7.5

**Testing for Differences among the Dairies.** Suppose now that it is desired to use the observed values in Table 11.21 to test the hypothesis that there are no differences among the dairies, that is, to test the hypotheses (11.7.11). In this example, the statistic  $U_A^2$  defined by Eq. (11.7.12) has the  $F$  distribution with three and six degrees of freedom. Using the ANOVA table in Table 11.24, we find that  $U_A^2 = 6.33/0.4567 = 13.86$ . The corresponding  $p$ -value is smaller than 0.025, the smallest value in the tables in this book. Using statistical software, we compute the  $p$ -value to be about 0.004. So the hypothesis that there are no differences among the dairies would be rejected at all levels of significance of 0.004 or more.  $\blacktriangleleft$

### Example 11.7.6

**Testing for Differences among the Methods of Measurement.** Suppose next that it is desired to use the observed values in Table 11.21 to test the hypothesis that each of the effects of the different methods of measurement is equal to 0, that is, to test the hypotheses (11.7.13). In this example, the statistic  $U_B^2$  defined by Eq. (11.7.14) has the  $F$  distribution with two and six degrees of freedom. Using the ANOVA table in Table 11.24, we find that  $U_B^2 = 11.08/0.4567 = 24.26$ . The  $p$ -value corresponding to this observation is about 0.001, so the hypothesis that there are no differences among the methods would be rejected at all levels of significance greater than 0.001.  $\blacktriangleleft$

## Summary

The two-way layout can be considered as a general linear model, but the hypotheses of interest concern more than one linear combination of the regression coefficients. An ANOVA table was developed for the two-way layout that can be used for forming test statistics for various hypotheses. When we have only one observation at each

combination of factor levels, we assume that the effects of the two factors are additive. Then we can test the two null hypotheses that each of the two factors make no difference to the means of the observations. These tests make use of the test statistics  $U_A^2$  in Eq. (11.7.12) and  $U_B^2$  in Eq. (11.7.14). If the corresponding null hypotheses are true, each of these statistics has an  $F$  distribution.

## Exercises

---

1. Suppose that the null hypothesis  $H_0$  in (11.7.11) is false. Show that  $E(S_A^2) = (I - 1)\sigma^2 + J \sum_{i=1}^I \alpha_i^2$ .

2. Consider a two-way layout in which the values of  $E(Y_{ij})$  for  $i = 1, \dots, I$  and  $j = 1, \dots, J$  are as given in each of the following four matrices. For each matrix, state whether the effects of the factors are additive.

a.

		Factor B	
		1	2
Factor A	1	5	7
	2	10	14

b.

		Factor B	
		1	2
Factor A	1	3	6
	2	4	7

c.

		Factor B			
		1	2	3	4
Factor A	1	3	-1	0	3
	2	8	4	5	8
3	4	0	1	4	

d.

		Factor B			
		1	2	3	4
Factor A	1	1	2	3	4
	2	2	4	6	8
3	3	6	9	12	

3. Show that if the effects of the factors in a two-way layout are additive, then there exist unique numbers  $\mu$ ,  $\alpha_1, \dots, \alpha_I$ , and  $\beta_1, \dots, \beta_J$  that satisfy Eqs. (11.7.2) and (11.7.3). Hint: Let  $\mu$  be the average of all  $\theta_i + \psi_j$  values, let  $\alpha_i$  equal  $\theta_i$  minus the average of the  $\theta_i$ 's, and similarly for  $\beta_j$ .

4. Suppose that in a two-way layout, with  $I = 2$  and  $J = 2$ , the values of  $E(Y_{ij})$  are as given in part (b) of Exercise 2. Determine the values of  $\mu, \alpha_1, \alpha_2, \beta_1$ , and  $\beta_2$  that satisfy Eqs. (11.7.2) and (11.7.3).

5. Suppose that in a two-way layout, with  $I = 3$  and  $J = 4$ , the values of  $E(Y_{ij})$  are as given in part (c) of Exercise 2. Determine the values of  $\mu, \alpha_1, \alpha_2, \alpha_3, \beta_1, \dots, \beta_4$  that satisfy Eqs. (11.7.2) and (11.7.3).

6. Verify that if  $\hat{\mu}, \hat{\alpha}_i$ , and  $\hat{\beta}_j$  are defined by Eq. (11.7.6), then  $\sum_{i=1}^I \hat{\alpha}_i = \sum_{j=1}^J \hat{\beta}_j = 0$ ;  $E(\hat{\mu}) = \mu$ ;  $E(\hat{\alpha}_i) = \alpha_i$  for  $i = 1, \dots, I$ ; and  $E(\hat{\beta}_j) = \beta_j$  for  $j = 1, \dots, J$ .

7. Show that if  $\hat{\mu}, \hat{\alpha}_i$ , and  $\hat{\beta}_j$  are defined by Eq. (11.7.6), then

$$\text{Var}(\hat{\mu}) = \frac{1}{IJ}\sigma^2,$$

$$\text{Var}(\hat{\alpha}_i) = \frac{I-1}{IJ}\sigma^2 \quad \text{for } i = 1, \dots, I,$$

$$\text{Var}(\hat{\beta}_j) = \frac{J-1}{IJ}\sigma^2 \quad \text{for } j = 1, \dots, J.$$

8. Show that the right sides of Eqs. (11.7.9) and (11.7.8) are equal.

9. Show that in a two-way layout, for all values of  $i, j, i'$ , and  $j'$  ( $i$  and  $i' = 1, \dots, I$ ;  $j$  and  $j' = 1, \dots, J$ ), the following four random variables  $W_1, W_2, W_3$ , and  $W_4$  are uncorrelated with one another:

$$W_1 = Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++},$$

$$W_2 = \bar{Y}_{i'+} - \bar{Y}_{++}, \quad W_3 = \bar{Y}_{+j'} - \bar{Y}_{++},$$

$$W_4 = \bar{Y}_{++}.$$

10. Show that

$$\sum_{i=1}^I (\bar{Y}_{i+} - \bar{Y}_{++})^2 = \sum_{i=1}^I \bar{Y}_{i+}^2 - I\bar{Y}_{++}^2$$

and

$$\sum_{j=1}^J (\bar{Y}_{+j} - \bar{Y}_{++})^2 = \sum_{j=1}^J \bar{Y}_{+j}^2 - J\bar{Y}_{++}^2.$$

**11.** Show that

$$\begin{aligned} & \sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++})^2 \\ &= \sum_{i=1}^I \sum_{j=1}^J Y_{ij}^2 - J \sum_{i=1}^I \bar{Y}_{i+}^2 - I \sum_{j=1}^J \bar{Y}_{+j}^2 + IJ\bar{Y}_{++}^2. \end{aligned}$$

**12.** In a study to compare the reflective properties of various paints and various plastic surfaces, three different types of paint were applied to specimens of five different types of plastic surfaces. Suppose that the observed results in appropriate coded units were as shown in Table 11.25. Determine the values of  $\hat{\mu}$ ,  $\hat{\alpha}_1$ ,  $\hat{\alpha}_2$ ,  $\hat{\alpha}_3$ , and  $\hat{\beta}_1, \dots, \hat{\beta}_5$ .

**Table 11.25** Data for Exercises 12–15

Type of paint	Type of surface				
	1	2	3	4	5
1	14.5	13.6	16.3	23.2	19.4
2	14.6	16.2	14.8	16.8	17.3
3	16.2	14.0	15.5	18.7	21.0

**13.** For the conditions of Exercise 12 and the data in Table 11.25, determine the value of the least-squares estimate of  $E(Y_{ij})$  for  $i = 1, 2, 3$ , and  $j = 1, \dots, 5$ , and determine the value of  $\hat{\sigma}^2$ .

**14.** For the conditions of Exercise 12 and the data in Table 11.25, test the hypothesis that the reflective properties of the three different types of paint are the same.

**15.** For the conditions of Exercise 12 and the data in Table 11.25, test the hypothesis that the reflective properties of the five different types of plastic surfaces are the same.

**16.** Prove the claim in Theorem 11.7.3 about the distribution of  $U_{A+B}^2$ .

## ★ 11.8 The Two-Way Layout with Replications

Suppose that we obtain more than one observation in each cell of a two-way layout. In addition to testing hypotheses about the separate effects of the two factors, we can also test the hypothesis that the additivity assumption (11.7.3) holds. However, the interpretations of the separate effects of the two factors are more complicated if the additivity assumption fails. When the additivity assumption fails, we say that there is interaction between the two factors.

### The Two-Way Layout with $K$ Observations in Each Cell

**Example**  
**11.8.1**

**Gasoline Consumption.** Suppose that an experiment is carried out by an automobile manufacturer to investigate whether a certain device, installed on an automobile, affects the amount of gasoline consumed by the automobile. The manufacturer produces three different models of automobiles, namely, a compact model, an intermediate model, and a standard model. Five cars of each model, which were equipped with this device, were driven over a fixed route through city traffic, and the gasoline consumption of each car was measured. Also, five cars of each model, which were not equipped with this device, were driven over the same route, and the gasoline consumption of each of these cars was measured. The results, in liters of gasoline consumed, are given in Table 11.26.

The same sorts of questions that arose in Sec. 11.7 arise here. For example, are the mean gasoline consumptions different for cars with and without the device? Are the mean gasoline consumptions different for the three car models? An additional question can be addressed in an example like this in which there are multiple obser-

**Table 11.26** Data for Example 11.8.1

	Compact model	Intermediate model	Standard model
<b>Equipped with device</b>	8.3	9.2	11.6
	8.9	10.2	10.2
	7.8	9.5	10.7
	8.5	11.3	11.9
	9.4	10.4	11.0
<b>Not equipped with device</b>	8.7	8.2	12.4
	10.0	10.6	11.7
	9.7	10.1	10.0
	7.9	11.3	11.1
	8.4	10.8	11.8

vations under each combination of factors. We can ask whether the effect (if any) of the device is different for the different car models.  $\blacktriangleleft$

We shall continue to consider problems of ANOVA involving a two-way layout. Now, however, instead of having just a single observation  $Y_{ij}$  for each combination of  $i$  and  $j$ , we shall have  $K$  independent observations  $Y_{ijk}$  for  $k = 1, \dots, K$ . In other words, instead of having just one observation in each cell of Table 11.20, we have  $K$  i.i.d. observations. The  $K$  observations in each cell are obtained under similar experimental conditions and are called *replications*. The total number of observations in this two-way layout with replications is  $IJK$ . We continue to assume that all the observations are independent, each observation has a normal distribution, and all the observations have the same variance  $\sigma^2$ .

We shall let  $\theta_{ij}$  denote the mean of each of the  $K$  observations in the  $(i, j)$  cell. Thus, for  $i = 1, \dots, I$ ;  $j = 1, \dots, J$ ; and  $k = 1, \dots, K$ , we have

$$E(Y_{ijk}) = \theta_{ij}. \quad (11.8.1)$$

In a two-way layout with replications, we shall no longer assume, as we did in Sec. 11.7, that the effects of the two factors are additive. Here we can assume that the expectations  $\theta_{ij}$  are arbitrary numbers. As we shall see later in this section, we can then test the hypothesis that the effects are additive.

It is easy to verify that the M.L.E., or least-squares estimator, of  $\theta_{ij}$  is simply the sample mean of the  $K$  observations in the  $(i, j)$  cell. Thus,

$$\hat{\theta}_{ij} = \frac{1}{K} \sum_{k=1}^K Y_{ijk} = \bar{Y}_{ij+}. \quad (11.8.2)$$

The M.L.E. of  $\sigma^2$  is therefore

$$\hat{\sigma}^2 = \frac{1}{IJK} \sum_{i=1}^I \sum_{j=1}^J \sum_{k=1}^K (Y_{ijk} - \bar{Y}_{ij+})^2. \quad (11.8.3)$$

In order to identify and discuss the effects of the two factors, and to examine the possibility that these effects are additive, it is helpful to replace the parameters  $\theta_{ij}$ , for  $i = 1, \dots, I$  and  $j = 1, \dots, J$ , with a new set of parameters  $\mu, \alpha_i, \beta_j$ , and  $\gamma_{ij}$ . These new parameters are defined by the following relations:

$$\theta_{ij} = \mu + \alpha_i + \beta_j + \gamma_{ij} \quad \text{for } i = 1, \dots, I \text{ and } j = 1, \dots, J, \quad (11.8.4)$$

and

$$\begin{aligned} \sum_{i=1}^I \alpha_i &= 0, & \sum_{j=1}^J \beta_j &= 0, \\ \sum_{i=1}^I \gamma_{ij} &= 0 \quad \text{for } j = 1, \dots, J, \\ \sum_{j=1}^J \gamma_{ij} &= 0 \quad \text{for } i = 1, \dots, I. \end{aligned} \quad (11.8.5)$$

It can be shown (see Exercise 1) that corresponding to each set of numbers  $\theta_{ij}$  for  $i = 1, \dots, I$  and  $j = 1, \dots, J$ , there exist unique numbers  $\mu, \alpha_i, \beta_j$ , and  $\gamma_{ij}$  that satisfy Eqs. (11.8.4) and (11.8.5).

The parameter  $\mu$  is called the *overall mean* or the *grand mean*. The parameters  $\alpha_1, \dots, \alpha_I$  are called the *main effects of factor A*, and the parameters  $\beta_1, \dots, \beta_J$  are called the *main effects of factor B*. The parameters  $\gamma_{ij}$ , for  $i = 1, \dots, I$  and  $j = 1, \dots, J$ , are called the *interactions*. It can be seen from Eqs. (11.8.1) and (11.8.4) that the effects of the factors A and B are additive if and only if all the interactions vanish, that is, if and only if  $\gamma_{ij} = 0$  for every combination of values of  $i$  and  $j$ .

The notation that has been developed in Sections 11.6 and 11.7 will again be used here. We shall replace a subscript of  $Y_{ijk}$  with a plus sign to indicate that we have summed the values of  $Y_{ijk}$  over all possible values of that subscript. If we have made two or three summations, we shall use two or three plus signs. We shall then place a bar over  $Y$  to indicate that we have divided this sum by the number of terms in the summation and have thereby obtained an average of the values of  $Y_{ijk}$  for the subscript or subscripts involved in the summation. For example,

$$\begin{aligned} \bar{Y}_{ij+} &= \frac{1}{K} \sum_{k=1}^K Y_{ijk}, \\ \bar{Y}_{+++} &= \frac{1}{IK} \sum_{i=1}^I \sum_{k=1}^K Y_{ijk}, \end{aligned}$$

and  $\bar{Y}_{+++}$  denotes the average of all  $IJK$  observations.

Similar logic to that used in the proof of Theorem 11.2.1 can be used to prove the following result. The details are left to Exercises 2 and 5).

**Theorem 11.8.1** The M.L.E.'s (and least-squares estimators) of  $\mu, \alpha_i$ , and  $\beta_j$  are as follows:

$$\begin{aligned} \hat{\mu} &= \bar{Y}_{+++,} \\ \hat{\alpha}_i &= \bar{Y}_{i++} - \bar{Y}_{+++,} \quad \text{for } i = 1, \dots, I, \\ \hat{\beta}_j &= \bar{Y}_{++j} - \bar{Y}_{+++,} \quad \text{for } j = 1, \dots, J. \end{aligned} \quad (11.8.6)$$

Also, for  $i = 1, \dots, I$  and  $j = 1, \dots, J$ ,

**Table 11.27** Cell averages in Example 11.8.2

	Compact model	Intermediate model	Standard model	Average for row
<b>Equipped with device</b>	$\bar{Y}_{11+} = 8.58$	$\bar{Y}_{12+} = 10.12$	$\bar{Y}_{13+} = 11.08$	$\bar{Y}_{1++} = 9.9267$
<b>Not equipped with device</b>	$\bar{Y}_{21+} = 8.94$	$\bar{Y}_{22+} = 10.20$	$\bar{Y}_{23+} = 11.40$	$\bar{Y}_{2++} = 10.1800$
<b>Average for column</b>	$\bar{Y}_{+1+} = 8.76$	$\bar{Y}_{+2+} = 10.16$	$\bar{Y}_{+3+} = 11.24$	$\bar{Y}_{+++} = 10.0533$

$$\begin{aligned}\hat{\gamma}_{ij} &= \bar{Y}_{ij+} - (\hat{\mu} + \hat{\alpha}_i + \hat{\beta}_j) \\ &= \bar{Y}_{ij+} - \bar{Y}_{i++} - \bar{Y}_{+j+} + \bar{Y}_{+++}.\end{aligned}\quad (11.8.7)$$

Also, for all values of  $i$  and  $j$ ,  $E(\hat{\mu}) = \mu$ ,  $E(\hat{\alpha}_i) = \alpha_i$ ,  $E(\hat{\beta}_j) = \beta_j$ , and  $E(\hat{\gamma}_{ij}) = \gamma_{ij}$ .

**Example  
11.8.2**

**Gasoline Consumption.** In Example 11.8.1, let the A factor be the device, and let the B factor be the car model. Then we have  $I = 2$ ,  $J = 3$ , and  $K = 5$ . The average value  $\bar{Y}_{ij+}$  for each of the six cells in Table 11.26 is presented in Table 11.27, which also gives the average value  $\bar{Y}_{i++}$  for each of the two rows, the average value  $\bar{Y}_{+j+}$  for each of the three columns, and the average value  $\bar{Y}_{+++}$  of all 30 observations.

It follows from Table 11.27 and Eqs. (11.8.6) and (11.8.7) that the values of the M.L.E.'s, or least-squares estimators, in this example are

$$\begin{array}{llll}\hat{\mu} &= 10.0533, & \hat{\alpha}_1 &= -0.1267, & \hat{\alpha}_2 &= 0.1267, \\ \hat{\beta}_1 &= -1.2933, & \hat{\beta}_2 &= 0.1067, & \hat{\beta}_3 &= 1.1867, \\ \hat{\gamma}_{11} &= -0.0533, & \hat{\gamma}_{12} &= 0.0867, & \hat{\gamma}_{13} &= -0.0333, \\ \hat{\gamma}_{21} &= 0.0533, & \hat{\gamma}_{22} &= -0.0867, & \hat{\gamma}_{23} &= 0.0333.\end{array}$$

In this example, the estimates of the interactions  $\hat{\gamma}_{ij}$  are small for all values of  $i$  and  $j$ . ◀

### Partitioning the Sum of Squares

Consider now the total sum of squares,

$$S_{\text{Tot}}^2 = \sum_{i=1}^I \sum_{j=1}^J \sum_{k=1}^K (Y_{ijk} - \bar{Y}_{+++})^2. \quad (11.8.8)$$

We shall now indicate how  $S_{\text{Tot}}^2$  can be partitioned into four smaller independent sums of squares, each of which is associated with a particular type of variation among the observations. Under various null hypotheses, each sum of squares (divided by  $\sigma^2$ ) will have a  $\chi^2$  distribution.

**Theorem  
11.8.2**

Let  $S_{\text{Tot}}^2$  be as defined in Eq. (11.8.8). Then

$$S_{\text{Tot}}^2 = S_A^2 + S_B^2 + S_{\text{Int}}^2 + S_{\text{Resid}}^2, \quad (11.8.9)$$

where

$$\begin{aligned} S_A^2 &= JK \sum_{i=1}^I (\bar{Y}_{i++} - \bar{Y}_{+++})^2, \\ S_B^2 &= IK \sum_{j=1}^J (\bar{Y}_{+j+} - \bar{Y}_{+++})^2, \\ S_{\text{Int}}^2 &= K \sum_{i=1}^I \sum_{j=1}^J (\bar{Y}_{ij+} - \bar{Y}_{i++} - \bar{Y}_{+j+} + \bar{Y}_{+++})^2, \\ S_{\text{Resid}}^2 &= \sum_{i=1}^I \sum_{j=1}^J \sum_{k=1}^K (Y_{ijk} - \bar{Y}_{ij+})^2. \end{aligned} \quad (11.8.10)$$

In addition,  $S_{\text{Resid}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $IJ(K - 1)$  degrees of freedom. If all  $\alpha_i = 0$ , then  $S_A^2/\sigma^2$  has the  $\chi^2$  distribution with  $I - 1$  degrees of freedom. If all  $\beta_j = 0$ , then  $S_B^2/\sigma^2$  has the  $\chi^2$  distribution with  $J - 1$  degrees of freedom. If all  $\gamma_{ij} = 0$ , then  $S_{\text{Int}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $(I - 1)(J - 1)$  degrees of freedom. The four sums of squares are mutually independent.

**Proof** The proof of (11.8.9) is left to the reader in Exercise 7.

The random variable  $S_{\text{Resid}}^2/\sigma^2$  is the sum of  $IJ$  independent random variables of the form  $\sum_{k=1}^K (Y_{ijk} - \bar{Y}_{ij+})^2/\sigma^2$ . According to Theorem 8.3.1, each of these  $IJ$  random variables has the  $\chi^2$  distribution with  $K - 1$  degrees of freedom. Hence, the sum of all  $IJ$  of them has the  $\chi^2$  distribution with  $IJ(K - 1)$  degrees of freedom. If all of the  $\alpha_i = 0$ , then  $\bar{Y}_{1++}, \dots, \bar{Y}_{I++}$  all have the normal distribution with mean  $\mu$  and variance  $\sigma^2/JK$ . Theorem 8.3.1 implies that  $S_A^2/\sigma^2$  has the  $\chi^2$  distribution with  $I - 1$  degrees of freedom. Similarly, if all  $\beta_j = 0$ , then  $S_B^2/\sigma^2$  has the  $\chi^2$  distribution with  $J - 1$  degrees of freedom.

The number of degrees of freedom for  $S_{\text{Int}}^2$  can be determined as follows: If all of the  $\gamma_{ij} = 0$ , then the additivity assumption holds, and  $S_{\text{Int}}^2$  is the same as  $S_{\text{Resid}}^2$  from Sec. 11.7 except for the fact that each  $\bar{Y}_{ij+}$  has the normal distribution with mean  $\mu + \alpha_i + \beta_j$  and variance  $\sigma^2/K$  instead of variance  $\sigma^2$ . This means that if all  $\gamma_{ij} = 0$ , then  $S_{\text{Int}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $(I - 1)(J - 1)$  degrees of freedom.

Finally, it can be shown that all of the sums of squares in relations (11.8.10) are independent (see Exercise 8 for a related result). ■

The claims in Theorem 11.8.2 are summarized in Table 11.28, which is the ANOVA table for the two-way layout with  $K$  observations per cell.

### Example 11.8.3

**Gasoline Consumption.** Using the sample means computed in Example 11.8.2, we can form the ANOVA table in Table 11.29. We shall use the mean squares in Table 11.29 to test various hypotheses about the effects of the factors after we develop test procedures. ◀

### Testing Hypotheses

As mentioned before, the effects of the factors  $A$  and  $B$  are additive if and only if all the interactions  $\gamma_{ij}$  vanish. Hence, to test whether the effects of the factors are

**Table 11.28** General ANOVA table for two-way layout with replication

Source of variation	Degrees of freedom	Sum of squares	Mean square
Main effects of $A$	$I - 1$	$S_A^2$	$S_A^2/(I - 1)$
Main effects of $B$	$J - 1$	$S_B^2$	$S_B^2/(J - 1)$
Interactions	$(I - 1)(J - 1)$	$S_{\text{Int}}^2$	$S_{\text{Int}}^2/[(I - 1)(J - 1)]$
Residuals	$IJ(K - 1)$	$S_{\text{Resid}}^2$	$S_{\text{Resid}}^2/[IJ(K - 1)]$
Total	$IJK - 1$	$S_{\text{Tot}}^2$	

**Table 11.29** ANOVA table for data from Example 11.8.2.

Source of variation	Degrees of freedom	Sum of squares	Mean square
Main effects of device	1	0.4813	0.4813
Main effects of model	2	30.92	15.46
Interactions	2	0.1147	0.0573
Residuals	24	18.22	0.7590
Total	29	49.73	

additive, we must test the following hypotheses:

$$\begin{aligned} H_0: \quad \gamma_{ij} = 0 & \quad \text{for } i = 1, \dots, I \text{ and } j = 1, \dots, J, \\ H_1: \quad \text{The hypothesis } H_0 \text{ is not true.} \end{aligned} \tag{11.8.11}$$

It follows from Theorem 11.8.2 that when the null hypothesis  $H_0$  is true, the random variable  $S_{\text{Int}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $(I - 1)(J - 1)$  degrees of freedom. Furthermore, regardless of whether or not  $H_0$  is true, the independent random variable  $S_{\text{Resid}}^2/\sigma^2$  has the  $\chi^2$  distribution with  $IJ(K - 1)$  degrees of freedom. Thus, when  $H_0$  is true, the following random variable  $U_{AB}^2$  has the  $F$  distribution with  $(I - 1)(J - 1)$  and  $IJ(K - 1)$  degrees of freedom:

$$U_{AB}^2 = \frac{IJ(K - 1)S_{\text{Int}}^2}{(I - 1)(J - 1)S_{\text{Resid}}^2}, \tag{11.8.12}$$

which is also the ratio of the interaction mean square to the residual mean square.

The null hypothesis  $H_0$  would be rejected at level  $\alpha_0$  if

$$U_{AB}^2 \geq F_{(I-1)(J-1), IJ(K-1)}^{-1}(1 - \alpha_0),$$

where  $F_{(I-1)(J-1), IJ(K-1)}^{-1}$  is the quantile function of the  $F$  distribution with  $(I - 1)(J - 1)$  and  $IJ(K - 1)$  degrees of freedom.

**Example  
11.8.4**

**Gasoline Consumption.** Suppose that it is desired to use the data from Example 11.8.2 to test the null hypothesis that the effects of equipping a car with the device and using a particular model are additive, against the alternative that these effects are not additive. In other words, suppose that it is desired to test the hypotheses (11.8.11). Using the mean squares in Table 11.29 and Eq. (11.8.12), we compute that  $U_{AB}^2 = 0.0573/0.7590 = 0.076$ . The corresponding  $p$ -value can be found using statistical software, and its value is 0.9275. Hence, the null hypothesis that the effects are additive would not be rejected at any common level of significance.  $\blacktriangleleft$

If the null hypothesis  $H_0$  in (11.8.11) is rejected, then it suggests that at least some of the interactions  $\gamma_{ij}$  are not 0. Therefore, the means of the observations for certain combinations of  $i$  and  $j$  will be larger than the means of the observations for other combinations, and both factor  $A$  and factor  $B$  affect these means. In this case, because both factor  $A$  and factor  $B$  affect the means of the observations, there is not usually any further interest in testing whether either the main effects  $\alpha_1, \dots, \alpha_I$  or the main effects  $\beta_1, \dots, \beta_J$  are zero.

On the other hand, if the null hypothesis  $H_0$  in (11.8.11) is not rejected (as is the case in Example 11.8.4), then we might decide to act as if all the interactions are 0. If, in addition, all the main effects  $\alpha_1, \dots, \alpha_I$  were 0, then the mean value of each observation would not depend in any way on the value of  $i$ . In this case, factor  $A$  would have no effect on the observations. Therefore, if the null hypothesis  $H_0$  in (11.8.11) is not rejected, we might be interested in testing the following hypotheses:

$$\begin{aligned} H_0: \quad & \alpha_i = 0 \text{ and } \gamma_{ij} = 0 \text{ for } i = 1, \dots, I \text{ and } j = 1, \dots, J, \\ H_1: \quad & \text{The hypothesis } H_0 \text{ is not true.} \end{aligned} \quad (11.8.13)$$

Indeed, we might be interested in testing these hypotheses even if we had not first tested the hypotheses (11.8.11).

According to Theorem 11.8.2, if  $H_0$  is true, then  $S_A^2/\sigma^2$  and  $S_{\text{Int}}^2/\sigma^2$  are independent having  $\chi^2$  distributions with  $I - 1$  and  $(I - 1)(J - 1)$  degrees of freedom, respectively. It follows that, when  $H_0$  in (11.8.13) is true, the following random variable  $U_A^2$  has the  $F$  distribution with  $I - 1 + (I - 1)(J - 1) = (I - 1)J$  and  $IJ(K - 1)$  degrees of freedom:

$$U_A^2 = \frac{IJ(K - 1)[S_A^2 + S_{\text{Int}}^2]}{(I - 1)JS_{\text{Resid}}^2}. \quad (11.8.14)$$

If we did not test the hypotheses (11.8.11) first, then we can reject  $H_0$  in (11.8.13) at level  $\alpha_0$  if  $U_A^2 \geq F_{(I-1)J, IJ(K-1)}^{-1}(1 - \alpha_0)$ .

If we first tested (11.8.11) and failed to reject the null hypothesis, there are two important considerations to emphasize before proceeding with a test of (11.8.13). First, the size of the second test, the test of (11.8.13), should be calculated *conditional* on having failed to reject the null hypothesis in (11.8.11). That is, if the second test is to reject the null hypothesis in (11.8.13) if  $T \geq c$  (for some statistic  $T$ ), then the size of the second test should be the conditional probability

$$\Pr(T \geq c \mid U_{AB}^2 < F_{(I-1)(J-1), IJ(K-1)}^{-1}(1 - \alpha_0)). \quad (11.8.15)$$

Calculation of this conditional probability is beyond the scope of this book, but it can be approximated using simulation methods that will be introduced in Chapter 12. (See Example 12.3.4 for an illustration.)

The second consideration involves the choice of test statistic  $T$  for testing (11.8.13). For the case in which we did not first test (11.8.11), the statistic  $U_A^2$  in

(11.8.14) is a sensible test statistic. However, if we have already failed to reject the null hypothesis in (11.8.11), a better test statistic might be

$$V_A^2 = \frac{IJ(K-1)S_A^2}{(I-1)S_{\text{Resid}}^2}. \quad (11.8.16)$$

One reason for this is that, with  $T = V_A^2$ , the probability in (11.8.15) will often be closer to  $\alpha_0$  than with  $T = U_A^2$ . For instance, if  $IJ(K-1)$  is large and  $H_0$  is true, then  $S_{\text{Resid}}^2$  should be close to  $\sigma^2$  with high probability. In this case, since  $S_{\text{Int}}^2$  and  $S_A^2$  are independent random variables, the random variables  $V_A^2$  and  $U_{AB}^2$  should be nearly independent as well. This will make the test based on  $V_A^2$  nearly independent of whether or not the test based on  $U_{AB}^2$  rejected its null hypothesis. On the other hand, because

$$U_A^2 = \frac{1}{J}[V_A^2 + (J-1)U_{AB}^2],$$

we see that the dependence between  $U_A^2$  and  $U_{AB}^2$  is likely to be quite high under all circumstances.

So, if we first test (11.8.11) and fail to reject the null hypothesis, we should then use  $V_A^2$  to test (11.8.13). We would then reject the null hypothesis if  $V_A^2 > c$ , where  $c$  is some constant. Unfortunately, we still cannot find a useable expression for  $c$  other than to note that the size of this second test, conditional on the first test, is (11.8.15) with  $T = V_A^2$ . We can use simulation methods to compute this if necessary. (See Example 12.3.4.) The overall size of this two-stage procedure is larger than  $\alpha_0$ . (See Exercise 19.) In practice, it is common to let  $c = F_{I-1, IJ(K-1)}^{-1}(1 - \alpha_0)$  and pretend as if (11.8.15) with  $T = V_A^2$  is essentially  $\alpha_0$ .

**Example  
11.8.5**

**Gasoline Consumption.** Suppose now that it is desired to test the null hypothesis that the device has no effect on gasoline consumption for all of the car models tested, against the alternative that the device does affect gasoline consumption. In other words, suppose that it is desired to test the hypotheses (11.8.13). If we had not first tested (11.8.11), then we would use Eq. (11.8.14) and the numbers in Table 11.29 to compute  $U_A^2 = 24(0.4813 + 0.1147)/[3(18.22)] = 0.2616$ . The corresponding  $p$ -value from the  $F$  distribution with 3 and 24 degrees of freedom is 0.8523. Hence, the null hypothesis would not be rejected at the usual levels of significance.

On the other hand, since we did test (11.8.11) first, we should instead use  $V_A^2 = 0.4813/0.7590 = 0.6341$ . We cannot compute the exact conditional  $p$ -value associated with this observed value. However, using the method to be described in Example 12.3.4, we can approximate the  $p$ -value to be about 0.43, given that we failed to reject the null hypothesis in (11.8.11). We can also use the method of Example 12.3.4 to approximate the probabilities in (11.8.15) for  $T = U_A^2$  and for  $T = V_A^2$ . With  $\alpha_0 = 0.05$ , these approximations are, respectively, 0.019 and 0.048. Notice how close the test based on  $V_A^2$  comes to having the nominal size  $\alpha_0 = 0.05$ , while the conditional size of the test based on  $U_A^2$  is much smaller.  $\blacktriangleleft$

Similarly, we may want to find out whether all the main effects of factor  $B$ , as well as the interactions, are 0. In this case, we would test the following hypotheses:

$$\begin{aligned} H_0: \quad \beta_j &= 0 \text{ and } \gamma_{ij} = 0 \quad \text{for } i = 1, \dots, I, \text{ and } j = 1, \dots, J, \\ H_1: \quad \text{The hypothesis } H_0 &\text{ is not true.} \end{aligned} \quad (11.8.17)$$

By analogy with Eq. (11.8.14), it follows that when  $H_0$  is true, the following random variable  $U_B^2$  has the  $F$  distribution with  $I(J - 1)$  and  $IJ(K - 1)$  degrees of freedom:

$$U_B^2 = \frac{IJ(K - 1)[S_B^2 + S_{\text{Int}}^2]}{I(J - 1)S_{\text{Resid}}^2}. \quad (11.8.18)$$

Again, if we do not first test (11.8.11), then the hypothesis  $H_0$  should be rejected at level  $\alpha_0$  if  $U_B^2 > F_{I(J-1),IJ(K-1)}^{-1}(1 - \alpha_0)$ . If we test (11.8.11) first and fail to reject the null hypothesis, then we should reject  $H_0$  in (11.8.17) if  $V_B^2$  is too large, where  $V_B^2 = \frac{IJ(K-1)S_B^2}{(J-1)S_{\text{Resid}}^2}$ . The conditional level of this test must be computed by simulation, also.

In a given problem, if the null hypothesis in (11.8.11) is not rejected and the null hypotheses in both (11.8.13) and (11.8.17) are rejected, then we may be willing to proceed with further studies and experimentation by using a model in which it is assumed that the effects of factor  $A$  and factor  $B$  are approximately additive and the effects of both factors are important.

The results obtained in Example 11.8.5 do not provide any indication that the device is effective. Nevertheless, it can be seen from Table 11.27 that for each of the three models, the average consumption of gasoline for the cars that were equipped with the device is smaller than the average consumption for the cars that were not so equipped. If we assume that the effects of the device and the model of automobile are additive, then regardless of the model of the automobile that is used, the M.L.E. of the reduction in gasoline consumption over the given route that is achieved by equipping an automobile with the device is  $\hat{\alpha}_2 - \hat{\alpha}_1 = 0.2534$  liter.

### The Two-Way Layout with Unequal Numbers of Observations in the Cells

Consider again a two-way layout with  $I$  rows and  $J$  columns, but suppose now that instead of there being  $K$  observations in each cell, some cells have more observations than others. For  $i = 1, \dots, I$  and  $j = 1, \dots, J$ , we shall let  $K_{ij}$  denote the number of observations in the  $(i, j)$  cell. Thus, the total number of observations is  $\sum_{i=1}^I \sum_{j=1}^J K_{ij}$ . We shall assume that every cell contains at least one observation, and we shall again let  $Y_{ijk}$  denote the  $k$ th observation in the  $(i, j)$  cell. For each value of  $i$  and  $j$ , the values of the subscript  $k$  are  $1, \dots, K_{ij}$ . We shall also assume, as before, that all the observations  $Y_{ijk}$  are independent; each has a normal distribution;  $\text{Var}(Y_{ijk}) = \sigma^2$  for all values of  $i$ ,  $j$ , and  $k$ ; and  $E(Y_{ijk}) = \mu + \alpha_i + \beta_j + \gamma_{ij}$ , where these parameters satisfy the conditions given in Eq. (11.8.5).

As usual, we shall let  $\bar{Y}_{ij+}$  denote the average of the observations in the  $(i, j)$  cell. It can then be shown that for  $i = 1, \dots, I$  and  $j = 1, \dots, J$ , the M.L.E.'s, or least-squares estimators, are as follows:

$$\begin{aligned} \hat{\mu} &= \frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J \bar{Y}_{ij+}, \quad \hat{\alpha}_i = \frac{1}{J} \sum_{j=1}^J \bar{Y}_{ij+} - \hat{\mu}, \\ \hat{\beta}_j &= \frac{1}{I} \sum_{i=1}^I \bar{Y}_{ij+} - \hat{\mu}, \quad \hat{\gamma}_{ij} = \bar{Y}_{ij+} - \hat{\mu} - \hat{\alpha}_i - \hat{\beta}_j. \end{aligned} \quad (11.8.19)$$

These estimators are intuitively reasonable and analogous to those given in Eqs. (11.8.6) and (11.8.7).

Suppose now, however, that it is desired to test hypotheses such as (11.8.11), (11.8.13), or (11.8.17). The construction of appropriate tests becomes somewhat more difficult because, in general, the sums of squares analogous to those given in Eq. (11.8.10) will not be independent when there are unequal numbers of observations in the different cells. Hence, the test procedures presented earlier in this section cannot be directly copied here. It is necessary to develop other sums of squares that will be independent and will reflect the different types of variations in the data in which we are interested. We shall not consider the problem further in this book. This and other problems of ANOVA are described in the advanced book by Scheffé (1959).

## Summary

We extended the analysis of the two-way layout to cases in which we have equal numbers of observations at all combinations of levels of the two factors. One additional null hypothesis that we can test in this case is that the effects of the two factors are additive. (We assumed that the effects were additive when we had only one observation per cell.) If we reject the null hypothesis of additivity, we typically do not test any further hypotheses. If we don't reject this null hypothesis, we might still be interested in whether one of the two factors has any effect at all on the means of the observations. Even if we do not first test the null hypothesis that the effects of the two factors are additive, we might still be interested in whether one of the factors has an effect. The precise form of a test of one of these last hypotheses depends on whether we first test that the effects are additive.

---

## Exercises

- Show that for every set of numbers  $\theta_{ij}$  ( $i = 1, \dots, I$  and  $j = 1, \dots, J$ ), there exists a unique set of numbers  $\mu$ ,  $\alpha_i$ ,  $\beta_j$ , and  $\gamma_{ij}$  ( $i = 1, \dots, I$  and  $j = 1, \dots, J$ ) that satisfy Eqs. (11.8.4) and (11.8.5).

- Verify that Eq. (11.8.6) gives the M.L.E.'s of the parameters of the two-way layout with replication.

- Suppose that in a two-way layout, the values of  $\theta_{ij}$  are as given in each of the four matrices presented in parts (a), (b), (c), and (d) of Exercise 2 of Sec. 11.7. For each matrix, determine the values of  $\mu$ ,  $\alpha_i$ ,  $\beta_j$ , and  $\gamma_{ij}$  that satisfy Eqs. (11.8.4) and (11.8.5).

- Verify that if  $\hat{\alpha}_i$ ,  $\hat{\beta}_j$ , and  $\hat{\gamma}_{ij}$  are as given by Eqs. (11.8.6) and (11.8.7), then  $\sum_{i=1}^I \hat{\alpha}_i = 0$ ,  $\sum_{j=1}^J \hat{\beta}_j = 0$ ,  $\sum_{i=1}^I \hat{\gamma}_{ij} = 0$  for  $j = 1, \dots, J$ , and  $\sum_{j=1}^J \hat{\gamma}_{ij} = 0$  for  $i = 1, \dots, I$ .

- Verify that if  $\hat{\mu}$ ,  $\hat{\alpha}_i$ ,  $\hat{\beta}_j$ , and  $\hat{\gamma}_{ij}$  are as given by Eqs. (11.8.6) and (11.8.7), then  $E(\hat{\mu}) = \mu$ ,  $E(\hat{\alpha}_i) = \alpha_i$ ,  $E(\hat{\beta}_j) = \beta_j$ , and  $E(\hat{\gamma}_{ij}) = \gamma_{ij}$  for all values of  $i$  and  $j$ . Hint: Each of

the random variables in this exercise is a linear function of the  $Y_{ijk}$ 's, and hence the expectations are the same linear combinations of the expectations of the  $Y_{ijk}$ 's.

- Show that if  $\hat{\mu}$ ,  $\hat{\alpha}_i$ ,  $\hat{\beta}_j$ , and  $\hat{\gamma}_{ij}$  are as given by Eqs. (11.8.6) and (11.8.7), then the following results are true for all values of  $i$  and  $j$ :

$$\begin{aligned}\text{Var}(\hat{\mu}) &= \frac{I}{IJK} \sigma^2, & \text{Var}(\hat{\alpha}_i) &= \frac{(I-1)}{IJK} \sigma^2, \\ \text{Var}(\hat{\beta}_j) &= \frac{(J-1)}{IJK} \sigma^2, & \text{Var}(\hat{\gamma}_{ij}) &= \frac{(I-1)(J-1)}{IJK} \sigma^2.\end{aligned}$$

- Verify Eq. (11.8.9).
- In a two-way layout with  $K$  observations in each cell, show that for all values of  $i$ ,  $i_1$ ,  $i_2$ ,  $j$ ,  $j_1$ ,  $j_2$ , and  $k$ , the following five random variables are uncorrelated with one another:

$$Y_{ijk} - \bar{Y}_{ij+}, \hat{\alpha}_{i_1}, \hat{\beta}_{j_1}, \hat{\gamma}_{i_2 j_2}, \text{ and } \hat{\mu}.$$

9. Verify that  $U_{AB}^2$  also equals

$$\frac{\left( \begin{array}{l} IJK(K-1) \left( \sum_{i=1}^I \sum_{j=1}^J \bar{Y}_{ij+}^2 - J \sum_{i=1}^I \bar{Y}_{i++}^2 \right. \\ \left. - I \sum_{j=1}^J \bar{Y}_{+j+}^2 + IJ\bar{Y}_{+++}^2 \right) \end{array} \right)}{\left( \begin{array}{l} (I-1)(J-1) \left( \sum_{i=1}^I \sum_{j=1}^J \sum_{k=1}^K Y_{ijk}^2 \right. \\ \left. - K \sum_{i=1}^I \sum_{j=1}^J \bar{Y}_{ij+}^2 \right) \end{array} \right)}.$$

10. Suppose that in an experimental study to determine the combined effects of receiving both a stimulant and a tranquilizer, three different types of stimulants and four different types of tranquilizers are administered to a group of rabbits. Each rabbit in the experiment receives one of the stimulants and then, 20 minutes later, receives one of the tranquilizers. After one hour, the response of the rabbit is measured in appropriate units. In order that each possible pair of drugs may be administered to two different rabbits, 24 rabbits are used in the experiment. The responses of these 24 rabbits are given in Table 11.30. Determine the values of  $\hat{\mu}$ ,  $\hat{\alpha}_i$ ,  $\hat{\beta}_j$ , and  $\hat{\gamma}_{ij}$  for  $i = 1, 2, 3$  and  $j = 1, 2, 3, 4$ , and determine also the value of  $\hat{\sigma}^2$ .

**Table 11.30** Data for Exercises 10–15

Stimulant	Tranquilizer			
	1	2	3	4
1	11.2	7.4	7.1	9.6
	11.6	8.1	7.0	7.6
2	12.7	10.3	8.8	11.3
	14.0	7.9	8.5	10.8
3	10.1	5.5	5.0	6.5
	9.6	6.9	7.3	5.7

11. For the conditions of Exercise 10 and the data in Table 11.30, test the hypothesis that every interaction between a stimulant and a tranquilizer is 0.

12. For the conditions of Exercise 10 and the data in Table 11.30, test the hypothesis that all three stimulants yield the same responses.

13. For the conditions of Exercise 10 and the data in Table 11.30, test the hypothesis that all four tranquilizers yield the same responses.

14. For the conditions of Exercise 10 and the data in Table 11.30, test the following hypotheses:

$$\begin{aligned} H_0: \quad & \mu = 8, \\ H_1: \quad & \mu \neq 8. \end{aligned}$$

15. For the conditions of Exercise 10 and the data in Table 11.30, test the following hypotheses:

$$\begin{aligned} H_0: \quad & \alpha_2 \leq 1, \\ H_1: \quad & \alpha_2 > 1. \end{aligned}$$

16. In a two-way layout with unequal numbers of observations in the cells, show that if  $\hat{\mu}$ ,  $\hat{\alpha}_i$ ,  $\hat{\beta}_j$ , and  $\hat{\gamma}_{ij}$  are as given by Eq. (11.8.19), then  $E(\hat{\mu}) = \mu$ ,  $E(\hat{\alpha}_i) = \alpha_i$ ,  $E(\hat{\beta}_j) = \beta_j$ , and  $E(\hat{\gamma}_{ij}) = \gamma_{ij}$  for all values of  $i$  and  $j$ .

17. Verify that if  $\hat{\mu}$ ,  $\hat{\alpha}_i$ ,  $\hat{\beta}_j$ , and  $\hat{\gamma}_{ij}$  are as given by Eq. (11.8.19), then  $\sum_{i=1}^I \hat{\alpha}_i = 0$ ,  $\sum_{j=1}^J \hat{\beta}_j = 0$ ,  $\sum_{i=1}^I \hat{\gamma}_{ij} = 0$  for  $j = 1, \dots, J$ , and  $\sum_{j=1}^J \hat{\gamma}_{ij} = 0$  for  $i = 1, \dots, I$ .

18. Show that if  $\hat{\mu}$  and  $\hat{\alpha}_i$  are as given by Eq. (11.8.19), then for  $i = 1, \dots, I$ ,

$$\text{Cov}(\hat{\mu}, \hat{\alpha}_i) = \frac{\sigma^2}{IJ^2} \left[ \sum_{j=1}^J \frac{1}{K_{ij}} - \frac{1}{I} \sum_{r=1}^I \sum_{j=1}^J \frac{1}{K_{rj}} \right].$$

Also, show that this covariance is 0 if all  $K_{ij}$  are the same.

19. Recall the two-stage testing procedure described in this section: First test (11.8.11) at level  $\alpha_0$ . If you reject the null hypothesis, stop. If you don't reject the null hypothesis, then test (11.8.13). Let  $\beta_0$  be the conditional size of the second test given that the first test doesn't reject the null hypothesis. Assume that both null hypotheses are true. Find the probability that this two-stage procedure rejects at least one of the null hypotheses.

20. The study referred to in Exercise 10 in Sec. 11.6 actually included another factor in addition to size of vehicle. There were two different filters, a standard filter and a newly developed filter. Table 11.19 has data only from the standard filter. The corresponding data for the new filter are in Table 11.31.

**Table 11.31** Data for Exercise 20. This table has data for the vehicles with the new filter.

Vehicle size	Noise values
Small	820, 820, 820, 825, 825, 825
Medium	820, 820, 825, 815, 825, 825
Large	775, 775, 775, 770, 760, 765

- a. Construct the ANOVA table for the two-way layout that includes the data from both Tables 11.19 and 11.31.
- b. Compute the  $p$ -value for testing the null hypothesis that there is no interaction.
- c. Compute the  $p$ -value for testing the null hypothesis that the vehicles of all three sizes produce the same level of noise on average.
- d. Compute the  $p$ -value for testing the null hypothesis that both filters result in the same level of noise on average.

## 11.9 Supplementary Exercises

- 1.** Consider the data in Example 11.2.2 on page 703. Suppose that we fit a simple linear regression of the natural logarithm of pressure on boiling point.
- a. Find a 90 percent confidence interval (bounded interval) for the slope  $\beta_1$ .
  - b. Test the null hypothesis  $H_0 : \beta_1 = 0$  versus  $H_1 : \beta_1 \neq 0$  at level  $\alpha_0 = 0.1$ .
  - c. Find a 90 percent prediction interval for pressure (not logarithm of pressure) when the boiling point is 204.6.
- 2.** Suppose that  $(X_i, Y_i), i = 1, \dots, n$ , form a random sample of size  $n$  from the bivariate normal distribution with means  $\mu_1$  and  $\mu_2$ , variances  $\sigma_1^2$  and  $\sigma_2^2$ , and correlation  $\rho$ , and let  $\hat{\mu}_i$ ,  $\hat{\sigma}_i^2$ , and  $\hat{\rho}$  denote their M.L.E.'s Also, let  $\hat{\beta}_2$  denote the M.L.E. of  $\beta_2$  in the regression of  $Y$  on  $X$ . Show that
- $$\hat{\beta}_2 = \hat{\rho} \hat{\sigma}_2 / \hat{\sigma}_1.$$
- Hint:* See Exercise 24 of Sec. 7.6.
- 3.** Suppose that  $(X_i, Y_i), i = 1, \dots, n$ , form a random sample of size  $n$  from the bivariate normal distribution with means  $\mu_1$  and  $\mu_2$ , variances  $\sigma_1^2$  and  $\sigma_2^2$ , and correlation  $\rho$ . Determine the mean and the variance of the following statistic  $T$ , given the observed values  $X_1 = x_1, \dots, X_n = x_n$ :
- $$T = \frac{\sum_{i=1}^n (x_i - \bar{x}) Y_i}{\sum_{i=1}^n (x_i - \bar{x})^2}.$$
- 4.** Let  $\theta_1, \theta_2$ , and  $\theta_3$  denote the unknown angles of a triangle, measured in degrees ( $\theta_i > 0$  for  $i = 1, 2, 3$ , and  $\theta_1 + \theta_2 + \theta_3 = 180$ ). Suppose that each angle is measured by an instrument that is subject to error, and the measured values of  $\theta_1, \theta_2$ , and  $\theta_3$  are found to be  $y_1 = 83, y_2 = 47$ , and  $y_3 = 56$ , respectively. Determine the least-squares estimates of  $\theta_1, \theta_2$ , and  $\theta_3$ .
- 5.** Suppose that a straight line is to be fitted to  $n$  points  $(x_1, y_1), \dots, (x_n, y_n)$  such that  $x_2 = x_3 = \dots = x_n$  but  $x_1 \neq x_2$ . Show that the least-squares line will pass through the point  $(x_1, y_1)$ .
- 6.** Suppose that a least-squares line is fitted to the  $n$  points  $(x_1, y_1), \dots, (x_n, y_n)$  in the usual way by minimizing the sum of squares of the vertical deviations of the points from the line, and another least-squares line is fitted by minimizing the sum of squares of the horizontal deviations of the points from the line. Under what conditions will these two lines coincide?
- 7.** Suppose that a straight line  $y = \beta_1 + \beta_2 x$  is to be fitted to the  $n$  points  $(x_1, y_1), \dots, (x_n, y_n)$  in such a way that the sum of the squared perpendicular (or orthogonal) distances from the points to the line is a minimum. Determine the optimal values of  $\beta_1$  and  $\beta_2$ .
- 8.** Suppose that twin sisters are each to take a certain mathematics examination. They know that the scores they will obtain on the examination have the same mean  $\mu$ , the same variance  $\sigma^2$ , and positive correlation  $\rho$ . Assuming that their scores have a bivariate normal distribution, show that after each twin learns her own score, the expected value of her sister's score is between her own score and  $\mu$ .
- 9.** Suppose that a sample of  $n$  observations is formed from  $k$  subsamples containing  $n_1, \dots, n_k$  observations ( $n_1 + \dots + n_k = n$ ). Let  $x_{ij}$  ( $j = 1, \dots, n_i$ ) denote the observations in the  $i$ th subsample, and let  $\bar{x}_{i+}$  and  $v_i^2$  denote the sample mean and the sample variance of that subsample:
- $$\bar{x}_{i+} = \frac{1}{n_i} \sum_{j=1}^{n_i} x_{ij}, \quad v_i^2 = \frac{1}{n_i} \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_{i+})^2.$$
- Finally, let  $\bar{x}_{++}$  and  $v^2$  denote the sample mean and the sample variance of the entire sample of  $n$  observations:
- $$\bar{x}_{++} = \frac{1}{n} \sum_{i=1}^k \sum_{j=1}^{n_i} x_{ij}, \quad v^2 = \frac{1}{n} \sum_{i=1}^k \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_{++})^2.$$
- Determine an expression for  $v^2$  in terms of  $\bar{x}_{++}, \bar{x}_{i+}$ , and  $v_i^2$  ( $i = 1, \dots, k$ ).
- 10.** Consider the linear regression model
- $$Y_i = \beta_1 w_i + \beta_2 x_i + \varepsilon_i \quad \text{for } i = 1, \dots, n,$$

where  $(w_1, x_1), \dots, (w_n, x_n)$  are given pairs of constants and  $\varepsilon_1, \dots, \varepsilon_n$  are i.i.d. random variables, each of which has the normal distribution with mean 0 and variance  $\sigma^2$ . Determine explicitly the M.L.E.'s of  $\beta_1$  and  $\beta_2$ .

**11.** Determine an unbiased estimator of  $\sigma^2$  in a two-way layout with  $K$  observations in each cell ( $K \geq 2$ ).

**12.** In a two-way layout with one observation in each cell, construct a test of the null hypothesis that all the effects of both factor  $A$  and factor  $B$  are 0.

**13.** In a two-way layout with  $K$  observations in each cell ( $K \geq 2$ ), construct a test of the null hypothesis that all the main effects for factor  $A$  and factor  $B$ , and also all the interactions, are 0.

**14.** Suppose that each of two different varieties of corn is treated with two different types of fertilizer in order to compare the yields, and that  $K$  independent replications are obtained for each of the four combinations. Let  $X_{ijk}$  denote the yield on the  $k$ th replication of the combination of variety  $i$  with fertilizer  $j$  ( $i = 1, 2$ ;  $j = 1, 2$ ;  $k = 1, \dots, K$ ). Assume that all the observations are independent and normally distributed, each distribution has the same unknown variance, and  $E(X_{ijk}) = \mu_{ij}$  for  $k = 1, \dots, K$ . Explain in words what the following hypotheses mean, and describe how to carry out a test of them:

$$H_0: \mu_{11} - \mu_{12} = \mu_{21} - \mu_{22},$$

$H_1$ : The hypothesis  $H_0$  is not true.

**15.** Suppose that  $W_1, W_2$ , and  $W_3$  are independent random variables, each of which has a normal distribution with the following means and variances:

$$E(W_1) = \theta_1 + \theta_2, \quad \text{Var}(W_1) = \sigma^2,$$

$$E(W_2) = \theta_1 + \theta_2 - 5, \quad \text{Var}(W_2) = \sigma^2,$$

$$E(W_3) = 2\theta_1 - 2\theta_2, \quad \text{Var}(W_3) = 4\sigma^2.$$

Determine the M.L.E.'s of  $\theta_1, \theta_2$ , and  $\sigma^2$ , and determine also the joint distribution of these estimators.

**16.** Suppose that it is desired to fit a curve of the form  $y = \alpha x^\beta$  to a given set of  $n$  points  $(x_i, y_i)$  with  $x_i > 0$  and  $y_i > 0$  for  $i = 1, \dots, n$ . Explain how this curve can be fitted either by direct application of the method of least squares or by first transforming the problem into one of fitting a straight line to the  $n$  points  $(\log x_i, \log y_i)$  and then applying the method of least squares. Discuss the conditions under which each of these methods is appropriate.

**17.** Consider a problem of simple linear regression, and let  $e_i = Y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i$  denote the residual of the observation  $Y_i$  ( $i = 1, \dots, n$ ), as defined in Definition 11.3.2. Evaluate  $\text{Var}(e_i)$  for given values of  $x_1, \dots, x_n$ , and show that it is a decreasing function of the distance between  $x_i$  and  $\bar{x}$ .

**18.** Consider a general linear model with  $n \times p$  design matrix  $\mathbf{Z}$ , and let  $\mathbf{W} = \mathbf{Y} - \mathbf{Z}\hat{\beta}$  denote the vector of residuals. (In other words, the  $i$ th coordinate of  $\mathbf{W}$  is  $Y_i - \hat{Y}_i$ , where  $\hat{Y}_i = z_{i0}\hat{\beta}_0 + \dots + z_{ip-1}\hat{\beta}_{p-1}$ .)

a. Show that  $\mathbf{W} = \mathbf{D}\mathbf{Y}$ , where

$$\mathbf{D} = \mathbf{I} - \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'.$$

b. Show that the matrix  $\mathbf{D}$  is *idempotent*; that is,  $\mathbf{DD} = \mathbf{D}$ .

c. Show that  $\text{Cov}(\mathbf{W}) = \sigma^2\mathbf{D}$ .

**19.** Consider a two-way layout in which the effects of the factors are additive so that Eq. (11.7.1) is satisfied, and let  $v_1, \dots, v_I$  and  $w_1, \dots, w_J$  be arbitrary given positive numbers. Show that there exist unique numbers  $\mu, \alpha_1, \dots, \alpha_I$ , and  $\beta_1, \dots, \beta_J$  such that

$$\sum_{i=1}^I v_i \alpha_i = \sum_{j=1}^J w_j \beta_j = 0$$

and

$$E(Y_{ij}) = \mu + \alpha_i + \beta_j \quad \text{for } i = 1, \dots, I \text{ and } j = 1, \dots, J.$$

**20.** Consider a two-way layout in which the effects of the factors are additive, as in Exercise 19; suppose also that there are  $K_{ij}$  observations per cell, where  $K_{ij} > 0$  for  $i = 1, \dots, I$  and  $j = 1, \dots, J$ . Let  $v_i = K_{i+}$  for  $i = 1, \dots, I$ , and let  $w_j = K_{+j}$  for  $j = 1, \dots, J$ . Assume that  $E(Y_{ijk}) = \mu + \alpha_i + \beta_j$  for  $k = 1, \dots, K_{ij}$ ,  $i = 1, \dots, j$ , and  $j = 1, \dots, J$ , where  $\sum_{i=1}^I v_i \alpha_i = \sum_{j=1}^J w_j \beta_j = 0$ , as in Exercise 19. Verify that the least-squares estimators of  $\mu, \alpha_i$ , and  $\beta_j$  are as follows:

$$\hat{\mu} = \bar{Y}_{+++},$$

$$\hat{\alpha}_i = \frac{1}{K_{i+}} Y_{i++} - \bar{Y}_{+++} \quad \text{for } i = 1, \dots, I,$$

$$\hat{\beta}_j = \frac{1}{K_{+j}} Y_{++j} - \bar{Y}_{+++} \quad \text{for } j = 1, \dots, J.$$

**21.** Consider again the conditions of Exercises 19 and 20, and let the estimators  $\hat{\mu}, \hat{\alpha}_i$ , and  $\hat{\beta}_j$  be as given in Exercise 20. Show that  $\text{Cov}(\hat{\mu}, \hat{\alpha}_i) = \text{Cov}(\hat{\mu}, \hat{\beta}_j) = 0$ .

**22.** Consider again the conditions of Exercise 19 and 20, and suppose that the numbers  $K_{ij}$  have the following proportionality property:

$$K_{ij} = \frac{K_{i+} K_{+j}}{n} \quad \text{for } i = 1, \dots, I \text{ and } j = 1, \dots, J.$$

Show that  $\text{Cov}(\hat{\alpha}_i, \hat{\beta}_j) = 0$ , where the estimators  $\hat{\alpha}_i$  and  $\hat{\beta}_j$  are as given in Exercise 20.

- 23.** In a three-way layout with one observation in each cell, the observations  $Y_{ijk}$  ( $i = 1, \dots, I$ ;  $j = 1, \dots, J$ ;  $k = 1, \dots, K$ ) are assumed to be independent and normally distributed, with a common variance  $\sigma^2$ . Suppose that  $E(Y_{ijk}) = \theta_{ijk}$ . Show that for every set of numbers  $\theta_{ijk}$ , there exists a unique set of numbers  $\mu, \alpha_i^A, \alpha_j^B, \alpha_k^C, \beta_{ij}^{AB}, \beta_{ik}^{AC}, \beta_{jk}^{BC}$ , and  $\gamma_{ijk}$  ( $i = 1, \dots, I$ ;  $j = 1, \dots, J$ ;  $k = 1, \dots, K$ ) such that

$$\begin{aligned}\alpha_+^A &= \alpha_+^B = \alpha_+^C = 0, \\ \beta_{i+}^{AB} &= \beta_{j+}^{AB} = \beta_{k+}^{AB} = \beta_{i+}^{AC} = \beta_{j+}^{AC} = \beta_{k+}^{AC} = 0, \\ \gamma_{ij+} &= \gamma_{i+k} = \gamma_{j+k} = 0,\end{aligned}$$

and

$$\theta_{ijk} = \mu + \alpha_i^A + \alpha_j^B + \alpha_k^C + \beta_{ij}^{AB} + \beta_{ik}^{AC} + \beta_{jk}^{BC} + \gamma_{ijk},$$

for all values of  $i, j$ , and  $k$ .

- 24.** The 2000 U.S. presidential election was very close, especially in the state of Florida. Indeed, newscasters were unable to predict a winner the day after the election because they could not decide who was going to win Florida's 25 electoral votes. Many voters in Palm Beach County complained that they were confused by the design of the ballot and might have voted for Patrick Buchanan instead of Al Gore, as they had intended. Table 11.32 displays the official ballot counts (after all official recounts) for each county. There was no reason, prior to the election, to think that Patrick Buchanan would gather a significantly higher percent of the vote in Palm Beach County than in any other Florida county.

- a. Draw a plot of the vote count for Patrick Buchanan against the total vote count with one point for each

county. Identify the point corresponding to Palm Beach County.

- b. Given the complaints about the Palm Beach ballot, it might be sensible to treat the data point for Palm Beach County as being different from the others. Fit a simple linear regression model with  $Y$  being the vote for Buchanan and  $X$  being the total vote in each county, excluding Palm Beach County.
- c. Plot the residuals from the regression in part (b) against the  $X$  variable. Do you notice any pattern in the plot?
- d. The variance of the vote for each candidate in a county ought to depend on the total vote in the county. The larger the total vote, the more variance you expect in the vote for each candidate. For this reason, the assumptions of the simple linear regression model would not hold. As an alternative, fit a simple linear regression with  $Y$  being the logarithm of the vote for Buchanan and  $X$  being the logarithm of the total vote in each county. Continue to exclude Palm Beach County.
- e. Plot the residuals from the regression in part (d) against the  $X$  variable. Do you notice any pattern in the plot?
- f. Using the model fit in part (d), form a 99 percent prediction interval for the Buchanan vote (not the logarithm of the Buchanan vote) in Palm Beach County.
- g. Let  $B$  be the upper endpoint of the interval you found in part (f). Just suppose that the actual number of people in Palm Beach County who voted for Buchanan had actually been  $B$  instead of 3411. Also suppose that the remaining  $3411 - B$  voters had actually voted for Gore. Would this have changed the winner of the total popular vote for the State of Florida?

**Table 11.32** County votes for Bush, Gore, and Buchanan in the 2000 presidential election for the state of Florida. The total column includes all 11 candidates that were on the ballot. The absentee row includes overseas absentee ballots that were not included in individual county totals. These data came from the official state of Florida election Web site, which has since been moved or deleted.

## 12.1 What Is Simulation?

*Simulation is a way to use high-speed computer power to substitute for analytical calculation. The law of large numbers tells us that if we observe a large sample of i.i.d. random variables with finite mean, then the average of these random variables should be close to their mean. If we can get a computer to produce such a large i.i.d. sample, then we can average the random variables instead of trying (and possibly failing) to calculate their mean analytically. For a specific problem, one needs to figure out what types of random variables one needs, how to make a computer produce them, and how many one needs in order to have any confidence in the numerical result. Each of these issues will be addressed to some extent in this chapter.*

### Proof of Concept

We begin with some simple examples of simulation to answer questions that we can already answer analytically just to show that simulation does what it advertises. Also, these simple examples will raise some of the issues to which one must attend when trying to answer more difficult questions using simulation.

---

**Example**

**12.1.1**

**The Mean of a Distribution.** The mean of the uniform distribution on the interval  $[0, 1]$  is known to be  $1/2$ . If we had available a large number of i.i.d. uniform random variables on the interval  $[0, 1]$ , say,  $X_1, \dots, X_n$ , the law of large numbers says that  $\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i$  should be close to the mean  $1/2$ . Table 12.1 gives the averages of several different simulated samples of size  $n$  from the uniform distribution on  $[0, 1]$  for several different values of  $n$ . It is not difficult to see that the averages are close to  $0.5$  in most cases, but there is quite a bit of variation, especially for  $n = 100$ . There seems to be less variation for  $n = 1000$ , and even less for the two largest values of  $n$ .

---

**Example**

**12.1.2**

**A Normal Probability.** The probability that a standard normal random variable is at least  $1.0$  is known to be  $0.1587$ . If we had available a large number of i.i.d. standard normal random variables, say,  $X_1, \dots, X_n$ , we could create Bernoulli random variables  $Y_1, \dots, Y_n$  defined by  $Y_i = 1$  if  $X_i \geq 1.0$  and  $Y_i = 0$  if not. Then the law of large numbers says that  $\bar{Y} = \frac{1}{n} \sum_{i=1}^n Y_i$  should be close to the mean of  $Y_i$ , namely,

**Table 12.1** Results of several different simulations in Example 12.1.1

<i>n</i>	Replications of the simulation				
100	0.485	0.481	0.484	0.569	0.441
1000	0.497	0.506	0.480	0.498	0.499
10,000	0.502	0.501	0.499	0.498	0.498
100,000	0.502	0.499	0.500	0.498	0.499

**Table 12.2** Results of several different simulations in Example 12.1.2

<i>n</i>	Replications of the simulation				
100	0.16	0.18	0.17	0.22	0.14
1000	0.135	0.171	0.174	0.159	0.171
10,000	0.160	0.163	0.158	0.152	0.156
100,000	0.158	0.158	0.158	0.159	0.161

$\Pr(X_i \geq 1.0) = 0.1587$ . Notice that  $\bar{Y}$  is merely the proportion of the simulated  $X_i$  values that are at least 1.0. Table 12.2 gives the proportions of  $X_i \geq 1.0$  for several different simulated samples of size  $n$  from the standard normal distribution for several different values of  $n$ . It is not difficult to see that the proportions are somewhat close to 0.1587, but there is still quite a bit of variability from one simulation to the next.  $\blacktriangleleft$

As we mentioned earlier, there is no need for simulation in the above examples. These were just to illustrate that simulation can do what it claims. However, one needs to be aware that, no matter how large a sample is simulated, the average of an i.i.d. sample of random variables is not necessarily going to be equal to its mean. One needs to be able to take the variability into account. The variability is apparent in Tables 12.1 and 12.2. We shall address the issue of the variability of simulations later in the chapter.

The reader might also be wondering how we obtained all of the uniform and normal random variables used in the examples. Virtually every commercial statistical software package has a simulator for i.i.d. uniform random variables on the interval  $[0, 1]$ . Later in the chapter, we shall discuss ways to make use of these for simulating other distributions. One such method was already discussed in Chapter 3 on page 170.

### Examples in which Simulation Might Help

Next, we present some examples where the basic questions are relatively simple to describe, but analytic solution would be tedious at best.

**Example  
12.1.3**

Waiting for a Break. Two servers, A and B, in a fast-food restaurant start serving customers at the same time. They agree to meet for a break after each of them has

**Figure 12.1** Histogram of sample of 10,000 simulated waiting times  $Z$  in Example 12.1.3.

served 10 customers. Presumably, one of them will finish before the other and have to wait. How long, on average, will one of the servers have to wait for the other?

Suppose that we model all service times, regardless of the server, as i.i.d. random variables having the exponential distribution with parameter 0.3 customers per minute. Then the time it takes one server to serve 10 customers has the gamma distribution with parameters 10 and 0.3. Let  $X$  be the time it takes A to serve 10 customers, and let  $Y$  be the time it takes B to serve 10 customers. We are asked to compute the mean of  $|X - Y|$ . The most straightforward way of finding this mean analytically would require a two-dimensional integral over the union of two non-rectangular regions.

On the other hand, suppose that a computer can provide us with as many independent gamma random variables as we desire. We can then obtain a pair  $(X, Y)$  and compute  $Z = |X - Y|$ . We then repeat this process independently as many times as we want and average all the observed  $Z$  values. The average should be close to the mean of  $Z$ .

Without going into details, we actually simulated 10,000 pairs of  $(X, Y)$  values and averaged the resulting  $Z$  values to get 11.71 minutes. A histogram of the simulated  $Z$  values is in Fig. 12.1. As a confidence builder, we simulated another 10,000 pairs and got an average of 11.77. ◀

**Example  
12.1.4**

**Long Run of Heads.** You overheard someone say that they just got 12 consecutive heads while flipping a seemingly fair coin. The probability of getting 12 heads in a row in 12 independent flips of a fair coin is  $(0.5)^{12}$ , a very small number. If the person had obtained 12 tails in a row, you probably would have heard about that instead. Even so, the probability of 12 of the same side is only  $(0.5)^{11}$ . But then you learn that the person actually flipped the coin 100 times, and the 12 heads in a row appeared somewhere during those 100 flips. Presumably, you are less surprised to learn that the person got a run of 12 of the same side somewhere in a sequence of 100 flips. But how much larger is the probability of a run of 12 when one flips 100 times?

Suppose that we can make a computer flip a fair coin as many times as we wish. We could ask it to flip 100 times and then check whether there was a run of length 12 or more. Let  $X = 1$  if there is a run of 12 or more, and let  $X = 0$  if not. We then repeat this process independently as many times as we want and average all the observed  $X$  values. The average should be close to the mean of  $X$ , which is the probability of obtaining a run of 12 or more in 100 flips.

Without going into details, Fig. 12.2 shows a histogram of the longest runs in 10,000 repetitions of the experiment described above. For each of the 10,000 runs, we calculated  $X$  as above and found the average to be 0.0214, still a small number,

**Figure 12.2** Histogram of sample of 10,000 longest runs (head or tail). Each run was observed in 100 flips of a fair coin.

but not nearly so small as  $(0.5)^{11}$ . We also repeated the calculation of the average with another 10,000 sets of 100 flips and got 0.0229.  $\blacktriangleleft$

A number of details were left out of exactly how the simulations were performed in the above examples. However, it is clear what random variables we wanted to observe, namely,  $Z$  in Example 12.1.3 and  $X$  in Example 12.1.4. Many simulations can address more than one question. For instance, in Example 12.1.4, we recorded the 10,000 lengths of the longest runs even though our primary interest was in whether or not the longest run was 12 or more. We could also have tried to calculate the expected length of the longest run or other properties of the distribution of the longest run. In Example 12.1.3, we could have tried to approximate the probability that one person has to wait at least 15 minutes, etc.

Figures 12.1 and 12.2 illustrate that there is variation among the 10,000 repetitions of a simulated experiment. Furthermore, each of the examples showed that a complete rerunning of all 10,000 simulated experiments can be expected to produce a different answer to each of our questions. How much different the answers should be is a matter that we shall address in Sec. 12.2, where we use the Chebyshev inequality and the central limit theorem to help us decide how many times to repeat the basic experiment. Exactly how one simulates 100 flips of a coin or a pair of gamma random variables will be taken up in Sec. 12.3.

## Summary

Suppose that we want to know the mean of some function  $g$  of a random variable or random vector  $W$ . For instance, in Example 12.1.3 we can let  $W = (X, Y)$  and  $g(W) = |X - Y|$ . If a computer can supply a large number of i.i.d. random variables (or random vectors) with the distribution of  $W$ , one can use the average of the simulated values of  $g(W)$  to approximate the mean of  $g(X)$ . One must be careful to take the variability in  $g(W)$  into account when deciding how much confidence to place in the approximation.

## Exercises

For each of the exercises in this section, you could also perform the simulations described with various numbers of replications if you have appropriate computer software available. Most of the distributions involved are commonly available in computer software. If a distribution is not available, the simulations can wait until methods for simulating specific distributions are introduced in Sec. 12.3.

1. Assume that one can simulate as many i.i.d. exponential random variables with parameter 1 as one wishes. Explain how one could use simulation to approximate the mean of the exponential distribution with parameter 1.
2. If  $X$  has the p.d.f.  $1/x^2$  for  $x > 1$ , the mean of  $X$  is infinite. What would you expect to happen if you simulated a large number of random variables with this p.d.f. and computed their average?
3. If  $X$  has the Cauchy distribution, the mean of  $X$  does not exist. What would you expect to happen if you simulated a large number of Cauchy random variables and computed their average?
4. Suppose that one can simulate as many i.i.d. Bernoulli random variables with parameter  $p$  as one wishes. Explain how to use these to approximate the mean of the geometric distribution with parameter  $p$ .
5. Two servers A and B in a fast-food restaurant each start their first customers at the same time. After finishing her second customer, A notices that B has not yet finished

his first customer. A then chides B for being slow, and B responds that A just got a couple of easier customers. Suppose that we model all service times, regardless of the server, as i.i.d. random variables having the exponential distribution with parameter 0.4. Let  $X$  be the sum of the first two service times for server A, and let  $Y$  be the first service time for server B. Assume that you can simulate as many i.i.d. exponential random variables with parameter 0.4 as you wish.

- a. Explain how to use such random variables to approximate  $\Pr(X < Y)$ .
- b. Explain why  $\Pr(X < Y)$  is the same no matter what the common parameter is of the exponential distributions. That is, we don't need to simulate exponentials with parameter 0.4. We could use any parameter that is convenient, and we should get the same answer.
- c. Find the joint p.d.f. of  $X$  and  $Y$ , and write the two-dimensional integral whose value would be  $\Pr(X < Y)$ .

## 12.2 Why Is Simulation Useful?

*Statistical simulations are used to estimate features of distributions such as means of functions, quantiles, and other features that we cannot compute in closed form. When using a simulation estimator, it is good to compute a measure of how precise the estimator is, in addition to the estimate itself.*

### Examples of Simulation

Simulation is a technique that can be used to help shed light on how a complicated system works even if detailed analysis is unavailable. For example, engineers can simulate traffic patterns in the vicinity of a construction project to see what effects various proposed restrictions might have. A physicist can simulate the behavior of gas molecules under conditions that are covered by no known theory. Statistical simulations are used to estimate probabilistic features of our models that we cannot compute analytically. Because simulation introduces an element of randomness into an analysis, it is sometimes called *Monte Carlo analysis*, named after the famous European gambling center.

---

**Example  
12.2.1**

**The M.S.E. of the Sample Median.** Suppose that we are about to observe a random sample of size  $n$  from a Cauchy distribution centered at an unknown value  $\mu$ . The p.d.f. of each observation is

$$f(x) = \frac{1}{\pi} (1 + [x - \mu]^2)^{-1},$$

and the parameter  $\mu$  is the median of the distribution. Suppose that we are interested in how well the sample median  $M$  performs as an estimator of  $\mu$ . In particular, we want to calculate the M.S.E.  $E([M - \mu]^2)$ . If we could generate a sample of  $n$  random variables from a Cauchy distribution centered at  $\mu$ , we could compute the sample median  $M$  and calculate  $Y = (M - \mu)^2$ . The M.S.E. is then  $\theta = E(Y)$ . If we could

generate a large number  $v$  of i.i.d. random variables with the same distribution as  $Y$ , say,  $Y^{(1)}, \dots, Y^{(v)}$ , then the law of large numbers would tell us that  $Z = \frac{1}{v} \sum_{i=1}^v Y^{(i)}$  should be close to  $\theta$ . To do this, we could generate  $nv$  i.i.d. Cauchy random variables centered at  $\mu$ . Then we could divide them into  $v$  sets of  $n$  each and use each set of  $n$  to compute a sample median  $M^{(i)}$  for  $i = 1, \dots, v$  and then compute  $Y^{(i)} = (M^{(i)} - \mu)^2$ . This is actually how several of the numbers in the tables in Sec. 10.7 were computed. These tables contain the M.S.E.'s of various estimators computed from random samples with various distributions. For example, the numbers corresponding to the sample median in Table 10.39 on page 675 are precisely what we have been discussing in this example.  $\blacktriangleleft$

**Note: Notation to Distinguish Simulations.** We shall use superscripts in parentheses to distinguish different simulated values of the same random variable from each other. For instance, in Example 12.2.1, we used  $Y^{(i)}$  to stand for the  $i$ th simulated value of  $Y$ . In what follows, we may be simulating subscripted random variables. For example,  $\mu_i^{(j)}$  would stand for the  $j$ th simulated value of  $\mu_i$ .

Example 12.2.1 illustrates the main features of many statistical simulations. Suppose that the quantity in which we are interested can be expressed as the expected value of some random variable that has the distribution  $F$ . Then we should try to generate a large sample of random variables with the distribution  $F$  and average them. It is often the case, as in Example 12.2.1, that the distribution  $F$  is itself very complicated. In such cases, we need to construct random variables with the distribution  $F$  from simpler random variables whose distributions are more familiar. In Example 12.2.1, the M.S.E. is the mean of the random variable  $Y = (M - \mu)^2$ , where  $M$  is itself the sample median of a sample of  $n$  Cauchy random variables centered at  $\mu$ . We cannot easily simulate a random variable with the distribution of  $Y$  in one step, but we can simulate  $n$  Cauchy random variables and then find their sample median  $M$  and finally compute  $Y = (M - \mu)^2$ , which will have the desired distribution. We then repeat the simulation of  $Y$  many times.

Not all statistical simulations involve the mean of a random variable.

**Example  
12.2.2**

**The Median of a Complicated Distribution.** Let  $X$  be an exponential random variable with unknown parameter  $\mu$ . Suppose that  $\mu$  has a distribution with the p.d.f.  $g$ . We are interested in the median of  $X$ . The marginal distribution of  $X$  has the p.d.f.

$$f(x) = \int_0^\infty \mu e^{-\mu x} g(\mu) d\mu.$$

This integral might not be one that we can compute. However, suppose that we can generate a large sample of random variables  $\mu^{(1)}, \dots, \mu^{(v)}$  having the p.d.f.  $g$ . Then, for each  $i = 1, \dots, v$ , we can simulate  $X^{(i)}$  having the exponential distribution with parameter  $\mu^{(i)}$ . The random variables  $X^{(1)}, \dots, X^{(v)}$  would then be a random sample from the distribution with the p.d.f.  $f$ . The median of the sample  $X^{(1)}, \dots, X^{(v)}$  should be close to the median of the distribution with the p.d.f.  $f$ .  $\blacktriangleleft$

**Example  
12.2.3**

**A Clinical Trial.** Consider the four treatment groups described in Example 2.1.4 on page 57. For  $i = 1, 2, 3, 4$ , let  $P_i$  be the probability that a patient in treatment group  $i$  will not relapse after treatment. We might be interested in how likely it is that the  $P_i$ 's differ by certain amounts. We might assume that the  $P_i$ 's are independent a priori with beta distributions having parameters  $\alpha_0$  and  $\beta_0$ . The posterior distributions of the  $P_i$ 's are also independent beta distributions with parameters  $\alpha_0 + x_i$  and  $\beta_0 + n_i - x_i$ , where  $n_i$  is the number of subjects in group  $i$ , and  $x_i$  is the number of patients in group

$i$  who do not relapse. We could simulate a large number  $v$  of vectors  $(P_1, P_2, P_3, P_4)$  with the above beta distributions. Then we could try to answer any question we wanted about the posterior distribution of  $(P_1, P_2, P_3, P_4)$ . For example, we could estimate  $\Pr(P_i > P_4)$  for  $i = 1, 2, 3$ , where  $i = 4$  stands for the placebo group. This probability tells us how likely it is that each treatment is better than no treatment. We could estimate  $\Pr(P_i > P_4)$  by finding the proportion of sampled  $(P_1, P_2, P_3, P_4)$  vectors in which the  $i$ th coordinate is greater than the fourth coordinate. We could also estimate the probability that  $P_i$  is the largest, or the probability that all four  $P_i$  are within  $\epsilon$  of each other.  $\blacktriangleleft$

**Example**  
**12.2.4**

**Comparing Two Normal Means with Unequal Variances.** On page 593 in Chapter 9, we considered how to test hypotheses concerning the means of two different normal distributions when the variances are unknown and different. This problem has a relatively simple solution in the Bayesian framework using simulation. Our parameters will be  $\mu_x$ ,  $\tau_x$ ,  $\mu_y$ , and  $\tau_y$ . Conditional on the parameters, let  $X_1, \dots, X_m$  be i.i.d. having the normal distribution with mean  $\mu_x$  and precision  $\tau_x$ . Also let  $Y_1, \dots, Y_n$  be i.i.d. (and independent of the  $X$ 's) having the normal distribution with mean  $\mu_y$  and precision  $\tau_y$ . Assume that we use natural conjugate priors for the parameters with  $(\mu_x, \tau_x)$  independent of  $(\mu_y, \tau_y)$  in the prior distribution. (It is not necessary for the  $X$  parameters to be independent of the  $Y$  parameters, but it makes the presentation simpler.) Sec. 8.6 contains details on how to obtain the posterior distributions of the parameters. Since the  $X$  data and  $X$  parameters are independent of the  $Y$  data and  $Y$  parameters, we can calculate each posterior distribution separately. Let the hyperparameters of the posterior distribution of  $(\mu_x, \tau_x)$  be  $\alpha_{x1}, \beta_{x1}, \mu_{x1}$ , and  $\lambda_{x1}$ . Similarly, let the hyperparameters of the posterior distribution of  $(\mu_y, \tau_y)$  be  $\alpha_{y1}, \beta_{y1}, \mu_{y1}$ , and  $\lambda_{y1}$ . In order to test hypotheses about  $\mu_x - \mu_y$ , we need the posterior distribution of  $\mu_x - \mu_y$ . This distribution is not analytically tractable. If we can simulate a large collection of parameter vectors from their joint posterior distribution, we can compute  $\mu_x - \mu_y$  for each sampled vector, and these values will form a sample from the posterior distribution of  $\mu_x - \mu_y$ . To be more specific, let  $v$  be a large number, and for each  $i = 1, \dots, v$ , we want to simulate  $(\mu_x^{(i)}, \mu_y^{(i)}, \tau_x^{(i)}, \tau_y^{(i)})$  from the joint posterior distribution. To do this, we need to simulate independent gamma random variables  $\tau_x^{(i)}$  and  $\tau_y^{(i)}$  with the appropriate posterior distributions. After simulating these, we can simulate  $\mu_x^{(i)}$  from the normal distribution with mean  $\mu_{x1}$  and variance  $1/(\lambda_{x1}\tau_x^{(i)})$ . Similarly, we can simulate  $\mu_y^{(i)}$  from the normal distribution with mean  $\mu_{y1}$  and variance  $1/(\lambda_{y1}\tau_y^{(i)})$ . Then  $\mu_x^{(i)} - \mu_y^{(i)}$  for  $i = 1, \dots, v$  is a sample from the posterior distribution of  $\mu_x - \mu_y$ . We shall illustrate this methodology in Example 12.3.8 after we discuss some methods for simulating pseudo-random numbers with various distributions.  $\blacktriangleleft$

The simulation in Example 12.2.4 can be extended in a straightforward fashion to a comparison of three or more normal distributions with unequal variances. With more than two means to compare, questions arise about what exactly to calculate to summarize the comparison. That is, there is not just one difference like  $\mu_x - \mu_y$  that captures the differences between three or more means. We shall consider this situation in more detail in Examples 12.3.7 and 12.5.6.

**Example**  
**12.2.5**

**Estimating a Standard Deviation.** Let  $X$  be a random variable whose standard deviation  $\theta$  is important to estimate. Suppose that we cannot calculate  $\theta$  in closed form, but we can simulate many pseudo-random values  $X^{(1)}, \dots, X^{(v)}$  with the same distribution

as  $X$ . Then we could compute the sample standard deviation

$$S_v = \left( \frac{1}{v} \sum_{i=1}^v (X^{(i)} - \bar{X})^2 \right)^{1/2},$$

as an estimator of  $\theta$ , where  $\bar{X} = \frac{1}{v} \sum_{i=1}^v X^{(i)}$ . Since  $S_v$  is not an average, the law of large numbers does not tell us that it converges in probability to  $\theta$ . However, if we let  $Y^{(i)} = X^{(i)2}$ , we can rewrite  $S_v$  as  $(\bar{Y} - \bar{X}^2)^{1/2}$ . In this form, we see that  $S_v = g(\bar{X}, \bar{Y})$ , where  $g(x, y) = (y - x^2)^{1/2}$ . Notice that  $g$  is continuous at every point  $(x, y)$  such that  $y \geq x^2$ . The law of large numbers tells us that  $\bar{Y}$  converges in probability to  $E(X^2)$  and that  $\bar{X}$  converges in probability to  $E(X)$ . Since  $E(X^2) \geq E(X)$ , we can apply Exercise 16 in Sec. 6.2 to conclude that  $S_v$  converges in probability to  $g(E(X), E(X^2)) = \theta$ .  $\blacktriangleleft$

All of the examples above involve the generation of a large number of random variables with specific distributions. Some discussion of this topic appeared in Chapter 3 beginning on page 170. Sections 12.3 and 12.5 will also discuss methods for generating random variables with specific distributions. Sections 12.4 and 12.6 will present particular classes of problems in which statistical simulation is used successfully.

### Which Mean Do You Mean?

Simulation analyses add an additional layer of probability distributions and sampling distributions of statistics to an already probability-laden statistical analysis. A typical statistical analysis involves a probability model for a random sample of data  $X_1, \dots, X_n$ . This probability model specifies the distribution of each  $X_i$ , and this distribution might have parameters such as its mean, median, variance, and other measures that we are interested in estimating or testing. We then form statistics (functions of the data), say,  $\mathbf{Y}$ . These functions might include sample versions of the very parameters that we wish to estimate, such as a sample mean, sample median, sample variance, and the like. The distribution of  $\mathbf{Y}$  has been called its sampling distribution. This sampling distribution also might have a mean, median, variance, and other measures that we need to calculate or deal with in some way. So far, we have three versions of mean, median, variance, and others, and we have not even begun discussing simulation.

A simulation analysis might be used to try to estimate a parameter  $\theta$  of the sampling distribution of the statistics  $\mathbf{Y}$ . Typically, one would simulate i.i.d. pseudo-random  $\mathbf{Y}^{(1)}, \dots, \mathbf{Y}^{(v)}$  each with the same distribution as (the sampling distribution of)  $\mathbf{Y}$ . We then compute a summary statistic  $Z$  of  $\mathbf{Y}^{(1)}, \dots, \mathbf{Y}^{(v)}$  and use  $Z$  to estimate  $\theta$ . This  $Z$  might itself be a sample mean, sample median, sample variance, or other measure of the  $\mathbf{Y}^{(1)}, \dots, \mathbf{Y}^{(v)}$  sample. The distribution of  $Z$  will be called its *simulation distribution* or *Monte Carlo distribution*. Features of the simulation distribution, such as its mean, median, and variance, will be called the simulation mean, simulation median, and simulation variance to make clear to which level we have climbed in this ever-expanding tree of terminology. Here is an example to illustrate all of the various levels.

---

**Example**  
**12.2.6**

**Five or More Variances.** Let  $X_1, \dots, X_n$  be i.i.d. random variables with a continuous distribution having c.d.f.  $F$ . Let  $\psi$  denote the variance of  $X_i$ . Suppose that we decide to use the sample variance  $Y = \sum_{i=1}^n (X_i - \bar{X})^2/n$  to estimate  $\psi$ . As part of deciding

**Table 12.3** Levels of probability distributions, statistics, and parameters in a typical simulation analysis

Distribution (D) or sample (S)	Parameter (P) or statistic (S)
(D) Population distribution $F$	(P) Mean, variance, median, etc. $\psi$
(S) Sample $X = (X_1, \dots, X_n)$ from $F$	(S) Estimator $Y$ of $\psi$ based on $X$ , e.g., sample mean, sample variance, sample median, etc.
(D) Sampling distribution $G$ of $Y$	(P) Mean, variance, median, etc., $\theta$ of the sampling distribution of $Y$
(S) Simulated sample $\mathbf{Y} = (Y^{(1)}, \dots, Y^{(v)})$ from $G$	(S) Estimator $Z$ of $\theta$ based on $\mathbf{Y}$ , e.g., sample mean, sample variance, sample median, etc., of $\mathbf{Y}$ .
(D) Simulation distribution $H$ of $Z$	(P) Variance of simulation distribution (simulation variance)
(S) Simulated data (differs by example)	(S) Estimator of simulation variance, (depends on specific example)

how good  $Y$  is as an estimator of  $\psi$ , we are interested in its variance  $\theta = \text{Var}(Y)$ . That is,  $\theta$  is the variance of the sampling distribution of  $Y$ . Suppose that we cannot calculate  $\theta$  in closed form, but suppose that it is easy to simulate from the distribution  $F$ . We might then simulate  $nv$  values  $X_i^{(j)}$  for  $j = 1, \dots, v, i = 1, \dots, n$ . For each  $j$ , we compute the sample variance  $Y^{(j)}$  of the sample  $X_1^{(j)}, \dots, X_n^{(j)}$ . That is,  $Y^{(j)} = \sum_{i=1}^n (X_i^{(j)} - \bar{X}^{(j)})^2/n$ . The  $Y^{(j)}$  values all have the same distribution as  $Y$  itself, the sampling distribution of  $Y$ . Since we are interested in  $\text{Var}(Y)$ , we might compute the sample variance  $Z$  of the sample  $Y^{(1)}, \dots, Y^{(v)}$ . That is,  $Z = \sum_{i=1}^v (Y^{(i)} - \bar{Y})^2/v$ . We would then use  $Z$  to estimate  $\theta$ . If  $Z$  is large, it suggests that  $Y$  has large variance, and so  $Y$  is not a very good estimator of  $\psi$ . Unless we are willing to collect more data or search for a better estimator, we are stuck with a poor estimator of  $\psi$ .

Finally,  $Z$  might not be a good estimator of  $\theta$  because our simulation size  $v$  might not be large enough. If this is the case, we can simulate more  $Y^{(j)}$  values. That is, we can increase the simulation size  $v$  to get a better simulation estimator of  $\theta$ . (This will not make  $Y$  a better estimator of  $\psi$ , but it will give us a better idea of how good or bad an estimator it is.) Hence, we shall also try to estimate the variance of  $Z$  (its simulation variance). Precisely how to do this varies from one example to the next, so we shall not give any details here. However, we shall explain how to estimate the simulation variance of  $Z$  for the most popular types of simulation later in this section.

This estimation of variance has to end somewhere, and we shall end it with  $\text{Var}(Z)$ . That is, we shall *not* try to assess how good our estimator of  $\text{Var}(Z)$  is. All of these levels of distributions and estimation are illustrated in Table 12.3. ◀

Example 12.2.6 is not intended to illustrate any simulation methodology. It is intended to illustrate the various levels at which probability concepts (such as variance) and their sample versions enter into a simulation study of a statistical analysis. It is important to be able to tell which variance or which sample variance is being discussed if one is to avoid becoming hopelessly confused. In this chapter, we shall focus on the features of the simulated samples, in particular the simulation distribution of statistics computed from the simulated samples. However, our examples will necessarily involve parameters and statistics that arose at earlier levels. Furthermore, the analysis of a simulation distribution will make use of the same methods (central

limit theorem, law of large numbers, delta method, etc.) that we learned how to use with nonsimulated data.

## Assessing Uncertainty about Simulation Results

The last step in Example 12.2.6 (summarized in the last two rows of Table 12.3) is an important part of every simulation analysis. That is, we should always attempt to assess the uncertainty in a simulation. This uncertainty is most easily assessed via the simulation variance of the simulated quantity. For instance, in Example 12.2.1, let  $v = 1000$  and  $\theta = 0$ . We can create 1000 samples of  $n$  Cauchy random variables, calculate  $M^{(i)}$ , the median of the  $i$ th sample, and compute the value  $Y^{(i)} = (M^{(i)} - 0)^2$ . We can then average the 1000 values of  $Y^{(i)}$ . We could repeat this exercise several times, and we would not get the same result every time. This is due to the fact that, even with a large  $v$  like 1000, an estimator such as  $Z = \frac{1}{v} \sum_{i=1}^v Y^{(i)}$  is still a random variable with positive variance (its simulation variance). The smaller the simulation variance is, the more certain we can be that our estimator  $Z$  is close to what we are trying to estimate. But we need to estimate or bound the simulation variance before we can assess the amount of uncertainty. How we estimate the simulation variance of a result  $Z$  depends on whether  $Z$  is an average of simulated values, a smooth function of one or more averages, or a sample quantile of simulated values. The square root of our estimate of the simulation variance will be called the *simulation standard error*, and it is an estimate of the simulation standard deviation of  $Z$ . The simulation standard error is a popular way to summarize uncertainty about a simulation for two reasons. First, it has the same units of measurement as the quantity that was estimated (unlike the simulation variance). Second, the simulation standard error is useful for saying how likely it is that the simulation estimator is close to the parameter being estimated. We shall explain this second point in more detail after we show how to calculate the simulation standard error in several common cases.

**Example**  
**12.2.7**

**The Simulation Standard Error of an Average.** Suppose that the goal of the simulation analysis is to estimate the mean  $\theta$  of some random variable  $Y$ . The simulation estimator  $Z$  will generally be the average of a large number of simulated values. A straightforward way to estimate the simulation variance for an average is the following: Suppose that we simulate some quantity  $Y$  a large number  $v$  of times in order to estimate the mean  $\theta$ . That is, suppose that we simulate independent  $Y^{(1)}, \dots, Y^{(v)}$  for large  $v$ . Suppose also that the estimator of  $\theta$  is  $Z = \frac{1}{v} \sum_{i=1}^v Y^{(i)}$ , and each  $Y^{(i)}$  has mean  $\theta$  and finite variance  $\sigma^2$ . The sample standard deviation of the sample  $Y^{(1)}, \dots, Y^{(v)}$  is the square root of the sample variance, namely,

$$\hat{\sigma} = \left( \frac{1}{v} \sum_{i=1}^v (Y^{(i)} - \bar{Y})^2 \right)^{1/2}. \quad (12.2.1)$$

If  $v$  is large, then  $\hat{\sigma}$  should be close to  $\sigma$ . The central limit theorem says that  $Z$  should have approximately the normal distribution with mean  $\theta$  and variance  $\sigma^2/v$ . Since we usually do not know  $\sigma^2$ , we shall estimate it by  $\hat{\sigma}^2$ . This makes our estimator of the simulation variance of  $Z$  equal to  $\hat{\sigma}^2/v$ , and the simulation standard error is  $\hat{\sigma}/v^{1/2}$ .

**Example**  
**12.2.8**

**The Simulation Standard Error of a Smooth Function of Another Estimator.** Sometimes, after estimating a quantity  $\psi$ , we also wish to estimate a smooth function of it:  $g(\psi)$ . For example, we might need to estimate the square root or the logarithm of some

mean. Or, we might have estimated a variance  $\theta^2$ , and now we want an estimator of  $\theta$ , the corresponding standard deviation. In general, suppose that the parameter that we wish to estimate by simulation is  $\theta = g(\psi)$ , where we already have an estimator  $W$  of  $\psi$ . Suppose further that our estimator  $W$  has approximately the normal distribution with mean  $\psi$  and variance  $\sigma^2/v$ , where  $v$  is large compared to  $\sigma^2$ . Finally, suppose that we also have an estimator  $\hat{\sigma}$  of  $\sigma$  that we obtained while calculating  $W$ . For example,  $W$  might itself be the average of  $v$  i.i.d. simulated random variables  $Y^{(i)}$  with mean  $\psi$  and variance  $\sigma^2$ . In this case, Eq. (12.2.1) will be our estimator of  $\sigma$ . Let  $Z = g(W)$  be our estimator of  $\theta$ . The delta method (see Sec. 6.3) says that  $Z$  has approximately the normal distribution with mean  $\theta = g(\psi)$  and variance  $[g'(\psi)]^2\sigma^2/v$ . For example, if  $g(\psi) = \psi^{1/2}$ , then  $W^{1/2}$  has approximately the normal distribution with mean  $\psi^{1/2}$  and variance  $\sigma^2/[4\psi v]$ . We already have estimates of  $\sigma$  and  $\psi$ , so our simulation standard error of  $Z$  is  $|g'(W)|\hat{\sigma}/v^{1/2}$ .  $\blacktriangleleft$

---

**Example**  
**12.2.9**

**The Simulation Standard Error of a Sample Quantile.** Suppose that the goal of a simulation analysis is to estimate the  $p$  quantile  $\theta_p$  of some distribution  $G$ . Typically, we simulate a large number  $v$  of pseudo-random values  $Y^{(1)}, \dots, Y^{(v)}$  with distribution  $G$  and use the sample  $p$  quantile as our estimator. On page 676, we pointed out that the sample  $p$  quantile from a large random sample of size  $m$  has approximately the normal distribution with mean  $\theta_p$  and variance  $p(1-p)/[mg^2(\theta_p)]$ , where  $g$  is the p.d.f. of the distribution  $G$ . All we care about right now is that this approximate variance has the form  $\sigma^2/m$ , where  $\sigma^2 = p(1-p)/g^2(\theta_p)$  is some number that does not depend on  $m$ . Suppose that we simulate  $k$  independent random samples each of size  $m$  from the distribution  $G$ . Typically, this is done by choosing the size  $v$  of the original simulated sample  $Y^{(1)}, \dots, Y^{(v)}$  to be  $v = km$ , and then splitting the  $v$  simulated values into  $k$  subsamples of size  $m$  each. Compute the sample  $p$  quantile of each of the  $k$  random samples and call these simulated sample  $p$  quantiles  $Z_1, \dots, Z_k$ . To make use of the approximate normal distribution for the sample quantiles,  $m$  needs to be large. Next, compute the sample standard deviation of  $Z_1, \dots, Z_k$ :

$$S = \left( \frac{1}{k} \sum_{i=1}^k (Z_i - \bar{Z})^2 \right)^{1/2}, \quad (12.2.2)$$

where  $\bar{Z}$  is the average of the  $k$  sample  $p$  quantiles. If we treat each  $Z_i$  as a single simulation, then  $S^2$  is an estimator of the variance of  $Z_i$ . But we just pointed out that the variance of  $Z_i$  is approximately  $\sigma^2/m$ . Hence,  $S^2$  is an estimator of  $\sigma^2/m$ . In other words, an estimator of  $\sigma$  is  $\hat{\sigma} = m^{1/2}S$ . Finally, combine all  $k$  samples into a single sample of size  $v = km$ , and compute the sample  $p$  quantile  $Z$  as our Monte Carlo estimator of  $\theta_p$ . As we noted earlier,  $Z$  has approximately the normal distribution with mean  $\theta_p$  and variance  $\sigma^2/v$ . We just constructed an estimator  $\hat{\sigma}$  of  $\sigma$ , so our estimator of the simulation variance of  $Z$  is  $\hat{\sigma}^2/v = mS^2/v = S^2/k$ , and the simulation standard error is  $S/k^{1/2}$ .  $\blacktriangleleft$

---

**Example**  
**12.2.10**

**The Simulation Standard Error of a Sample Variance.** Suppose that the goal of a simulation analysis is to estimate the variance  $\theta$  of some estimator  $Y$ . (Example 12.2.6 was based on such a situation.) Suppose that we simulate  $Y^{(1)}, \dots, Y^{(v)}$  and use  $Z = \frac{1}{v} \sum_{i=1}^v (Y^{(i)} - \bar{Y})^2$  to estimate  $\theta$ . We now need to estimate the simulation variance of  $Z$ . We shall rewrite  $Z$  as a smooth function of two averages and then apply a two-dimensional generalization of the delta method (see Exercise 12) in order to estimate the simulation variance. Let  $W^{(i)} = Y^{(i)2}$  so that  $Z = \bar{W} - \bar{Y}^2$ , where  $\bar{W}$  is

the average of  $W^{(1)}, \dots, W^{(v)}$ . Now  $Z$  is a smooth function of two averages. The two-dimensional delta method developed in Exercise 12 can be applied. (The details for this very case can be derived in Exercise 13.) The results of Exercise 13 provide the following approximation to the asymptotic variance of  $Z$ . First, compute the sample variance of  $W^{(1)}, \dots, W^{(v)}$  and call it  $V$ . Next, compute the sample covariance between the  $Y$ 's and  $W$ 's:

$$C = \frac{1}{v} \sum_{i=1}^v (Y^{(i)} - \bar{Y})(W^{(i)} - \bar{W}).$$

The estimator of  $\text{Var}(Z)$  is then

$$\widehat{\text{Var}}(Z) = \frac{1}{v} (4\bar{Y}^2 Z - 4\bar{Y}C + V). \quad (12.2.3)$$

Also, the simulation distribution of  $Z$  is approximately the normal distribution with mean  $\theta$  and variance that is estimated by Eq. (12.2.3). The simulation standard error is the square root of (12.2.3).  $\blacktriangleleft$

**Do We Have Enough Simulations?** Let  $Z$  be our Monte Carlo estimator of some parameter  $\theta$  based on  $v$  simulations. Now that we are able to estimate the simulation variance of  $Z$ , we can begin to answer questions about how close we think  $Z$  is to  $\theta$ . We can also try to see if we need to do more simulations in order to be confident that  $Z$  is close enough to  $\theta$ . Suppose, as in all of the cases considered so far, that  $Z$  has approximately the normal distribution with mean  $\theta$  and variance  $\sigma^2/v$ , where  $\sigma^2$  is a number that does not depend on the simulation size. For each  $\epsilon > 0$ ,

$$\Pr(|Z - \theta| \leq \epsilon) \approx 2\Phi\left(\epsilon v^{1/2}/\sigma\right) - 1, \quad (12.2.4)$$

where  $\Phi$  is the standard normal c.d.f. We can use this type of approximation to help us to say how likely it is that  $Z$  is close to  $\theta$ . We can replace  $v^{1/2}/\sigma$  by 1 over the simulation standard error of  $Z$  in Eq. (12.2.4) to approximate the probability that  $|Z - \theta| \leq \epsilon$ . We can also use (12.2.4) to decide how many more simulations to do if  $v$  was not large enough. For example, suppose that we want the probability in Eq. (12.2.4) to be  $\gamma$ . Then we should let

$$v = \left[ \Phi^{-1}\left(\frac{1+\gamma}{2}\right) \frac{\sigma}{\epsilon} \right]^2. \quad (12.2.5)$$

Since we will hardly ever know  $\sigma$  ahead of time, it is common to estimate it by doing a preliminary simulation of size  $v_0$  and computing  $\hat{\sigma}$  based on that preliminary simulation.

**Example**  
**12.2.11**

**The M.S.E. of the Sample Median.** It is not difficult to see that we can take  $\mu = 0$  in Example 12.2.1 without loss of generality. The reason is the following: Let  $M^{(i)}$  be the sample median of  $X_1^{(i)}, \dots, X_n^{(i)}$  where each  $X_j^{(i)}$  is a Cauchy random variable centered at  $\mu$ . Then  $M^{(i)} - \mu$  is also the sample median of  $X_1^{(i)} - \mu, \dots, X_n^{(i)} - \mu$ , and each  $X_j^{(i)} - \mu$  is a Cauchy random variable centered at 0. Because our calculation is based on the values  $Y^{(i)} = (M^{(i)} - \mu)^2$  for  $i = 1, \dots, v$ , we get the same result whether  $\mu = 0$  or not. So, let  $\mu = 0$ . This makes  $Y^{(i)} = M^{(i)2}$ , and  $\sigma^2$  is now the variance of  $M^{(i)2}$ . (Even though a Cauchy random variable does not even have a first moment defined, it can be shown that the sample median of at least nine i.i.d. Cauchy random variables has a finite fourth moment.) Suppose that we want our estimator  $Z = \bar{Y}$  of  $\theta$  to be within  $\epsilon = 0.01$  of  $\theta$  with probability  $\gamma = 0.95$ . That

is, we want  $\Pr(|Z - \theta| \leq 0.01) = 0.95$ . Since  $Z$  is an average, we can compute an estimate  $\hat{\sigma}$  of  $\sigma$  by using Eq. (12.2.1). Suppose that we simulate  $v_0 = 1000$  samples of size  $n = 20$  from a Cauchy distribution, compute the 1000 values of  $Y^{(i)}$ , and then compute  $\hat{\sigma} = 0.3892$ . According to Eq. (12.2.5) with  $\sigma$  replaced by 0.3892, we need  $v = [1.96 \times 0.3892/0.01]^2 = 5820$ . Hence, we need approximately 4820 additional simulations.  $\blacktriangleleft$

After performing any additional simulations suggested by Eq. (12.2.5), one should recompute  $\hat{\sigma}$ . If it is much larger than the preliminary estimate, then additional simulations should be performed.

**Example**  
**12.2.12**

**The Median of a Complicated Distribution.** In Example 12.2.2, suppose that the p.d.f.  $g$  is the p.d.f. of the gamma distribution with parameters 3 and 1. Suppose that we want the probability to be 0.99 that our estimator of the median is within 0.001 of the true median. We begin with an initial simulation of size  $v_0 = 10,000$ . We then simulate  $\mu^{(1)}, \dots, \mu^{(10,000)}$  from the gamma distribution with parameters 3 and 1. For each  $i$ , we simulate  $X^{(i)}$  having the exponential distribution with parameter  $\mu^{(i)}$ . We treat  $X^{(1)}, \dots, X^{(10,000)}$  as  $k = 20$  samples of size  $m = 500$  each, and we compute the sample median  $Z_1, \dots, Z_{20}$  of each of the 20 samples. After performing these initial simulations, suppose that we observe the value  $S = 0.01597$  for Eq. (12.2.2). This makes  $\hat{\sigma} = 0.3570$ . Plugging this value into (12.2.5) for  $\sigma$  with  $\gamma = 0.99$  and  $\epsilon = 0.001$  yields  $v = 845,747.4$ . This means that we need a total of 845,748 simulations to reach our desired level of confidence in the simulated result. Just to check, we simulated a total of 900,000 values and computed the sample median 0.2593 as well as a new value of  $S^2$  based on  $k = 100$  subsamples of size  $m = 6200$  each. The new value of  $\hat{\sigma}$  is 0.4529. Substituting 0.4529 for  $\sigma$  in Eq. (12.2.5) yields a new  $v = 1,360,939$ , which means that we still need another 460,939 simulations.  $\blacktriangleleft$

## ◆ Simulating Real Processes

In many scientific fields, real physical or social processes are modeled as having random components. For example, stock prices are often modeled as having lognormal distributions as in Example 5.6.10. Many processes involving waiting times and service are modeled using Poisson processes. The simple probability models that have been developed earlier in this text are merely the building blocks of which such models of real processes are constructed. Here, we shall give two examples of slightly more complicated models that can be constructed using the distributions we already know. The analyses of these models can be simplified by the use of simulation.

**Example**  
**12.2.13**

**Option Pricing.** In Example 5.6.10, we introduced the formula of Black and Scholes (1973) for pricing options. In that example, the option was to buy shares at price  $q$  of a stock whose value at time  $u$  (in the future) is a random variable  $S_u$  with a known lognormal distribution. Many financial analysts believe that the standard deviation  $\sigma$  of  $\log(S_u)$  in Example 5.6.10 should not be treated as a known constant. For example, we could treat  $\sigma$  as a random variable with a p.d.f.  $f(\sigma)$ . To be precise, we shall continue to assume that  $S_u = S_0 e^{(r-\sigma^2/2)u + \sigma u^{1/2} Z}$ , but now we shall assume that both  $Z$  and  $\sigma$  are random variables. For convenience, we shall assume that they are independent. We shall let  $Z$  have the standard normal distribution, and we shall let  $\tau = 1/\sigma^2$  have the gamma distribution with known parameters  $\alpha$  and  $\beta$ . The parameters  $\alpha$  and  $\beta$  might result from estimating the variance of stock prices based on historical data combined with expert opinion of stock analysts. For example,

they might be the posterior hyperparameters that result from applying a Bayesian analysis to a sample of stock prices. It is easy to see that  $E(S_u|\sigma) = S_0 e^{ru}$  for all  $\sigma$ , and hence the law of total probability for expectations (Theorem 4.7.1) implies that  $E(S_u) = S_0 e^{ru}$ . This is what we need for risk neutrality. The price for the option considered in Example 5.6.10 is the mean of the random variable  $e^{-ru}h(S_u)$ , where

$$h(s) = \begin{cases} s - q & \text{if } s > q, \\ 0 & \text{otherwise.} \end{cases}$$

The Black-Scholes formula (5.6.18) is just the conditional mean of  $e^{-ru}h(S_u)$  given  $\sigma$ . To estimate the marginal mean of  $e^{-ru}h(S_u)$ , we could simulate a large number of values  $\sigma^{(i)}$  ( $i = 1, \dots, v$ ) from the distribution of  $\sigma$ , substitute each  $\sigma^{(i)}$  into (5.6.18), and average the results.

As an example, suppose that we take the same numerical situation from the end of Example 5.6.10 with  $u = 1$ ,  $r = 0.06$ , and  $q = S_0$ . This time, suppose that  $1/\sigma^2$  has the gamma distribution with parameters 2 and 0.0127. (These numbers make  $E(\sigma) = 0.1$ , but  $\sigma$  has substantial variability.) We can sample  $v = 1,000,000$  values of  $\sigma$  from this distribution and compute (5.6.18) for each value. The average, in our simulation, is  $0.0756S_0$ , and the simulation standard error is  $1.814S_0 \times 10^{-5}$ . The option price is only slightly higher than it was when we assumed that we knew  $\sigma$ . When the distribution of  $S_u$  is even more complicated, one can simulate  $S_u$  directly and estimate the mean of  $h(S_u)$ . ◀

In the following example, each simulation requires a large number of steps, but each step is relatively simple. The combination of several simple steps into one complicated step is very common in simulations of real processes.

**Example  
12.2.14**

**A Service Queue with Impatient Customers.** Consider a queue to which customers arrive according to a Poisson process with rate  $\lambda$  per hour. Suppose that the queue has a single server. Each customer who arrives at the queue counts the length  $r$  of the queue (including the customer being served) and decides to leave with probability  $p_r$ , for  $r = 1, 2, \dots$ . A customer who leaves does *not* enter the queue. Each customer who enters the queue waits in the order of arrival until the customer immediately in front is done being served, and then moves to the head of the queue. The time (in hours) to serve a customer, after reaching the head of the queue, is an exponential random variable with parameter  $\mu$ . Assume that all service times are independent of each other and of all arrival times.

We can use simulation to learn about the behavior of such a queue. For example, we could estimate the expected number of customers in the queue at a particular time  $t$  after the queue opens for business. To do this, we could simulate many, say,  $v$ , realizations of the queue operation. For each realization  $i$ , we count how many customers  $N^{(i)}$  are in the queue at time  $t$ . Then our estimator is  $\frac{1}{v} \sum_{i=1}^v N^{(i)}$ . To simulate a single realization, we could proceed as follows: Simulate interarrival times  $X_1, X_2, \dots$  of the Poisson process as i.i.d. exponential random variables with parameter  $\lambda$ . Let  $T_j = \sum_{i=1}^j X_i$  be the time at which customer  $j$  arrives. Stop simulating at the first  $k$  such that  $T_k > t$ . Only the first  $k - 1$  customers have even arrived at the queue by time  $t$ . For each  $j = 1, \dots, k - 1$ , simulate a service time  $Y_j$  having the exponential distribution with parameter  $\mu$ . Let  $Z_j$  stand for the time at which the  $j$ th customer reaches the head of the queue, and let  $W_j$  stand for the time at which the  $j$ th customer leaves the queue. For example,  $Z_1 = X_1$  and  $W_1 = X_1 + Y_1$ . For  $j > 1$ , the  $j$ th customer first counts the length of the queue and decides whether or not to leave. Let  $U_{i,j} = 1$  if customer  $i$  is still in the queue when customer  $j$  arrives ( $i < j$ ),

and let  $U_{i,j} = 0$  if customer  $i$  has already left the queue. Then

$$U_{i,j} = \begin{cases} 1 & \text{if } W_i \geq T_j, \\ 0 & \text{otherwise.} \end{cases}$$

The number of customers in the queue when the  $j$ th customer arrives is  $r = \sum_{i=1}^{j-1} U_{i,j}$ . We then simulate a random variable  $V_j$  having the Bernoulli distribution with parameter  $p_r$ . If  $V_j = 1$ , customer  $j$  leaves the queue so that  $W_j = T_j$ . If customer  $j$  stays in the queue, then this customer reaches the head of the queue at time

$$Z_j = \max\{T_j, W_1, \dots, W_{j-1}\}.$$

That is, the  $j$ th customer either reaches the head of the queue immediately upon arrival (if nobody is still being served) or as soon as all of the previous  $j - 1$  customers have left, whichever comes later. Also,  $W_j = Z_j + Y_j$  if customer  $j$  stays. For each  $j = 1, \dots, k - 1$ , the  $j$ th customer is in the queue at time  $t$  if and only if  $W_j \geq t$ .

As a numerical example, suppose that  $\lambda = 2$ ,  $\mu = 1$ ,  $t = 3$ , and  $p_r = 1 - 1/r$ , for  $r \geq 1$ . Suppose that the first  $k = 6$  simulated interarrival times are

$$0.215, 0.713, 1.44, 0.174, 0.342, 0.382.$$

The sum of the first five of these times is 2.884, but the sum of all six is 3.266. So, at most five customers are in the queue at time  $t = 3$ . Suppose that the simulated service times for the first five customers are

$$0.251, 2.215, 2.855, 0.666, 2.505.$$

We cannot simulate the  $V_j$ 's in advance, because we do not yet know how many customers will be in the queue when each customer  $j$  arrives. Figure 12.3 shows a time line of the simulation of the process that we are about to describe. Begin with customer 1, who has  $T_1 = Z_1 = 0.215$  and  $W_1 = 0.215 + 0.251 = 0.466$ . For customer 2,  $T_2 = T_1 + 0.713 = 0.928 > W_1$ , so nobody is in the queue when customer 2 arrives and  $Z_2 = T_2 = 0.928$ . Then  $W_2 = Z_2 + 2.215 = 3.143$ . For customer 3,  $T_3 = T_2 + 1.44 = 2.368 < W_2$ , so  $r = 1$ . Because  $p_1 = 0$ , customer 3 stays, and there is no need to

**Figure 12.3** One simulation of a service queue. The bottom line is the time line for Example 12.2.14. Each customer is represented by one horizontal line segment. The vertical line at  $t = 3$  crosses the horizontal lines for those customers still in the queue at time  $t = 3$ .

simulate  $V_3$ . Then  $Z_3 = W_2 = 3.143$ , and  $W_3 = Z_3 + 2.855 = 5.998$ . For customer 4,  $T_4 = T_3 + 0.174 = 2.542$ . Since  $W_1 < T_4 < W_2$ , we have  $r = 2$  customers in the queue. We then simulate  $V_4$  having the Bernoulli distribution with parameter  $p_2 = 1/2$ . Suppose that we simulate  $V_4 = 1$ , so customer 4 leaves, and we ignore the fourth simulated service time. This makes  $W_4 = T_4 = 2.542$ . For customer 5,  $T_5 = T_4 + 0.342 = 2.884$ , and customers 2 and 3 are still in the queue. We need to simulate  $V_5$  having the Bernoulli distribution with parameter  $p_2 = 1/2$ . Suppose that  $V_5 = 0$ , so customer 5 stays. Then  $Z_5 = W_3 = 5.988$ , and  $W_5 = Z_5 + 2.505 = 8.393$ . Finally,  $W_j \geq 3$  for  $j = 2, 3, 5$ . This means that there are  $N^{(1)} = 3$  customers in the queue at time  $t = 3$ , as illustrated in Fig. 12.3. Needless to say, a computer should be programmed to do this calculation for a large simulation. 

## Summary

If we wish to compute the expected value  $\theta$  of some random variable  $Y$ , but cannot perform the necessary calculation in closed form, we can use simulation. In general, we would simulate a large random sample  $Y^{(1)}, \dots, Y^{(v)}$  from the same distribution as  $Y$ , and then compute the sample mean  $Z$  as our estimator. We can also estimate a quantile  $\theta_p$  of a distribution in a similar fashion. If  $Y^{(1)}, \dots, Y^{(v)}$  is a large sample from the distribution, we can compute the sample  $p$  quantile  $Z$ . It is always a good idea to compute some measure of how good a simulation estimator is. One common measure is the simulation standard error of  $Z$ , an estimate of the standard deviation of the simulation distribution of  $Z$ . Alternatively, one could perform enough simulations to make sure that the probability is high that the  $Z$  is close to the parameter being estimated.

## Exercises

- 1.** Eq. (12.2.4) is based on the assumption that  $Z$  has approximately a normal distribution. Occasionally, the normal approximation is not good enough. In such cases, one can let

$$v = \frac{\sigma^2}{\epsilon^2(1 - \gamma)}. \quad (12.2.6)$$

To be precise, let  $Z$  be the average of  $v$  independent random variables with mean  $\mu$  and variance  $\sigma^2$ . Prove that if  $v$  is at least as large as the number in Eq. (12.2.6), then  $\Pr(|Z - \mu| \leq c) \geq \gamma$ . *Hint:* Use the Chebyshev inequality (6.2.3).

- 2.** In Example 12.2.11, how large would  $v$  need to be according to Eq. (12.2.6)?

- 3.** Suppose that we have available as many i.i.d. standard normal random variables as we desire. Let  $X$  stand for a random variable having the normal distribution with mean 2 and variance 49. Describe a method for estimating  $E(\log(|X| + 1))$  using simulation.

- 4.** Use a pseudo-random number generator to simulate a sample of 15 independent observations in which 13 of the

15 are drawn from the uniform distribution on the interval  $[-1, 1]$  and the other two are drawn from the uniform distribution on the interval  $[-10, 10]$ . For the 15 values that are obtained, calculate the values of (a) the sample mean, (b) the trimmed means for  $k = 1, 2, 3$ , and 4 (see Sec. 10.7), and (c) the sample median. Which of these estimators is closest to 0?

- 5.** Repeat Exercise 4 ten times, using a different pseudo-random sample each time. In other words, construct 10 independent samples, each of which contains 15 observations and each of which satisfies the conditions of Exercise 4.

- a.** For each sample, which of the estimators listed in Exercise 4 is closest to 0?
- b.** For each of the estimators listed in Exercise 4, determine the square of the distance between the estimator and 0 in each of the 10 samples, and determine the average of these 10 squared distances. For which of the estimators is this average squared distance from 0 smallest?

6. Suppose that  $X$  and  $Y$  are independent, that  $X$  has the beta distribution with parameters 3.5 and 2.7, and that  $Y$  has the beta distribution with parameters 1.8 and 4.2. We are interested in the mean of  $X/(X + Y)$ . You may assume that you have the ability to simulate as many random variables with whatever beta distributions you wish.

- a. Describe a simulation plan that will produce a good estimator of the mean of  $X/(X + Y)$  if enough simulations are performed.

- b. Suppose that you want to be 98 percent confident that your estimator is no more than 0.01 away from the actual value of  $E[X/(X + Y)]$ . Describe how you would determine an appropriate size for the simulation.

7. Consider the numbers in Table 10.40 on page 676. Suppose that you have available as many standard normal random variables and as many uniform random variables on the interval  $[0, 1]$  as you desire. You want to perform a simulation to obtain the number in the “Sample median” row and  $\epsilon = 0.05$  column.

- a. Describe how to perform such a simulation. Hint: Let  $X$  and  $U$  be independent such that  $X$  has the standard normal distribution and  $U$  has the uniform distribution on the interval  $[0, 1]$ . Let  $0 < \epsilon < 1$ , and find the distribution of

$$Y = \begin{cases} X & \text{if } U > \epsilon, \\ 10X & \text{if } U < \epsilon. \end{cases}$$

- b. Perform the simulation on a computer.

8. Consider the same situation described in Exercise 7. This time, consider the number in the “Trimmed mean for  $k = 2$ ” row and  $\epsilon = 0.1$  column.

- a. Describe how to perform a simulation to produce this number.
- b. Perform the simulation on a computer.

9. In Example 12.2.12, we can actually compute the median  $\theta$  of the distribution of the  $X_i$  in closed form. Calculate the true median, and see how far the simulated value was from the true value. Hint: Find the marginal p.d.f. of  $X$  by using the law of total probability for random variables (3.6.12) together with Eq. (5.7.10). The c.d.f. and quantile function are then easy to derive.

10. Let  $X_1, \dots, X_{21}$  be i.i.d. with the exponential distribution that has parameter  $\lambda$ . Let  $M$  stand for the sample median. We wish to compute the M.S.E. of  $M$  as an estimator of the median of the distribution of the  $X_i$ 's.

- a. Determine the median of the distribution of  $X_1$ .
- b. Let  $\theta$  be the M.S.E. of the sample median when  $\lambda = 1$ . Prove that the M.S.E. of the sample median equals  $\theta/\lambda^2$  in general.
- c. Describe a simulation method for estimating  $\theta$ .

11. In Example 12.2.4, there is a slightly simpler way to simulate a sample from the posterior distribution of  $\mu_x - \mu_y$ . Suppose that we can simulate as many independent  $t$  pseudo-random variables as we wish with whatever degrees of freedom we want. Explain how we could use these  $t$  random variables to simulate a sample from the posterior distribution of  $\mu_x - \mu_y$ .

12. Let  $(Y_1, W_1), \dots, (Y_n, W_n)$  be an i.i.d. sample of random vectors with finite covariance matrix

$$\Sigma = \begin{pmatrix} \sigma_{yy} & \sigma_{yw} \\ \sigma_{yw} & \sigma_{ww} \end{pmatrix}.$$

Let  $\bar{Y}$  and  $\bar{W}$  be the sample averages. Let  $g(y, w)$  be a function with continuous partial derivatives  $g_1$  and  $g_2$  with respect to  $y$  and  $w$ , respectively. Let  $Z = g(\bar{Y}, \bar{W})$ . The two-dimensional Taylor expansion of  $g$  around a point  $(y_0, w_0)$  is

$$g(y, w) = g(y_0, w_0) + g_1(y_0, w_0)(y - y_0) + g_2(y_0, w_0)(w - w_0), \quad (12.2.7)$$

plus an error term that we shall ignore here. Let  $(y, w) = (\bar{Y}, \bar{W})$  and  $(y_0, w_0) = (E(Y), E(W))$  in Eq. (12.2.7). To the level of approximation of Eq. (12.2.7), prove that

$$\begin{aligned} \text{Var}(Z) &= g_1(E(Y), E(W))^2 \sigma_{yy} \\ &\quad + 2g_1(E(Y), E(W))g_2(E(Y), E(W))\sigma_{yw} \\ &\quad + g_2(E(Y), E(W))^2 \sigma_{ww}. \end{aligned}$$

Hint: Use the formula for the variance of a linear combination of random variables derived in Sec. 4.6.

13. Use the two-dimensional delta method from Exercise 12 to derive the estimator of the simulation variance of a sample variance as given in Eq. (12.2.3). Hint: Replace  $E(Y)$  and  $E(W)$  by  $\bar{Y}$  and  $\bar{W}$ , respectively, and replace  $\Sigma$  by the sample variances and sample covariance.

14. Let  $Y$  be a random variable with some distribution. Suppose that you have available as many pseudo-random variables as you want with the same distribution as  $Y$ . Describe a simulation method for estimating the skewness of the distribution of  $Y$ . (See Definition 4.4.1.)

15. Suppose that the price of a stock at time  $u$  in the future is a random variable  $S_u = S_0 e^{\alpha u + W_u}$ , where  $S_0$  is the current price,  $\alpha$  is a constant, and  $W_u$  is a random variable with known distribution. Suppose that you have available as many i.i.d. random variables as you wish with the distribution of  $W_u$ . Suppose that the m.g.f.  $\psi(t)$  of  $W_u$  is known and finite on an interval that contains  $t = 1$ .

- a. What number should  $\alpha$  equal in order that  $E(S_u) = e^{\alpha u} S_0$ ?
- b. We wish to price an option to purchase one share of this stock at time  $u$  for the price  $q$ . Describe how you could use simulation to estimate the price of such an option.

- 16.** Consider a queue to which customers arrive according to a Poisson process with rate  $\lambda$  per hour. Suppose that the queue has two servers. Each customer who arrives at the queue counts the length  $r$  of the queue (including any customers being served) and decides to leave with probability  $p_r$ , for  $r = 2, 3, \dots$ . A customer who leaves does *not* enter the queue. Each customer who enters the queue waits in the order of arrival until at least one of the two servers is available, and then begins being served by the available

server. If both servers are available, the customer chooses randomly between the two servers with probability  $1/2$  for each, independent of all other random variables. For server  $i$  ( $i = 1, 2$ ), the time (in hours) to serve a customer, after beginning service, is an exponential random variable with parameter  $\mu_i$ . Assume that all service times are independent of each other and of all arrival times. Describe how to simulate the number of customers in the queue (including any being served) at a specific time  $t$ .

## 12.3 Simulating Specific Distributions

*In order to perform statistical simulations, we must be able to obtain pseudo-random values from a variety of distributions. In this section, we introduce some methods for simulating from specific distributions.*

Most computer packages with statistical capability are able to generate pseudo-random numbers with the uniform distribution on the interval  $[0, 1]$ . We shall assume throughout the remainder of this section that one has available an arbitrarily large sample of what appear to be i.i.d. random variables (pseudo-random numbers) with the uniform distribution on the interval  $[0, 1]$ . Usually, we need random variables with other distributions, and the purpose of this section is to review some common methods for transforming uniform random variables into random variables with other distributions.

### The Probability Integral Transformation

In Chapter 3, we introduced the probability integral transformation for transforming a uniform random variable  $X$  on the interval  $[0, 1]$  into a random variable  $Y$  with a continuous strictly increasing c.d.f.  $G$ . The method is to set  $Y = G^{-1}(X)$ . This method works well if  $G^{-1}$  is easily computed.

**Example  
12.3.1**

**Generating Exponential Pseudo-Random Variables.** Suppose that we want  $Y$  to have the exponential distribution with parameter  $\lambda$ , where  $\lambda$  is a known constant. The c.d.f. of  $Y$  is

$$G(y) = \begin{cases} 1 - e^{-\lambda y} & \text{if } y \geq 0, \\ 0 & \text{if } y < 0. \end{cases}$$

We can easily invert this function to obtain

$$G^{-1}(x) = -\log(1-x)/\lambda, \quad \text{if } 0 < x < 1.$$

If  $X$  has the uniform distribution on the interval  $[0, 1]$ , then  $-\log(1-X)/\lambda$  has the exponential distribution with parameter  $\lambda$ .  $\blacktriangleleft$

### Special-Purpose Algorithms

There are cases in which the desired c.d.f.  $G$  is not easy to invert. For example, if  $G$  is the standard normal c.d.f., then  $G^{-1}$  must be obtained by numerical approximation.

However, there is a clever method for transforming two independent uniform random variables on the interval  $[0, 1]$  into two standard normal random variables. The method was described by Box and Müller (1958).

**Example  
12.3.2**

**Generating Two Independent Standard Normal Variables.** Let  $X_1, X_2$  be independent with the uniform distribution on the interval  $[0, 1]$ . The joint p.d.f. of  $(X_1, X_2)$  is

$$f(x_1, x_2) = 1, \quad \text{for } 0 < x_1, x_2 < 1.$$

Define

$$Y_1 = [-2 \log(X_1)]^{1/2} \sin(2\pi X_2),$$

$$Y_2 = [-2 \log(X_1)]^{1/2} \cos(2\pi X_2).$$

The inverse of this transformation is

$$X_1 = \exp[-(Y_1^2 + Y_2^2)/2],$$

$$X_2 = \frac{1}{2\pi} \arctan(Y_1/Y_2).$$

Using the methods of Sec. 3.9, we compute the Jacobian, which is the determinant of the matrix of partial derivatives of the inverse function:

$$\begin{pmatrix} -y_1 \exp[-(y_1^2 + y_2^2)/2] & -y_2 \exp[-(y_1^2 + y_2^2)/2] \\ \frac{1}{2\pi y_2} \frac{1}{1+(y_1/y_2)^2} & -\frac{y_1}{2\pi y_2^2} \frac{1}{1+(y_1/y_2)^2} \end{pmatrix}.$$

The determinant of this matrix is  $J = \exp[-(y_1^2 + y_2^2)/2]/(2\pi)$ . The joint p.d.f. of  $(Y_1, Y_2)$  is then

$$\begin{aligned} g(y_1, y_2) &= f\left(\exp[-(y_1^2 + y_2^2)/2], \arctan(y_1/y_2)/(2\pi)\right) |J| \\ &= \exp[-(y_1^2 + y_2^2)/2]/(2\pi). \end{aligned}$$

This is the joint p.d.f. of two independent standard normal variables. ◀

## Acceptance/Rejection

Many other special-purpose methods exist for other distributions, also. We would like to present here one more general-purpose method that has wide applicability. The method is called *acceptance/rejection*. Let  $f$  be a p.d.f. and assume that we would like to sample a pseudo-random variable with this p.d.f. Assume that there exists another p.d.f.  $g$  with the following two properties:

- We know how to simulate a pseudo-random variable with p.d.f.  $g$ .
- There exists a constant  $k$  such that  $kg(x) \geq f(x)$  for all  $x$ .

To simulate a single  $Y$  with p.d.f.  $f$ , perform the following steps:

1. Simulate a pseudo-random  $X$  with p.d.f.  $g$  and an independent uniform pseudo-random variable  $U$  on the interval  $[0, 1]$ .
2. If

$$\frac{f(X)}{g(X)} \geq kU, \quad (12.3.1)$$

let  $Y = X$ , and stop the process.

3. If (12.3.1) fails, throw away  $X$  and  $U$ , and return to the first step.

If we need more than one  $Y$ , we repeat the entire process as often as needed. We now show that the p.d.f. of each  $Y$  is  $f$ .

**Theorem 12.3.1** The p.d.f. of  $Y$  in the acceptance/rejection method is  $f$ .

**Proof** First, we note that the distribution of  $Y$  is the conditional distribution of  $X$  given that (12.3.1) holds. That is, let  $A$  be the event that (12.3.1) holds, and let  $h(x, u|A)$  be the conditional joint p.d.f. of  $(X, U)$  given  $A$ . Then the p.d.f. of  $Y$  is  $\int h(x, u|A) du$ . This is because  $Y$  is constructed to be  $X$  conditional on (12.3.1) holding. The conditional p.d.f. of  $(X, U)$  given  $A$  is

$$h(x, u|A) = \frac{1}{\Pr(A)} \begin{cases} g(x) & \text{if } f(x)/g(x) \geq ku \text{ and } 0 < u < 1, \\ 0 & \text{otherwise.} \end{cases}$$

It is straightforward to calculate  $\Pr(A)$ , that is, the probability that  $U \leq f(X)/[kg(X)]$ .

$$\Pr(A) = \int_{-\infty}^{\infty} \int_0^{f(x)/[kg(x)]} g(x) du dx = \int_{-\infty}^{\infty} \frac{1}{k} f(x) dx = \frac{1}{k}.$$

So,

$$h(x, u|A) = k \begin{cases} g(x) & \text{if } f(x)/g(x) \geq ku \text{ and } 0 < u < 1, \\ 0 & \text{otherwise.} \end{cases}$$

The integral of this function over all  $u$  values for fixed  $x$  is the p.d.f. of  $Y$  evaluated at  $x$ :

$$\int h(x, u|A) du = k \int_0^{f(x)/[kg(x)]} g(x) du = f(x). \quad \blacksquare$$

Here is an example of the use of acceptance/rejection.

**Example 12.3.3**

**Simulating a Beta Distribution.** Suppose that we wish to simulate a random variable  $Y$  having the beta distribution with parameters 1/2 and 1/2. The p.d.f. of  $Y$  is

$$f(y) = \frac{1}{\pi} y^{-1/2} (1-y)^{-1/2}, \text{ for } 0 < y < 1.$$

Note that this p.d.f. is unbounded. However, it is easy to see that

$$f(y) \leq \frac{1}{\pi} (y^{-1/2} + (1-y)^{-1/2}), \quad (12.3.2)$$

for all  $0 < y < 1$ . The right side of Eq. (12.3.2) can be written as  $kg(y)$  with  $k = 4/\pi$  and

$$g(y) = \frac{1}{2} \left[ \frac{1}{2y^{1/2}} + \frac{1}{2(1-y)^{1/2}} \right].$$

This  $g$  is a half-and-half mixture of two p.d.f.'s  $g_1$  and  $g_2$ :

$$\begin{aligned} g_1(x) &= \frac{1}{2x^{1/2}}, \text{ for } 0 < x < 1, \\ g_2(x) &= \frac{1}{2(1-x)^{1/2}}, \text{ for } 0 < x < 1. \end{aligned} \quad (12.3.3)$$

We can easily simulate random variables from these distributions using the probability integral transformation. To simulate a random variable  $X$  with p.d.f.  $g$ , simulate three random independent variables  $U_1, U_2, U_3$  with uniform distributions on the

interval  $[0, 1]$ . If  $U_1 \leq 1/2$ , simulate  $X$  from  $g_1$  using the probability integral transformation applied to  $U_2$ . If  $U_1 > 1/2$ , simulate  $X$  from  $g_2$  using the probability integral transformation and  $U_2$ . If  $f(X)/g(X) \geq kU_3$ , let  $Y = X$ . If not, repeat the process.  $\blacktriangleleft$

When using the acceptance/rejection method, one must usually reject simulated values and resimulate. The probability of accepting a value is  $\Pr(A)$  in the proof of Theorem 12.3.1, namely,  $1/k$ . The larger  $k$  is, the harder it will be to accept. In Exercise 5, you will prove that the expected number of iterations until the first acceptance is  $k$ .

A common special case of acceptance/rejection is the simulation of a random variable conditional on some event. For example, let  $X$  be a random variable with the p.d.f.  $g$ , and suppose that we want the conditional distribution of  $X$  given that  $X > 2$ . Then the conditional p.d.f. of  $X$  given  $X > 2$  is

$$f(x) = \begin{cases} kg(x) & \text{if } x > 2, \\ 0 & \text{if } x \leq 2, \end{cases}$$

where  $k = 1/\int_2^\infty g(x) dx$ . Note that  $f(x) \leq kg(x)$  for all  $x$ , so acceptance/rejection is applicable. In fact, since  $f(X)/g(X)$  only takes the two values  $k$  and 0, we don't need to simulate the uniform  $U$  in the acceptance/rejection algorithm. We don't even need to compute the value  $k$ . We just reject each  $X \leq 2$ . Here is a version of the same algorithm to solve a question that was left open in Sec. 11.8.

**Example**  
**12.3.4**

**Computing the Size of a Two-Stage Test.** In Sec. 11.8, we studied the analysis of data from a two-way layout with replication. In that section, we introduced a two-stage testing procedure. First, we tested the hypotheses (11.8.11), and then, if we accepted the null hypothesis, we proceeded to test the hypotheses (11.8.13). Unfortunately, we were unable to compute the conditional size of the second test given that the first test accepted the null hypothesis. That is, we could not calculate (11.8.15) in closed form. However, we can use simulation to estimate the conditional size.

The two tests are based on  $U_{AB}^2$ , defined in Eq. (11.8.12), and  $V_A^2$ , defined in Eq. (11.8.16). The first test rejects the null hypothesis in (11.8.11) if  $U_{AB}^2 \geq d$ , where  $d$  is a quantile of the appropriate  $F$  distribution. The second test rejects its null hypothesis if  $V_A^2 \geq c$ , where  $c$  is yet to be determined. The random variables  $U_{AB}^2$  and  $V_A^2$  are both ratios of various mean squares. In particular, they share a common denominator  $MS_{\text{Resid}} = S_{\text{Resid}}^2/[IJ(K-1)]$ . In order to determine an appropriate critical value  $c$  for the second test, we need the conditional distribution of  $V_A^2$  given that  $U_{AB}^2 < d$ , and given that both null hypotheses are true. We can sample from that conditional distribution as follows: Let the interaction mean square be  $MS_{AB} = S_{\text{Int}}^2/[(I-1)(J-1)]$ , and let the mean square for factor A be  $MS_A = S_A^2/(I-1)$ . Then  $U_{AB}^2 = MS_{AB}/MS_{\text{Resid}}$  and  $V_A^2 = MS_A/MS_{\text{Resid}}$ . All of these mean squares are independent, and they all have different gamma distributions when the null hypotheses are both true. Most statistical computer packages will allow simulation of gamma random variables. So, we start by simulating many triples  $(MS_{AB}, MS_{\text{Resid}}, MS_A)$ . Then, for each simulated triple, we compute  $U_{AB}^2$  and  $V_A^2$ . If  $U_{AB}^2 \geq d$ , we discard the corresponding  $V_A^2$ . The undiscarded  $V_A^2$  values are a random sample from the conditional distribution that we need. The efficiency of this algorithm could be improved slightly by simulating  $MS_A$  and then computing  $V_A^2$  only when  $U_{AB}^2 < d$  is observed.  $\blacktriangleleft$

## Generating Functions of Other Random Variables

It often happens that there is more than one way to simulate from a particular distribution. For example, suppose that a distribution is defined as the distribution of a particular function of other random variables (in the way that the  $\chi^2$ ,  $t$ , and  $F$  distributions are). In such cases, there is a straightforward way to simulate the desired distribution. First, simulate the random variables in terms of which the distribution is defined, and then calculate the appropriate function.

---

**Example  
12.3.5**

**Alternate Method for Simulating a Beta Distribution.** In Exercise 6 in Sec. 5.8, you proved the following: If  $U$  and  $V$  are independent, with  $U$  having the gamma distribution with parameters  $\alpha_1$  and  $\beta$ , and  $V$  having the gamma distribution with parameters  $\alpha_2$  and  $\beta$ , then  $U/(U + V)$  has the beta distribution with parameters  $\alpha_1$  and  $\alpha_2$ . So, if we have a method for simulating gamma random variables, we can simulate beta random variables. The case handled in Example 12.3.3 is  $\alpha_1 = \alpha_2 = 1/2$ . Let  $\beta = 1/2$  so that  $U$  and  $V$  would both have gamma distributions with parameters 1/2 and 1/2, also known as the  $\chi^2$  distribution with one degree of freedom. If we simulate two independent standard normal random variables  $X_1, X_2$  (for example, by the method of Example 12.3.2), then  $X_1^2$  and  $X_2^2$  are independent and have the  $\chi^2$  distribution with one degree of freedom. It follows that  $Y = X_1^2/(X_1^2 + X_2^2)$  has the beta distribution with parameters 1/2 and 1/2. ◀

As another example, to simulate a  $\chi^2$  random variable with 10 degrees of freedom, one could simulate 10 i.i.d. standard normals, square them, and add up the squares. Alternatively, one could simulate five random variables having the exponential distribution with parameter 1/2 and add them up.

---

**Example  
12.3.6**

**Generating Pseudo-Random Bivariate Normal Vectors.** Suppose that we wish to simulate a bivariate normal vector with the p.d.f. given in Eq. (5.10.2). This p.d.f. was constructed as the joint p.d.f. of

$$\begin{aligned} X_1 &= \sigma_1 Z_1 + \mu_1, \\ X_2 &= \sigma_2 [\rho Z_1 + (1 - \rho^2)^{1/2} Z_2] + \mu_2, \end{aligned} \quad (12.3.4)$$

where  $Z_1$  and  $Z_2$  are i.i.d. with the standard normal distribution. If we use the method of Example 12.3.2 to generate independent  $Z_1$  and  $Z_2$  with the standard normal distribution, we can use the formulas in (12.3.4) to transform these into  $X_1$  and  $X_2$ , which will then have the desired bivariate normal distribution. ◀

Most statistical computer packages have the capability of simulating pseudo-random variables with each of the continuous distributions that have been named in this text. The techniques of this section are really needed only for simulating less common distributions or when a statistical package is not available.

## Some Examples Involving Simulation of Common Distributions

---

**Example  
12.3.7**

**Bayesian Analysis of One-Way Layout.** We can perform a Bayesian analysis of a one-way layout using the same statistical model presented in Sec. 11.6 together with an improper prior for the model parameters. (We could use a proper prior, but the additional calculations would divert our attention from the simulation issues.) Let  $\tau = 1/\sigma^2$ , as we did in Sec. 8.6. The usual improper prior for the parameters  $(\mu_1, \dots, \mu_p, \tau)$  has “p.d.f.”  $1/\tau$ . The posterior joint p.d.f. is then proportional to  $1/\tau$

times the likelihood. The observed data are  $y_{ij}$  for  $j = 1, \dots, n_i$  and  $i = 1, \dots, p$ . The likelihood function is

$$(2\pi)^{-n/2} \tau^{n/2} \exp\left(-\frac{\tau}{2} \sum_{i=1}^p \sum_{j=1}^{n_i} (y_{ij} - \mu_i)^2\right),$$

where  $n = n_1 + \dots + n_p$ . To simplify the likelihood function, we can rewrite the sum of squares that appears in the exponent as

$$\sum_{i=1}^p \sum_{j=1}^{n_i} (y_{ij} - \mu_i)^2 = \sum_{i=1}^p n_i (\bar{y}_{i+} - \mu_i)^2 + S_{\text{Resid}}^2,$$

where  $\bar{y}_{i+}$  is the average of  $y_{i1}, \dots, y_{in_i}$  and

$$S_{\text{Resid}}^2 = \sum_{i=1}^p \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_{i+})^2$$

is the residual sum of squares. Then, the posterior p.d.f. is proportional to

$$\tau^{p/2} \exp\left(-\frac{\tau}{2} \sum_{i=1}^p n_i (\bar{y}_{i+} - \mu_i)^2\right) \tau^{(n-p)/2-1} \exp\left(-\frac{\tau}{2} S_{\text{Resid}}^2\right).$$

This expression is easily recognized as the product of the gamma p.d.f. for  $\tau$  with parameters  $(n-p)/2$  and  $S_{\text{Resid}}^2/2$  and the product of  $p$  normal p.d.f.'s for  $\mu_1, \dots, \mu_p$  with means  $\bar{y}_{i+}$  and precisions  $n_i \tau$  for  $i = 1, \dots, p$ . Hence, the posterior joint distribution of the parameters is the following: Conditional on  $\tau$ , the  $\mu_i$ 's are independent with  $\mu_i$  having the normal distribution with mean  $\bar{y}_{i+}$  and precision  $n_i \tau$ . The marginal distribution of  $\tau$  is the gamma distribution with parameters  $(n-p)/2$  and  $S_{\text{Resid}}^2/2$ .

If we simulate a large sample of parameters from the posterior distribution, we could begin to answer questions about what we have learned from the data. To do this, we would first simulate a large number of  $\tau$  values  $\tau^{(1)}, \dots, \tau^{(v)}$ . Most statistical programs allow the user to simulate gamma random variables with arbitrary first parameter and second parameter 1. So, we could simulate  $T^{(1)}, \dots, T^{(v)}$  having the gamma distribution with parameters  $(n-p)/2$  and 1. We could then let  $\tau^{(\ell)} = 2T^{(\ell)}/S_{\text{Resid}}^2$  for  $\ell = 1, \dots, v$ . Then, for each  $\ell$  simulate independent  $\mu_1^{(\ell)}, \dots, \mu_p^{(\ell)}$  with  $\mu_i^{(\ell)}$  having the normal distribution with mean  $\bar{y}_{i+}$  and variance  $1/[n_i \tau^{(\ell)}]$ .

As a specific example, consider the hot dog data in Example 11.6.2. We begin by simulating  $v = 60,000$  sets of parameters as described above. Now we can address the question of how much difference there is between the means. There are several ways to do this. We could compute the probability that all  $|\mu_i - \mu_j| > c$  for each positive  $c$ . We could compute the probability that at least one  $|\mu_i - \mu_j| > c$  for each positive  $c$ . We could compute the quantiles of  $\max_{i,j} |\mu_i - \mu_j|$ , of  $\min_{i,j} |\mu_i - \mu_j|$ , or of the average of all  $|\mu_i - \mu_j|$ . For example, in 99 percent of the 60,000 simulations, at least one  $|\mu_i^{(\ell)} - \mu_j^{(\ell)}| > 27.94$ . The simulation standard error of this estimator of the 0.99 quantile of  $\max_{i,j} |\mu_i - \mu_j|$  is 0.1117. (For the remainder of this example, we shall present only the simulation estimates and not their simulation standard errors.) In about 1/2 of the simulations, all  $|\mu_i^{(\ell)} - \mu_j^{(\ell)}| > 2.379$ . And in 99 percent of the simulations, the average of the differences was at least 14.59. Whether 27.94, 14.59, or 2.379 count as large differences depends on what decisions we need to make about the hot dogs. A useful way to summarize all of these calculations is through a plot of the sample c.d.f.'s of the largest, smallest, and average of the six  $|\mu_i - \mu_j|$  differences. (The sample c.d.f. of a set of numbers is defined at the very beginning of Sec. 10.6.)

**Figure 12.4** Sample c.d.f.'s of the maximum, average, and minimum of the six  $|\mu_i - \mu_j|$  differences for Example 12.3.7.

**Table 12.4** Posterior probabilities that each  $\mu_i$  is largest and smallest in Example 12.3.7

Type	Beef	Meat	Poultry	Specialty
$i$	1	2	3	4
$\Pr(\mu_i \text{ largest}   \mathbf{y})$	0.1966	0.3211	0	0.4823
$\Pr(\mu_i \text{ smallest}   \mathbf{y})$	0	0	1	0

Figure 12.4 contains such a plot for this example. If we are simply concerned with whether or not there are any differences at all between the four types of hot dogs, then the “Maximum” curve in Fig. 12.4 is the one to examine. (Can you explain why this is the case?)

We can also attempt to answer questions that we would have great difficulty addressing in the ANOVA framework of Chapter 11. For example, we could ask what is the probability that each  $\mu_i$  is the largest or smallest of the four. For each  $i$ , let  $N_i$  be the number of simulations  $j$  such that  $\mu_i^{(j)}$  is the smallest of  $\mu_1^{(j)}, \dots, \mu_4^{(j)}$ . Also let  $M_i$  be the number of simulations  $j$  such that  $\mu_i^{(j)}$  is the largest of the four means. Then  $N_i/60,000$  is our simulation estimate of the probability that  $\mu_i$  is the smallest mean, and  $M_i/60,000$  is our estimate of the probability that  $\mu_i$  is the largest mean. The results are summarized in Table 12.4. We see that  $\mu_3$  is almost certainly the smallest, while  $\mu_4$  has almost a 50 percent chance of being the largest.  $\blacktriangleleft$

### Example 12.3.8

**Comparing Copper Ores.** We shall illustrate the method of Example 12.2.4 using the data on copper ores from Example 9.6.5. Suppose that the prior distributions for all parameters are improper. The observed data consist of one sample of size 8 and another sample of size 10 with  $\bar{X} = 2.6$ ,  $\sum_{i=1}^8 (X_i - \bar{X})^2 = 0.32$ ,  $\bar{Y} = 2.3$ , and  $\sum_{j=1}^{10} (Y_j - \bar{Y})^2 = 0.22$ . The posterior distributions then have hyperparameters  $\mu_{x1} = 2.6$ ,  $\lambda_{x1} = 8$ ,  $\alpha_{x1} = 3.5$ ,  $\beta_{x1} = 0.16$ ,  $\mu_{y1} = 1.15$ ,  $\lambda_{y1} = 10$ ,  $\alpha_{y1} = 4.5$ , and  $\beta_{y1} = 0.11$ . The posterior distributions of  $\tau_x$  and  $\tau_y$  are, respectively, the gamma distribution with parameters 3.5 and 0.16 and the gamma distribution with parameters 4.5 and

**Figure 12.5** Histogram of simulated  $\mu_x - \mu_y$  values together with posterior c.d.f. of  $|\mu_x - \mu_y|$  for Example 12.3.8.

0.11. We can easily simulate, say, 10,000 pseudo-random values from each of these two distributions. For each simulated  $\tau_x$ , we simulate a  $\mu_x$  that has the normal distribution with mean 2.6 and variance  $1/(8\tau_x)$ . For each simulated  $\tau_y$ , we simulate a  $\mu_y$  that has the normal distribution with mean 2.3 and variance  $1/(10\tau_y)$ . Figure 12.5 contains a histogram of the 10,000 simulated  $\mu_x - \mu_y$  values together with the sample c.d.f. of  $|\mu_x - \mu_y|$ . It appears that  $\mu_x - \mu_y$  is almost always positive; indeed, it was positive for over 99 percent of the sampled values. The probability is quite high that  $|\mu_x - \mu_y| < 0.5$ , so that if 0.5 is not a large difference in this problem, we can be confident that  $\mu_x$  and  $\mu_y$  are pretty close. On the other hand, if 0.1 is a large difference, we can be confident that  $\mu_x$  and  $\mu_y$  are pretty far apart.  $\blacktriangleleft$

If all we care about in Example 12.3.8 is the distribution of  $\mu_x - \mu_y$ , then we could simulate  $\mu_x$  and  $\mu_y$  directly without first simulating  $\tau_x$  and  $\tau_y$ . Since  $\mu_x$  and  $\mu_y$  are independent in this example, we could simulate each of them from their respective marginal distributions.

### Example 12.3.9

**Power of the  $t$  Test.** In Theorem 9.5.3, we showed how the power function of the  $t$  test can be computed from the noncentral  $t$  distribution function. Not all statistical packages compute noncentral  $t$  probabilities. We can use simulation to estimate these probabilities. Let  $Y$  have the noncentral  $t$  distribution with  $m$  degrees of freedom and noncentrality parameter  $\psi$ . Then  $Y$  has the distribution of  $X_1/(X_2/m)^{1/2}$  where  $X_1$  and  $X_2$  are independent with  $X_1$  having the normal distribution with mean  $\psi$  and variance 1 and  $X_2$  having the  $\chi^2$  distribution with  $m$  degrees of freedom. A simple way to estimate the c.d.f. of  $Y$  is to simulate a large number of  $(X_1, X_2)$  pairs and compute the sample c.d.f. of the values of  $X_1/(X_2/m)^{1/2}$ .  $\blacktriangleleft$

**The Simulation Standard Error of a Sample c.d.f.** In Examples 12.3.7 and 12.3.8, we plotted the sample c.d.f.'s of functions of simulated data. We did not associate simulation standard errors with these functions. We could compute simulation standard errors for every value of the sample c.d.f., but there is a simpler way to summarize the uncertainty about a sample c.d.f. We can make use of the Glivenko-Cantelli lemma (Theorem 10.6.1). To summarize that result in the context of simulation, let  $Y^{(i)}$ ,  $(i = 1, \dots, v)$  be a simulated i.i.d. sample with c.d.f.  $G$ . Let  $G_v$  be the sample c.d.f. For each real  $x$ ,  $G_v(x)$  is the proportion of the simulated sample that is less than or equal to  $x$ . That is,  $G_v(x)$  is  $1/v$  times the number of  $i$ 's such that  $Y^{(i)} \leq x$ .

Theorem 10.6.1 says that if  $v$  is large, then

$$\Pr\left(|G_v(x) - G(x)| \leq \frac{t}{v^{1/2}}, \text{ for all } x\right) \approx H(t),$$

where  $H$  is the function in Table 10.32 on page 661. In particular, with  $t = 2$ ,  $H(t) = 0.9993$ . So we can declare (at least approximately) that  $|G_v(x) - G(x)| \leq 2/v^{1/2}$  simultaneously for all  $x$  with probability 0.9993. In Example 12.3.7, we had  $v = 60,000$ , so each curve in Fig. 12.4 should be accurate to within 0.008 with probability 0.9993. Indeed, all three curves simultaneously should be accurate to within 0.008 with probability 0.9979. (Prove this in Exercise 14.)

### Simulating a Discrete Random Variable

All of the examples so far in this section have concerned simulations of random variables with continuous distributions. Occasionally, one needs random variables with discrete distributions. Algorithms for simulating discrete random variables exist, and we shall describe some here.

**Example  
12.3.10**

**Simulating a Bernoulli Random Variable.** It is simple to simulate a pseudo-random Bernoulli random variable  $X$  with parameter  $p$ . Start with  $U$  having the uniform distribution on the interval  $[0, 1]$ , and let  $X = 1$  if  $U \leq p$ . Otherwise, let  $X = 0$ . Since  $\Pr(U \leq p) = p$ ,  $X$  has the correct distribution. This method can be used to simulate from any distribution that is supported on only two values. If

$$f(x) = \begin{cases} p & \text{if } x = t_1, \\ 1 - p & \text{if } x = t_2, \\ 0 & \text{otherwise,} \end{cases}$$

then let  $X = t_1$  if  $U \leq p$ , and let  $X = t_2$  otherwise. ◀

**Example  
12.3.11**

**Simulating a Discrete Uniform Random Variable.** Suppose that we wish to simulate pseudo-random variables from a distribution that has the p.f.

$$f(x) = \begin{cases} \frac{1}{n} & \text{if } x \in \{t_1, \dots, t_n\}, \\ 0 & \text{otherwise.} \end{cases} \quad (12.3.5)$$

The uniform distribution on the integers  $1, \dots, n$  is an example of such a distribution. A simple way to simulate a random variable with the p.f. (12.3.5) is the following: Let  $U$  have the uniform distribution on the interval  $[0, 1]$ , and let  $Z$  be the greatest integer less than or equal to  $nU + 1$ . It is easy to see that  $Z$  takes the values  $1, \dots, n$  with equal probability, and so  $X = t_Z$  has the p.f. (12.3.5). ◀

The method described in Example 12.3.11 does not apply to more general discrete distributions. However, the method of Example 12.3.11 is useful in simulations that are done in bootstrap analyses described in Sec. 12.6.

For general discrete distributions, there is an analog to the probability integral transformation. Suppose that a discrete distribution is concentrated on the values  $t_1 < \dots < t_n$  and that the c.d.f. is

$$F(x) = \begin{cases} 0 & \text{if } x < t_1, \\ q_i & \text{if } t_i \leq x < t_{i+1}, \text{ for } i = 1, \dots, n-1, \\ 1 & \text{if } x \geq t_n. \end{cases} \quad (12.3.6)$$

The following is the quantile function from Definition 3.3.2:

$$F^{-1}(p) = \begin{cases} t_1 & \text{if } 0 < p \leq q_1, \\ t_{i+1} & \text{if } q_i < p \leq q_{i+1}, \text{ for } i = 1, \dots, n-2, \\ t_n & \text{if } q_{n-1} < p < 1. \end{cases} \quad (12.3.7)$$

You can prove (see Exercise 13) that if  $U$  has the uniform distribution on the interval  $[0, 1]$ , then  $F^{-1}(U)$  has the c.d.f. in Eq. (12.3.6). This gives a straightforward, but inefficient, method for simulating arbitrary discrete distributions. Notice that the restriction that  $n$  be finite is not actually necessary. Even if the distribution has infinitely many possible values,  $F^{-1}$  can be defined by (12.3.7) by replacing  $n-2$  by  $\infty$  and removing the last branch.

---

**Example  
12.3.12**

**Simulating a Geometric Random Variable.** Suppose that we wish to simulate a pseudo-random  $X$  having the geometric distribution with parameter  $p$ . In the notation of Eq. (12.3.7),  $t_i = i - 1$  for  $i = 1, 2, \dots$ , and  $q_i = 1 - (1 - p)^i$ . Using the probability integral transformation, we would first simulate  $U$  with the uniform distribution on the interval  $[0, 1]$ . Then we would compare  $U$  to  $q_i$  for  $i = 1, 2, \dots$ , until the first time that  $q_i < U$  and set  $X = i$ . In this example, we can avoid the sequence of comparisons because we have a simple formula for  $q_i$ . The first  $i$  such that  $q_i < U$  is the greatest integer strictly less than  $\log(1 - U)/\log(1 - p)$ .  $\blacktriangleleft$

The probability integral transformation is very inefficient for discrete distributions that do not have a simple formula for  $q_i$  if the number of possible values is large. Walker (1974) and Kronmal and Peterson (1979) describe a more efficient method called the *alias method*. The alias method works as follows: Let  $f$  be the p.f. from which we wish to simulate a random variable  $X$ . Suppose that  $f(x) > 0$  for only  $n$  different values of  $x$ . First, we write  $f$  as an average of  $n$  p.f.'s that are concentrated on one or two values each. That is,

$$f(x) = \frac{1}{n}[g_1(x) + \dots + g_n(x)], \quad (12.3.8)$$

where each  $g_i$  is the p.f. of a distribution concentrated on one or two values only. We shall show how to do this in Example 12.3.13. To simulate  $X$ , first simulate an integer  $I$  that has the uniform distribution over the integers  $1, \dots, n$ . (Use the method of Example 12.3.11.) Then simulate  $X$  from the distribution with the p.f.  $g_I$ . The reader can prove in Exercise 17 that  $X$  has the p.f.  $f$ .

---

**Example  
12.3.13**

**Simulating a Binomial Random Variable Using the Alias Method.** Suppose that we need to simulate many random variables with a binomial distribution having parameters 9 and 0.4. The p.f.  $f$  of this distribution is given in a table at the end of this book. The distribution has  $n = 10$  different values with positive probability. Since the  $n$  probabilities must add to 1, there must be  $x_1$  and  $y_1$  such that  $f(x_1) \leq 1/n$  and  $f(y_1) \geq 1/n$ . For example,  $x_1 = 0$  and  $y_1 = 2$  have  $f(x_1) = 0.0101$  and  $f(y_1) = 0.1612$ . Define the first two-point p.f.,  $g_1$ , as

$$g_1(x) = \begin{cases} nf(x_1) & \text{if } x = x_1, \\ 1 - nf(x_1) & \text{if } x = y_1, \\ 0 & \text{otherwise.} \end{cases}$$

In our case,  $g_1(0) = 0.101$  and  $g_1(2) = 0.899$ . We then write  $f$  as  $f(x) = g_1(x)/n + f_1^*(x)$ , where

$$f_1^*(x) = \begin{cases} 0 & \text{if } x = x_1, \\ f(y_1) - g_1(y_1)/n & \text{if } x = y_1, \\ f(x) & \text{otherwise.} \end{cases}$$

In our example,  $f_1^*(2) = 0.0713$ . Now,  $f_1^*$  is positive at only  $n - 1$  different values, and the sum of the positive values of  $f_1^*$  is  $(n - 1)/n$ . Hence, there must exist  $x_2$  and  $y_2$  such that  $f_1^*(x_2) \leq 1/n$  and  $f_1^*(y_2) \geq 1/n$ . For example,  $x_2 = 2$  and  $y_2 = 3$  have  $f_1^*(x_2) = 0.0713$  and  $f_1^*(y_2) = 0.2508$ . Define  $g_2$  by

$$g_2(x) = \begin{cases} nf_1^*(x_2) & \text{if } x = x_2, \\ 1 - nf_1^*(x_2) & \text{if } x = y_2, \\ 0 & \text{otherwise.} \end{cases}$$

Here,  $g_2(2) = 0.713$ . Now write  $f_1^*(x) = g_2(x)/n + f_2^*(x)$ , where

$$f_2^*(x) = \begin{cases} 0 & \text{if } x = x_2, \\ f_1^*(y_2) - g_2(y_2)/n & \text{if } x = y_2, \\ f_1^*(x) & \text{otherwise.} \end{cases}$$

In our example,  $f_2^*(3) = 0.2221$ . Now,  $f_2^*$  takes only  $n - 2$  positive values that add up to  $(n - 2)/n$ . We can repeat this process  $n - 3$  more times, obtaining  $g_1, \dots, g_{n-1}$  and  $f_{n-1}^*$ . Here,  $f_{n-1}^*(x)$  takes only one positive value, at  $x = x_n$ , say, and  $f_{n-1}^*(x_n) = 1/n$ . Let  $g_n$  be a degenerate distribution at  $x_n$ . Then  $f(x) = [g_1(x) + \dots + g_n(x)]/n$  for all  $x$ .

After all of this initial setup, the alias method allows rapid simulation from  $f$  as follows: Simulate independent  $U$  and  $I$  with  $U$  having the uniform distribution on the interval  $[0, 1]$  and  $I$  having the uniform distribution on the integers  $1, \dots, n$  ( $n = 10$  in our example). If  $U \leq g_I(x_I)$ , set  $X = x_I$ . If  $U > g_I(x_I)$ , set  $X = y_I$ . Here, the values we need to perform the simulation are

$i$	1	2	3	4	5	6	7	8	9	10
$x_i$	0	2	1	6	7	3	8	9	4	5
$y_i$	2	3	3	3	3	4	4	4	5	—
$g_i(x_i)$	0.101	0.713	0.605	0.743	0.212	0.781	0.035	0.003	0.327	1

There is even a clever way to replace the two simulations of  $U$  and  $I$  with a single simulation. Simulate  $Y$  with the uniform distribution on the interval  $[0, 1]$ , and let  $I$  be the greatest integer less than or equal to  $nY + 1$ . Then let  $U = nY + 1 - I$ . (See Exercise 19.)

As an example, suppose that we simulate  $Y$  with the uniform distribution on the interval  $[0, 1]$ , and we obtain  $Y = 0.4694$ . Then  $I = 5$  and  $U = 0.694$ . Since  $0.694 > g_5(x_5) = 0.212$ , we set  $X = y_5 = 3$ . Figure 12.6 shows a histogram of 10,000 simulated values using the alias method.  $\blacktriangleleft$

All of the overhead required to set up the alias method is worth the effort only if we are going to simulate many random variables with the same discrete distribution.

**Figure 12.6** Histogram of 10,000 simulated binomial random variables in Example 12.3.13. The X marks appear at heights equal to  $10,000f(x)$  to illustrate the close agreement of the simulated and actual distributions.

## Summary

We have seen several examples of how to transform pseudo-random uniform variables into pseudo-random variables with other distributions. The acceptance/rejection method is widely applicable, but it might require many rejected simulations for each accepted one. Also, we have seen how we can simulate random variables that are functions of other random variables (such as a noncentral  $t$  random variable). Several examples illustrated how we can make use of simulated random variables with some of the common distributions. Readers who desire a thorough treatment of the generation of pseudo-random variables with distributions other than uniform can consult Devroye (1986).

## Exercises

1. Return to Exercise 10 in Sec. 12.2. Now that we know how to simulate exponential random variables, perform the simulation developed in that exercise as follows:
  - a. Perform  $v_0 = 2000$  simulations and compute both the estimate of  $\theta$  and its simulation standard error.
  - b. Suppose that we want our estimator of  $\theta$  to be within 0.01 of  $\theta$  with probability 0.99. How many simulations should we perform?
2. Describe how to convert a random sample  $U_1, \dots, U_n$  from the uniform distribution on the interval  $[0, 1]$  to a random sample of size  $n$  from the uniform distribution on the interval  $[a, b]$ .
3. Show how to use the probability integral transformation to simulate random variables with the two p.d.f.'s in Eq. (12.3.3).
4. Show how to simulate Cauchy random variables using the probability integral transformation.
5. Prove that the expected number of iterations of the acceptance/rejection method until the first acceptance is  $k$ . (*Hint:* Think of each iteration as a Bernoulli trial. What is the expected number of trials (not failures) until the first success?)
- 6.a. Show how to simulate a random variable having the Laplace distribution with parameters 0 and 1. The p.d.f. of the Laplace distribution with parameters  $\theta$  and  $\sigma$  is given in Eq. (10.7.5).
  - b. Show how to simulate a standard normal random variable by first simulating a Laplace random variable and then using acceptance/rejection. *Hint:* Maximize  $e^{-x^2/2}/e^{-x}$  for  $x \geq 0$ , and notice that both distributions are symmetric around 0.
7. Suppose that you have available as many i.i.d. standard normal pseudo-random numbers as you desire. Describe how you could simulate a pseudo-random number with an  $F$  distribution with four and seven degrees of freedom.
8. Let  $X$  and  $Y$  be independent random variables with  $X$  having the  $t$  distribution with five degrees of freedom and  $Y$  having the  $t$  distribution with seven degrees of freedom. We are interested in  $E(|X - Y|)$ .

- a. Simulate 1000 pairs of  $(X_i, Y_i)$  each with the above joint distribution and estimate  $E(|X - Y|)$ .
  - b. Use your 1000 simulated pairs to estimate the variance of  $|X - Y|$  also.
  - c. Based on your estimated variance, how many simulations would you need to be 99 percent confident that your estimator of  $E(|X - Y|)$  is within 0.01 of the actual mean?
9. Show how to use acceptance/rejection to simulate random variables with the following p.d.f.:

$$f(x) = \begin{cases} \frac{4}{3}x & \text{if } 0 < x \leq 0.5, \\ \frac{2}{3} & \text{if } 0.5 < x \leq 1.5, \\ \frac{8}{3} - \frac{4}{3}x & \text{if } 1.5 < x \leq 2, \\ 0 & \text{otherwise.} \end{cases}$$

10. Implement the simulation in Example 12.2.3 for the clinical trial of Example 2.1.4 on page 57. Simulate 5000 parameter vectors. Use a prior distribution with  $\alpha_0 = 1$  and  $\beta_0 = 1$ . Estimate the probability that the imipramine group has the highest probability of no relapse. Calculate how many simulations you would need to be 95 percent confident that your estimator is within 0.01 of the true probability.

11. In Example 12.3.7, we simulated the  $\tau$  values by first simulating gamma random variables with parameters  $(n - p)/2$  and 1. Suppose that our statistical software allows us to simulate  $\chi^2$  random variables instead. Which  $\chi^2$  distribution should we use and how would we convert the simulated  $\chi^2$ 's to have the appropriate gamma distribution?

12. Use the blood pressure data in Table 9.2 that was described in Exercise 10 of Sec. 9.6. Suppose now that we are not confident that the variances are the same for the two treatment groups. Perform a simulation of the sort done in Example 12.3.8 to obtain a sample from the posterior distribution of the parameters when we allow the variances to be unequal.

- a. Draw a plot of the sample c.d.f. of the absolute value of the difference between the two group means.

- b. Draw a histogram of the logarithm of the ratio of the two variances to see how close together they seem to be.

13. Let  $F^{-1}$  be defined as in Eq. (12.3.7). Let  $U$  have the uniform distribution on the interval  $[0, 1]$ . Prove that  $F^{-1}(U)$  has the c.d.f. in Eq. (12.3.6).

14. Refer to the three curves in Fig. 12.4. Call those three sample c.d.f.'s  $G_{v,1}$ ,  $G_{v,2}$ , and  $G_{v,3}$ , and call the three c.d.f.'s that they estimate  $G_1$ ,  $G_2$ , and  $G_3$ . Use the Glivenko-Cantelli lemma (Theorem 10.6.1) to show that

$$\Pr(|G_{v,i}(x) - G_i(x)| \leq 0.0082, \text{ for all } x \text{ and all } i)$$

is about 0.9979 or larger. *Hint:* Use the Bonferroni inequality (Theorem 1.5.8).

15. Prove that the acceptance/rejection method works for discrete distributions. That is, let  $f$  and  $g$  be p.f.'s rather than p.d.f.'s, but let the rest of the acceptance/rejection method be exactly as stated. *Hint:* The proof can be translated by replacing integrals over  $x$  by sums. Integrals over  $u$  should be left as integrals.

16. Describe how to use the discrete version of the probability integral transformation to simulate a Poisson pseudo-random variable with mean  $\theta$ .

17. Let  $f$  be a p.f., and assume that Eq. (12.3.8) holds, where each  $g_i$  is another p.f. Assume that  $X$  is simulated using the method described immediately after Eq. (12.3.8). Prove that  $X$  has the p.f.  $f$ .

18. Use the alias method to simulate a random variable having the Poisson distribution with mean 5. Use the table of Poisson probabilities in the back of the book, and assume that 16 is the largest value that a Poisson random variable can equal. Assume that all of the probability not accounted for by the values 0, ..., 15 is the value of the p.f. at  $k = 16$ .

19. Let  $Y$  have the uniform distribution on the interval  $[0, 1]$ . Define  $I$  to be the greatest integer less than or equal to  $nY + 1$ , and define  $U = nY + 1 - I$ . Prove that  $I$  and  $U$  are independent and that  $U$  has uniform distribution on the interval  $[0, 1]$ .

## 12.4 Importance Sampling

*Many integrals can usefully be rewritten as means of functions of random variables. If we can simulate large numbers of random variables with the appropriate distributions, we can use these to estimate integrals that might not be possible to compute in closed form.*

Simulation methods are particularly well suited to estimating means of random variables. If we can simulate many random variables with the appropriate distribution,

we can average the simulated values to estimate the mean. Because means of random variables with continuous distributions are integrals, we might wonder whether other integrals can also be estimated by simulation methods. In principle, all finite integrals can be estimated by simulation, although some care is needed to insure that the simulation results have finite variance.

Suppose that we wish to calculate  $\int_a^b g(x) dx$  for some function  $g$  with  $a$  and  $b$  both finite. We can rewrite this integral as

$$\int_a^b g(x) dx = \int_a^b (b-a)g(x) \frac{1}{b-a} dx = E[(b-a)g(X)], \quad (12.4.1)$$

where  $X$  is a random variable with the uniform distribution on the interval  $[a, b]$ . A simple Monte Carlo method is to simulate a large number of pseudo-random values  $X_1, \dots, X_v$  with the uniform distribution on the interval  $[a, b]$  and estimate the integral by  $\frac{b-a}{v} \sum_{i=1}^v g(X_i)$ . The method just described has two commonly recognized drawbacks. First, it cannot be applied to estimate integrals over unbounded regions. Second, it can be very inefficient. If  $g$  is much larger over one portion of the interval than over another, then the values  $g(X_i)$  will have large variance, and it will take a very large value  $v$  to get a good estimator of the integral.

A method that attempts to overcome both of the shortcomings just mentioned is called *importance sampling*. The idea of importance sampling is to do something very much like what we did in Eq. (12.4.1). That is, we shall rewrite the integral as the mean of some function of  $X$ , where  $X$  has a distribution that we can simulate easily.

Suppose that we are able to simulate a pseudo-random variable  $X$  with the p.d.f.  $f$  where  $f(x) > 0$  whenever  $g(x) > 0$ . Then we can write

$$\int g(x) dx = \int \frac{g(x)}{f(x)} f(x) dx = E(Y), \quad (12.4.2)$$

where  $Y = g(X)/f(X)$ . (If  $f(x) = 0$  for some  $x$  such that  $g(x) > 0$ , then the two integrals in Eq. (12.4.2) might not be equal.) If we simulate  $v$  independent values  $X_1, \dots, X_v$  with the p.d.f.  $f$ , we can estimate the integral by  $\frac{1}{v} \sum_{i=1}^v Y_i$  where  $Y_i = g(X_i)/f(X_i)$ . The p.d.f.  $f$  is called the *importance function*. It is acceptable, although inefficient, to have  $f(x) > 0$  for some  $x$  such that  $g(x) = 0$ . The key to efficient importance sampling is choosing a good importance function. The smaller the variance of  $Y$ , the better the estimator should be. That is, we would like  $g(X)/f(X)$  to be close to being a constant random variable.

### Example 12.4.1

**Choosing an Importance Function.** Suppose that we want to estimate  $\int_0^1 e^{-x} / (1+x^2) dx$ . Here are five possible choices of importance function:

$$\begin{aligned} f_0(x) &= 1, & \text{for } 0 < x < 1, \\ f_1(x) &= e^{-x}, & \text{for } 0 < x < \infty, \\ f_2(x) &= (1+x^2)^{-1}/\pi, & \text{for } -\infty < x < \infty, \\ f_3(x) &= e^{-x}/(1-e^{-1}), & \text{for } 0 < x < 1, \\ f_4(x) &= 4(1+x^2)^{-1}/\pi, & \text{for } 0 < x < 1. \end{aligned}$$

Each of these p.d.f.'s is positive wherever  $g$  is positive, and each one can be simulated using the probability integral transformation. As an example, we have simulated 10,000 uniforms on the interval  $[0, 1]$ ,  $U^{(1)}, \dots, U^{(10,000)}$ . We then applied the five probability integral transformations to this single set of uniforms so that our comparisons do not suffer from variation due to different underlying uniform samples.

**Table 12.5** Monte Carlo estimates and  $\hat{\sigma}_j$  for Example 12.4.1

$j$	0	1	2	3	4
$\bar{Y}_j$	0.5185	0.5110	0.5128	0.5224	0.5211
$\hat{\sigma}_j$	0.2440	0.4217	0.9312	0.0973	0.1409

Since the five p.d.f.'s are positive over different ranges, we should define

$$g(x) = \begin{cases} e^{-x}/(1+x^2) & \text{if } 0 < x < 1, \\ 0 & \text{otherwise.} \end{cases}$$

Let  $F_j$  stand for the c.d.f. corresponding to  $f_j$ , and let  $X_j^{(i)} = F_j^{-1}(U^{(i)})$  for  $i = 1, \dots, 10,000$  and  $j = 0, \dots, 4$ . Let  $Y_j^{(i)} = g(X_j^{(i)})/f_j(X_j^{(i)})$ . Then we obtain five different estimators of  $\int g(x) dx$ , namely,

$$\bar{Y}_j = \frac{1}{10,000} \sum_{i=1}^{10,000} Y_j^{(i)}, \quad \text{for } j = 0, \dots, 4.$$

For each  $j$ , we also compute the sample variance of the  $Y_j^{(i)}$  values,

$$\hat{\sigma}_j^2 = \frac{1}{10,000} \sum_{i=1}^{10,000} (Y_j^{(i)} - \bar{Y}_j)^2.$$

The simulation standard error of  $\bar{Y}_j$  is  $\hat{\sigma}_j/100$ . We list the five estimates together with the corresponding values of  $\hat{\sigma}_j$  in Table 12.5. The estimates are relatively close together, but some values of  $\hat{\sigma}_j$  are almost 10 times others. This can be understood in terms of how well each  $f_j$  approximates the function  $g$ . First, note that the two worst cases are those in which  $f_j$  is positive on an unbounded interval. This causes us to simulate a large number of  $X_j^{(i)}$  values for which  $g(X_j^{(i)}) = 0$  and hence  $Y_j^{(i)} = 0$ . This is highly inefficient. For example, with  $j = 2$ , 75 percent of the  $X_2^{(i)}$  values are outside of the interval  $(0, 1)$ . The remaining  $Y_2^{(i)}$  values must be very large in order for the average to come out near the correct answer. In other words, because the  $Y_2^{(i)}$  values are so spread out (they range between 0 and  $\pi$ ), we get a large value of  $\hat{\sigma}_2$ . On the other hand, with  $j = 3$ , there are no 0 values for  $Y_3^{(i)}$ . Indeed, the  $Y_3^{(i)}$  values only range from 0.3161 to 0.6321. This allows  $\hat{\sigma}_3$  to be quite small. The goal in choosing an importance function is to make the  $Y^{(i)}$  values have small variance. This is achieved by making the ratio  $g/f$  as close to constant as we can.  $\blacktriangleleft$

**Example  
12.4.2**

**Calculating a Mean with No Closed-Form Expression.** Let  $X$  have the gamma distribution with parameters  $\alpha$  and 1. Suppose that we want the mean of  $1/(1 + X + X^2)$ . We might wish to think of this mean as

$$\int_0^\infty \frac{1}{1+x+x^2} f_\alpha(x) dx, \tag{12.4.3}$$

where  $f_\alpha$  is the p.d.f. of the gamma distribution with parameters  $\alpha$  and 1. If  $\alpha$  is not small,  $f_\alpha(x)$  is close to 0 near  $x = 0$  and is only sizeable for  $x$  near  $\alpha$ . For large  $x$ ,

$1/(1+x+x^2)$  is a lot like  $1/x^2$ . If  $\alpha$  and  $x$  are both large, the integrand in (12.4.3) is approximately  $x^{-2}f_\alpha(x)$ . Since  $x^{-2}f_\alpha(x)$  is a constant times  $f_{\alpha-2}(x)$ , we could do importance sampling with importance function  $f_{\alpha-2}$ . For example, with  $\alpha = 5$ , we simulate 10,000 pseudo-random variables  $X^{(1)}, \dots, X^{(10,000)}$  having the gamma distribution with parameters 3 and 1. The sample mean of  $[1/(1+X^{(i)}+X^{(i)2})]f_5(X^{(i)})/f_3(X^{(i)})$  is 0.05184 with sample standard deviation 0.01465. For comparison, we also simulate 10,000 pseudo-random variables  $Y^{(1)}, \dots, Y^{(10,000)}$  with the gamma distribution having parameters 5 and 1. The average of the values of  $1/(1+Y^{(i)}+Y^{(i)2})$  is 0.05226 with sample standard deviation 0.05103, about 3.5 times as large as we get using the  $f_3$  importance function. With  $\alpha = 3$ , however, the two methods have nearly equal sample standard deviations. With  $\alpha = 10$ , the importance sampling has sample standard deviation about one-tenth as large as sampling directly from the distribution of  $X$ . As we noted earlier, when  $\alpha$  is large,  $1/x^2$  is a better approximation to  $1/(1+x+x^2)$  than it is when  $\alpha$  is small.  $\blacktriangleleft$

**Example  
12.4.3**

**Bivariate Normal Probabilities.** Let  $(X_1, X_2)$  have a bivariate normal distribution, and suppose that we are interested in the probability of the event  $\{X_1 \leq c_1, X_2 \leq c_2\}$  for specific values  $c_1, c_2$ . In general, we cannot explicitly calculate the double integral

$$\int_{-\infty}^{c_2} \int_{-\infty}^{c_1} f(x_1, x_2) dx_1 dx_2, \quad (12.4.4)$$

where  $f(x_1, x_2)$  is the joint p.d.f. of  $(X_1, X_2)$ . We can write the joint p.d.f. as  $f(x_1, x_2) = g_1(x_1|x_2)f_2(x_2)$ , where  $g_1$  is the conditional p.d.f. of  $X_1$  given  $X_2 = x_2$  and  $f_2$  is the marginal p.d.f. of  $X_2$ . Both of these p.d.f.'s are normal p.d.f.'s, as we learned in Sec. 5.10. In particular, the conditional distribution of  $X_1$  given  $X_2 = x_2$  is the normal distribution with mean and variance given by Eq. (5.10.8). We can explicitly perform the inner integration in (12.4.4) as

$$\begin{aligned} \int_{-\infty}^{c_1} f(x_1, x_2) dx_1 &= \int_{-\infty}^{c_1} g(x_1|x_2)f_2(x_2) dx_1 \\ &= f_2(x_2)\Phi\left(\frac{c_1 - \mu_1 - \rho\sigma_1(x_2 - \mu_2)/\sigma_2}{\sigma_1(1 - \rho)^{1/2}}\right), \end{aligned}$$

where  $\Phi$  is the standard normal c.d.f. The integral in (12.4.4) is then the integral of this last expression with respect to  $x_2$ . An efficient importance function might be the conditional p.d.f. of  $X_2$  given that  $X_2 \leq c_2$ . That is, let  $h$  be the p.d.f.

$$h(x_2) = \frac{(2\pi\sigma_2^2)^{-1/2} \exp\left(-\frac{1}{2\sigma_2^2}(x_2 - \mu_2)^2\right)}{\Phi\left(\frac{c_2 - \mu_2}{\sigma_2}\right)}, \quad \text{for } -\infty < x_2 \leq c_2. \quad (12.4.5)$$

It is not difficult to see that if  $U$  has the uniform distribution on the interval  $[0, 1]$ , then

$$W = \mu_2 + \sigma_2\Phi^{-1}\left[U\Phi\left(\frac{c_2 - \mu_2}{\sigma_2}\right)\right] \quad (12.4.6)$$

has the p.d.f.  $h$ . (See Exercise 5.) If we use  $h$  as an importance function and simulate  $W^{(1)}, \dots, W^{(v)}$  with this p.d.f., then our estimator of the integral (12.4.4) is

$$\frac{1}{v} \sum_{i=1}^v \Phi\left(\frac{c_1 - \mu_1 - \rho\sigma_1(W^{(i)} - \mu_2)/\sigma_2}{\sigma_1(1 - \rho)^{1/2}}\right) \Phi\left(\frac{c_2 - \mu_2}{\sigma_2}\right). \quad \blacktriangleleft$$

It is not always possible to guarantee that an importance sampling estimator will have finite variance. In the examples in this section, we have managed to find importance functions with the following property. The ratio of the function being integrated to the importance function is bounded. This property guarantees finite variance for the importance sampling estimator. (See Exercise 8.)

## ◆ Stratified Importance Sampling

Suppose that we are trying to estimate  $\theta = \int g(x) dx$ , and that we contemplate using the importance function  $f$ . The simulation variance of the importance sampling estimator of  $\theta$  arises from the variance of  $Y = g(X)/f(X)$ , where  $X$  has the p.d.f.  $f$ . Indeed, if we simulate an importance sample of size  $n$ , the simulation variance of our estimator is  $\sigma^2/n$ , where  $\sigma^2 = \text{Var}(Y)$ . Stratified importance sampling attempts to reduce the simulation variance by splitting  $\theta$  into  $\theta = \sum_{j=1}^k \theta_j$  and then estimating each  $\theta_j$  with much smaller simulation variance.

The stratified importance sampling algorithm is easiest to describe when  $X$  is simulated using the probability integral transformation. Let  $F$  be the c.d.f. corresponding to the p.d.f.  $f$ . First, we split  $\theta$  as follows. Define  $q_0 = -\infty$ ,  $q_j = F^{-1}(j/k)$  for  $j = 1, \dots, k-1$ , and  $q_k = \infty$ . Then define

$$\theta_j = \int_{q_{j-1}}^{q_j} g(x) dx,$$

for  $j = 1, \dots, k$ . Clearly,  $\theta = \sum_{j=1}^k \theta_j$ . Next, we estimate each  $\theta_j$  by importance sampling using the same importance function  $f$ , but restricted to the range of integration for  $\theta_j$ . That is, we estimate  $\theta_j$  using importance sampling with the importance function

$$f_j(x) = \begin{cases} kf(x) & \text{if } q_{j-1} \leq x < q_j, \\ 0 & \text{otherwise.} \end{cases}$$

(See Exercise 9 to see that  $f_j$  is indeed a p.d.f.) To simulate a random variable with the p.d.f.  $f_j$ , let  $V$  have the uniform distribution on the interval  $[(j-1)/k, j/k]$  and set  $X_j = F^{-1}(V)$ . The reader can prove (see Exercise 9) that  $X_j$  has the p.d.f.  $f_j$ . Let  $\sigma_j^2$  be the variance of  $g(X_j)/f_j(X_j)$ . Suppose that, for each  $j = 1, \dots, k$ , we simulate an importance sample of size  $m$  with the same distribution as  $X_j$ . The variance of the estimator of  $\theta_j$  will be  $\sigma_j^2/m$ . Since the  $k$  estimators of  $\theta_1, \dots, \theta_k$  are independent, the variance of the estimator of  $\theta$  will be  $\sum_{j=1}^k \sigma_j^2/m$ . To facilitate comparison to nonstratified importance sampling, let  $n = mk$ . Stratification will be an improvement if its variance is smaller than  $\sigma^2/n$ . Since  $n = mk$ , we would like to prove that at least

$$\sigma^2 \geq k \sum_{j=1}^k \sigma_j^2, \quad (12.4.7)$$

and preferably with strict inequality.

To prove (12.4.7), we note a close connection between the random variables  $X_j$  with the p.d.f.  $f_j$  and  $X$  with the p.d.f.  $f$ . Let  $J$  be a random variable with the discrete uniform distribution on the integers  $1, \dots, k$ . Define  $X^* = X_J$ , so that the conditional p.d.f. of  $X^*$  given  $J = j$  is  $f_j$ . You can prove (Exercise 11) that  $X^*$  and  $X$  have the same p.d.f. Let  $Y = g(X)/f(X)$  and

$$Y^* = \frac{g(X^*)}{f_j(X^*)} = \frac{g(X^*)}{kf(X^*)}.$$

Then  $\text{Var}(Y^*|J=j) = \sigma_j^2$  and  $kY^*$  has the same distribution as  $Y$ . So,

$$\sigma^2 = \text{Var}(Y) = \text{Var}(kY^*) = k^2 \text{Var}(Y^*). \quad (12.4.8)$$

Theorem 4.7.4 says that

$$\text{Var}(Y^*) = E \text{Var}(Y^*|J) + \text{Var}[E(Y^*|J)]. \quad (12.4.9)$$

By construction,  $E(Y^*|J = j) = \theta_j$  and  $\text{Var}(Y^*|J = j) = \sigma_j^2$ . Also,  $\text{Var}[E(Y^*|J)] \geq 0$  with strict inequality if the  $\theta_j$  are not all the same. Since  $\Pr(J = j) = 1/k$  for  $j = 1, \dots, k$ , we have

$$E \text{Var}(Y^*|J) = \frac{1}{k} \sum_{j=1}^k \sigma_j^2. \quad (12.4.10)$$

Combining Eqs. (12.4.8), (12.4.9), and (12.4.10), we obtain (12.4.7), with strict inequality if the  $\theta_j$  are not all equal.

### Example 12.4.4

**Illustration of Stratified Importance Sampling.** Consider the integral that we wanted to estimate in Example 12.4.1. The best importance function appeared to be  $f_3$ , with a simulation standard error of  $\hat{\sigma}_3/100 = 9.73 \times 10^{-4}$ . In the present example, we allocate 10,000 simulations among  $k = 10$  subsets of size  $m = 1000$  each and do stratified importance sampling by dividing the range of integration  $[0, 1]$  into 10 equal-length subintervals. Doing this, we get a Monte Carlo estimate of the integral of 0.5248. To estimate the simulation standard error, we need to estimate each  $\sigma_j$  by  $\hat{\sigma}_j^*$  and compute  $\sum_{j=1}^{10} \hat{\sigma}_j^{*2}/1000$ . In the simulation that we are discussing, the simulation standard error for stratified importance sampling is  $1.05 \times 10^{-4}$ , about one-tenth as small as the unstratified version. We can also do stratified importance sampling using  $k = 100$  subsets of size  $m = 100$ . In our simulation, the estimate of the integral is the same with simulation standard error of  $1.036 \times 10^{-5}$ .  $\blacktriangleleft$

The reason that stratified importance sampling works so well in Example 12.4.4 is that the function  $g(x)/f_3(x)$  is monotone, and this makes  $\theta_j$  change about as much as it can as  $j$  changes. Hence,  $\text{Var}[E(Y^*|J)]$  is large, making stratification very effective.  $\diamond$

## Summary

We introduced the method of importance sampling for calculating integrals by simulation. The idea of importance sampling for estimating  $\int g(x) dx$  is to choose a p.d.f.  $f$  from which we can simulate and such that  $g(x)/f(x)$  is nearly constant. Then we rewrite the integral as  $\int [g(x)/f(x)]f(x) dx$ . We can estimate this last integral by averaging  $g(X^{(i)})/f(X^{(i)})$  where  $X^{(1)}, \dots, X^{(v)}$  form a random sample with the p.d.f.  $f$ . A stratified version of importance sampling can produce estimators with even smaller variance.

## Exercises

- Prove that the formula in Eq. (12.4.1) is the same as importance sampling in which the importance function is the p.d.f. of the uniform distribution on the interval  $[a, b]$ .
- Let  $g$  be a function, and suppose that we wish to compute the mean of  $g(X)$  where  $X$  has the p.d.f.  $f$ . Suppose

that we can simulate pseudo-random values with the p.d.f.  $f$ . Prove that the following are the same:

- Simulate  $X^{(i)}$  values with the p.d.f.  $f$ , and average the values of  $g(X^{(i)})$  to obtain the estimator.
- Do importance sampling with importance function  $f$  to estimate the integral  $\int g(x)f(x) dx$ .

- 3.** Let  $Y$  have the  $F$  distribution with  $m$  and  $n$  degrees of freedom. We wish to estimate  $\Pr(Y > c)$ . Consider the p.d.f.

$$f(x) = \begin{cases} \frac{(n/2)c^{n/2}}{x^{n/2+1}} & \text{if } x > c, \\ 0 & \text{otherwise.} \end{cases}$$

- a.** Explain how to simulate pseudo-random numbers with the p.d.f.  $f$ .
- b.** Explain how to estimate  $\Pr(Y > c)$  using importance sampling with the importance function  $f$ .
- c.** Look at the form of the p.d.f. of  $Y$ , Eq. (9.7.2), and explain why importance sampling might be more efficient than sampling i.i.d.  $F$  random variables with  $m$  and  $n$  degrees of freedom if  $c$  is not small.

- 4.** We would like to calculate the integral  $\int_0^\infty \log(1+x) \exp(-x) dx$ .

- a.** Simulate 10,000 exponential random variables with parameter 1 and use these to estimate the integral. Also, find the simulation standard error of your estimator.
- b.** Simulate 10,000 gamma random variables with parameters 1.5 and 1 and use these to estimate the integral (importance sampling). Find the simulation standard error of the estimator. (In case you do not have the gamma function available,  $\Gamma(1.5) = \sqrt{\pi}/2$ .)
- c.** Which of the two methods appears to be more efficient? Can you explain why?

- 5.** Let  $U$  have the uniform distribution on the interval  $[0, 1]$ . Show that the random variable  $W$  defined in Eq. (12.4.6) has the p.d.f.  $h$  defined in Eq. (12.4.5).

- 6.** Suppose that we wish to estimate the integral

$$\int_1^\infty \frac{x^2}{\sqrt{2\pi}} e^{-0.5x^2} dx.$$

In parts (a) and (b) below, use simulation sizes of 1000.

- a.** Estimate the integral by importance sampling using random variables having a truncated normal distribution. That is, the importance function is

$$\frac{1}{\sqrt{2\pi}[1 - \Phi(1)]} e^{-0.5x^2}, \quad \text{for } x > 1.$$

- b.** Estimate the integral by importance sampling using random variables with the p.d.f.  $x \exp(0.5[1 - x^2])$ , for  $x > 1$ . Hint: Prove that such random variables can be obtained as follows: Start with a random variable that has the exponential distribution with parameter 0.5, add 1, then take the square root.
- c.** Compute and compare simulation standard errors for the two estimators in parts (a) and (b). Can you explain why one is so much smaller than the other?

- 7.** Let  $(X_1, X_2)$  have the bivariate normal distribution with both means equal to 0, both variances equal to 1, and the correlation equal to 0.5. We wish to estimate  $\theta = \Pr(X_1 \leq 2, X_2 \leq 1)$  using simulation.

- a.** Simulate a sample of 10,000 bivariate normal vectors with the above distribution. Use the proportion of vectors satisfying the two inequalities  $X_1 \leq 2$  and  $X_2 \leq 1$  as the estimator  $Z$  of  $\theta$ . Also compute the simulation standard error of  $Z$ .
- b.** Use the method described in Example 12.4.3 with 10,000 simulations to produce an alternative estimator  $Z'$  of  $\theta$ . Compute the simulation standard error of  $Z'$  and compare  $Z'$  to the estimate in part (a).
- 8.** Suppose that we wish to approximate the integral  $\int g(x) dx$ . Suppose that we have a p.d.f.  $f$  that we shall use as an importance function. Suppose that  $g(x)/f(x)$  is bounded. Prove that the importance sampling estimator has finite variance.
- 9.** Let  $F$  be a continuous strictly increasing c.d.f. with p.d.f.  $f$ . Let  $V$  have the uniform distribution on the interval  $[a, b]$  with  $0 \leq a < b \leq 1$ . Prove that the p.d.f. of  $X = F^{-1}(V)$  is  $f(x)/(b-a)$  for  $F^{-1}(a) \leq x \leq F^{-1}(b)$ . (If  $a = 0$ , let  $F^{-1}(a) = -\infty$ . If  $b = 1$ , let  $F^{-1}(b) = \infty$ .)
- 10.** For the situation described in Exercise 6, use stratified importance sampling as follows: Divide the interval  $(1, \infty)$  into five intervals that each have probability 0.2 under the importance distribution. Sample 200 observations from each interval. Compute the simulation standard error. Compare this simulation to the simulation in Exercise 6 for each of parts (a) and (b).

- 11.** In the notation used to develop stratified importance sampling, prove that  $X^* = X_J$  and  $X$  have the same distribution. Hint: The conditional p.d.f. of  $X^*$  given  $J = j$  is  $f_j$ . Use the law of total probability.

- 12.** Consider again the situation described in Exercise 15 of Sec. 12.2. Suppose that  $W_u$  has the Laplace distribution with parameters  $\theta = 0$  and  $\sigma = 0.1u^{1/2}$ . See Eq. (10.7.5) for the p.d.f.

- a.** Prove that the m.g.f. of  $W_u$  is
- $$\psi(t) = \left(1 - \frac{t^2 u}{100}\right)^{-1}, \quad \text{for } -10u^{-1/2} < t < 10u^{-1/2}.$$
- b.** Let  $r = 0.06$  be the risk-free interest rate. Simulate a large number  $v$  of values of  $W_u$  with  $u = 1$  and use these to estimate the price of an option to buy one share of this stock at time  $u = 1$  in the future for the current price  $S_0$ . Also compute the simulation standard error.
  - c.** Use importance sampling to improve on the simulation in part (b). Instead of simulating  $W_u$  values directly, simulate from the conditional distribution of  $W_u$  given that  $S_u > S_0$ . How much smaller is the simulation standard error?

- 13.** The method of *control variates* is a technique for reducing the variance of a simulation estimator. Suppose that we wish to estimate  $\theta = E(W)$ . A control variate is another random variable  $V$  that is positively correlated with  $W$  and whose mean  $\mu$  we know. Then, for every constant  $k > 0$ ,  $E(W - kV + k\mu) = \theta$ . Also, if  $k$  is chosen carefully,  $\text{Var}(W - kV + k\mu) < \text{Var}(W)$ . In this exercise, we shall see how to use control variates for importance sampling, but the method is very general. Suppose that we wish to compute  $\int g(x) dx$ , and we wish to use the importance function  $f$ . Suppose that there is a function  $h$  such that  $h$  is similar to  $g$  but  $\int h(x) dx$  is known to equal the value  $c$ . Let  $k$  be a constant. Simulate  $X^{(1)}, \dots, X^{(v)}$  with the p.d.f.  $f$ , and define

$$\begin{aligned} W^{(i)} &= \frac{g(X^{(i)})}{f(X^{(i)})}, \\ V^{(i)} &= \frac{h(X^{(i)})}{f(X^{(i)})}, \\ Y^{(i)} &= W^{(i)} - kV^{(i)}, \end{aligned}$$

for all  $i$ . Our estimator of  $\int g(x) dx$  is then

$$Z = \frac{1}{v} \sum_{i=1}^v Y^{(i)} + kc.$$

- a. Prove that  $E(Z) = \int g(x) dx$ .
- b. Let  $\text{Var}(W^{(i)}) = \sigma_W^2$  and  $\text{Var}(V^{(i)}) = \sigma_V^2$ . Let  $\rho$  be the correlation between  $W^{(i)}$  and  $V^{(i)}$ . Prove that the value of  $k$  that makes  $\text{Var}(Z)$  the smallest is  $k = \sigma_W \rho / \sigma_V$ .

- 14.** Suppose that we wish to integrate the same function  $g(x)$  as in Example 12.4.1.

- a. Use the method of control variates that was described in Exercise 13 to estimate  $\int g(x) dx$ . Let  $h(x) = 1/(1+x^2)$  for  $0 < x < 1$ , and  $k = e^{-0.5}$ . (This makes  $h$  about the same size as  $g$ .) Let  $f(x)$  be the function  $f_3$  in Example 12.4.1. How does the simulation standard error using control variates compare to not using control variates?
- b. Estimate the variances and correlation of the  $W^{(i)}$ 's and  $V^{(i)}$ 's (notation of Exercise 13) to see what a good value for  $k$  might be.

- 15.** The method of *antithetic variates* is a technique for reducing the variance of simulation estimators. Antithetic variates are negatively correlated random variables that share a common mean and common variance. The variance of the average of two antithetic variates is smaller than the variance of the average of two i.i.d. variables. In this exercise, we shall see how to use antithetic variates for importance sampling, but the method is very general. Suppose that we wish to compute  $\int g(x) dx$ , and we wish to use the importance function  $f$ . Suppose that we generate pseudo-random variables with the p.d.f.  $f$  using the probability integral transformation. That is, for  $i = 1, \dots, v$ , let  $X^{(i)} = F^{-1}(U^{(i)})$ , where  $U^{(i)}$  has the uniform distribution on the interval  $[0, 1]$  and  $F$  is the c.d.f. corresponding to the p.d.f.  $f$ . For each  $i = 1, \dots, v$ , define

$$\begin{aligned} T^{(i)} &= F^{-1}(1 - U^{(i)}), \\ W^{(i)} &= \frac{g(X^{(i)})}{f(X^{(i)})}, \\ V^{(i)} &= \frac{g(T^{(i)})}{f(T^{(i)})}, \\ Y^{(i)} &= 0.5 \left[ W^{(i)} + V^{(i)} \right]. \end{aligned}$$

Our estimator of  $\int g(x) dx$  is then  $Z = \frac{1}{v} \sum_{i=1}^v Y^{(i)}$ .

- a. Prove that  $T^{(i)}$  has the same distribution as  $X^{(i)}$ .
- b. Prove that  $E(Z) = \int g(x) dx$ .
- c. If  $g(x)/f(x)$  is a monotone function, explain why we would expect  $W^{(i)}$  and  $V^{(i)}$  to be negatively correlated.
- d. If  $W^{(i)}$  and  $V^{(i)}$  are negatively correlated, show that  $\text{Var}(Z)$  is less than the variance one would get with  $2v$  simulations without antithetic variates.

- 16.** Use the method of antithetic variates that was described in Exercise 15. Let  $g(x)$  be the function that we tried to integrate in Example 12.4.1. Let  $f(x)$  be the function  $f_3$  in Example 12.4.1. Estimate  $\text{Var}(Y^{(i)})$ , and compare it to  $\hat{\sigma}_3^2$  from Example 12.4.1.

- 17.** For each of the exercises in this section that requires a simulation, see if you can think of a way to use control variates or antithetic variates to reduce the variance of the simulation estimator.

## ★ 12.5 Markov Chain Monte Carlo

The techniques described in Sec. 12.3 for generating pseudo-random numbers with particular distributions are most useful for univariate distributions. They can be applied in many multivariate cases, but they often become unwieldy. A method based on Markov chains (see Sec. 3.10) became popular after publications by Metropolis et al. (1953) and Gelfand and Smith (1990). We shall present only the simplest form of Markov chain Monte Carlo in this section.

## The Gibbs Sampling Algorithm

We shall begin with an attempt to simulate a bivariate distribution. Suppose that the joint p.d.f. of  $(X_1, X_2)$  is  $f(x_1, x_2) = cg(x_1, x_2)$ , where we know the function  $g$  but not necessarily the value of the constant  $c$ . This type of situation arises often when computing posterior distributions. If  $X_1$  and  $X_2$  are the parameters, the function  $g$  might be the product of the prior p.d.f. times the likelihood function (in which the data are treated as known values). The constant  $c = 1 / \int g(x_1, x_2) dx_1 dx_2$  makes  $cg(x_1, x_2)$  the posterior p.d.f. Often it is difficult to compute  $c$ , although the methods of Sec. 12.4 might be helpful. Even if we can approximate the constant  $c$ , there are other features of the posterior distribution that we might not be able to compute easily, so simulation would be useful.

If the function  $g(x_1, x_2)$  has a special form, then there is a powerful algorithm for simulating vectors with the p.d.f.  $f$ . The required form can be described as follows: First, consider  $g(x_1, x_2)$  as a function of  $x_1$  for fixed  $x_2$ . This function needs to look like a p.d.f. (for  $X_1$ ) from which we know how to simulate pseudo-random values. Similarly, if we consider  $g(x_1, x_2)$  as a function of  $x_2$  for fixed  $x_1$ , the function needs to look like a p.d.f. for  $X_2$  from which can simulate.

**Example**  
**12.5.1**

**Sample from a Normal Distribution.** Suppose that we have observed a sample from the normal distribution with unknown mean  $\mu$  and unknown precision  $\tau$ . Suppose that we use a natural conjugate prior of the form described in Sec. 8.6. The product of the prior and the likelihood is given by Eq. (8.6.7) without the appropriate constant factor. We reproduce a version of that equation here for convenience:

$$\xi(\mu, \tau | \mathbf{x}) \propto \tau^{\alpha_1 + 1/2 - 1} \exp\left(-\tau \left[\frac{1}{2}\lambda_1(\mu - \mu_1)^2 + \beta_1\right]\right),$$

where  $\alpha_1$ ,  $\beta_1$ ,  $\mu_1$ , and  $\lambda_1$  are known values once the data have been observed. Considering this as a function of  $\mu$  for fixed  $\tau$ , it looks like the p.d.f. of the normal distribution with mean  $\mu_1$  and variance  $(\tau\lambda_1)^{-1}$ . Considering it as a function of  $\tau$  for fixed  $\mu$ , it looks like the p.d.f. of the gamma distribution with parameters  $\alpha_1 + 1/2$  and  $\lambda_1(\mu - \mu_1)^2/2 + \beta_1$ . Both of these distributions are easy to simulate. ◀

When we consider  $g(x_1, x_2)$  as a function of  $x_1$  for fixed  $x_2$ , we are looking at the conditional p.d.f. of  $X_1$  given  $X_2 = x_2$ , except for a multiplicative factor that does not depend on  $x_1$ . (See Exercise 1.) Similarly, when we consider  $g(x_1, x_2)$  as a function of  $x_2$  for fixed  $x_1$ , we are looking at the conditional p.d.f. of  $X_2$  given  $X_1 = x_1$ .

Once we have determined that the function  $g(x_1, x_2)$  has the desired form, our algorithm proceeds as follows:

1. Pick a starting value  $x_2^{(0)}$  for  $X_2$ , and set  $i = 0$ .
2. Simulate a new value  $x_1^{(i+1)}$  from the conditional distribution of  $X_1$  given  $X_2 = x_2^{(i)}$ .
3. Simulate a new value  $x_2^{(i+1)}$  from the conditional distribution of  $X_2$  given  $X_1 = x_1^{(i+1)}$ .
4. Replace  $i$  by  $i + 1$  and return to step 2.

The algorithm typically terminates when  $i$  reaches a sufficiently large value. Although there currently are no truly satisfactory convergence criteria, we shall introduce one convergence criterion later in this section. This algorithm is commonly called *Gibbs*

*sampling.* The name derives from an early use of the technique by Geman and Geman (1984) for sampling from a distribution that was known as the Gibbs distribution.

## Some Theoretical Justification

So far, we have given no justification for the Gibbs sampling algorithm. The justification stems from the fact that the successive pairs  $(x_1^{(1)}, x_2^{(1)}), (x_1^{(2)}, x_2^{(2)}) \dots$  form the observed sequence of states from a Markov chain. This Markov chain is much more complicated than any of the Markov chains encountered in Sec. 3.10 for two reasons. First, the states are two-dimensional, and second, the number of possible states is infinite rather than finite. Even so, one can easily recognize the basic structure of a Markov chain in the description of the Gibbs sampling algorithm. Suppose that  $i$  is the current value of the iteration index. The conditional distribution of the next state pair  $(X_1^{(i+1)}, X_2^{(i+1)})$  given all of the available state pairs  $(X_1^{(1)}, X_2^{(1)}), \dots, (X_1^{(i)}, X_2^{(i)})$  depends only on  $(X_1^{(i)}, X_2^{(i)})$ , the current state pair. This is the same as the defining property of finite Markov chains in Sec. 3.10.

Even if we agree that the sequence of pairs forms a Markov chain, why should we believe that they come from the desired distribution? The answer lies in a generalization of the second part of Theorem 3.10.4 to more general Markov chains. The generalization is mathematically too involved to present here, and it requires conditions that involve concepts that we have not introduced in this book.

Nevertheless, the Gibbs sampler is constructed from a joint distribution that one can show (see Exercise 2) is a stationary distribution for the resulting Markov chain. For the cases that we illustrate in this book, the distribution of the Gibbs sampler Markov chain does indeed converge to this stationary distribution as the number of transitions increases. (For a more general discussion, see Tierney, 1994.) Because of the close connection with Markov chains, Gibbs sampling (and several related techniques) are often called *Markov chain Monte Carlo*.

## When Does the Markov Chain Converge?

Although the distribution of a Markov chain may converge to its stationary distribution, after any finite time the distribution will not necessarily be the stationary distribution. In general, the distribution will get pretty close to the stationary distribution in finite time, but how do we tell, in a particular application, if we have sampled the Markov chain long enough to be confident that we are sampling from something close to the stationary distribution? Much work has been done to address this question, but there is no foolproof method. Several methods for assessing convergence of a Markov chain in a Monte Carlo analysis were reviewed by Cowles and Carlin (1996). Here we present one simple technique.

Begin by sampling several versions of the Markov chain starting at  $k$  different initial values  $x_{2,1}^{(0)}, \dots, x_{2,k}^{(0)}$ . These  $k$  Markov chains will be useful not only for assessing convergence but also for estimating the variances of our simulation estimators. It is wise to choose the initial values  $x_{2,1}^{(0)}, \dots, x_{2,k}^{(0)}$  to be quite spread out. This will help us to determine whether we have a Markov chain that is very slow to converge. Next, apply the Gibbs sampling algorithm starting at each of the  $k$  initial values. This gives us  $k$  independent Markov chains, all with the same stationary distribution. If the  $k$  Markov chains have been sampled for  $m$  iterations, we can think of the observed values of  $X_1$  (or of  $X_2$ ) as  $k$  samples of size  $m$  each. For ease of notation, let  $T_{l,j}$  stand for either the value of  $X_1$  or the value of  $X_2$  from the  $j$ th iteration of the

$i$ th Markov chain. (We shall repeat the following analysis once for  $X_1$  and once for  $X_2$ .) Now, treat  $T_{i,j}$  for  $j = 1, \dots, m$  as a sample of size  $m$  from the  $i$ th of  $k$  distributions for  $i = 1, \dots, k$ . If we have sampled long enough for the Markov chains to have converged approximately, then all  $k$  of these distributions should be nearly the same. This suggests that we use the  $F$  statistic from the discussion of analysis of variance (Sec. 11.6) to measure how close the  $k$  distributions are. The  $F$  statistic can be written as  $F = B/W$  where

$$B = \frac{m}{k-1} \sum_{i=1}^k (\bar{T}_{i+} - \bar{T}_{++})^2,$$

$$W = \frac{1}{k(m-1)} \sum_{i=1}^k \sum_{j=1}^m (T_{ij} - \bar{T}_{i+})^2.$$

Here we have used the same notation as in Sec. 11.6 in which the  $+$  subscript appears in a position wherever we have averaged over all values of the subscript in that position. If the  $k$  distributions are different, then  $F$  should be large. If the distributions are the same, then  $F$  should be close to 1. As we mentioned earlier, we compute two  $F$  statistics, one using the  $X_1$  coordinates and one using the  $X_2$  coordinates. Then we could declare that we have sampled long enough when both  $F$  statistics are simultaneously less than some number slightly larger than 1. Gelman et al. (1995) describe essentially this same procedure and recommend comparing the maximum of the two  $F$  statistics to  $1 + 0.44m$ . It is probably a good idea to start with at least  $m = 100$  (if the iterations are fast enough) before beginning to compute the  $F$  statistics. This will help to avoid accidentally declaring success due to some “lucky” early simulations. The initial sequence of iterations of the Markov chain, before we declare convergence, is commonly called *burn-in*. After the burn-in iterations, one would typically treat the ensuing iterations as observations from the stationary distribution. It is common to discard the burn-in iterations because we are not confident that their distribution is close to the stationary distribution. Iterations of a Markov Chain are dependent, however, so one should not treat them as an i.i.d. sample. Even though we computed an  $F$  statistic from the various dependent observations, we did not claim that the statistic had an  $F$  distribution. Nor did we compare the statistic to a quantile of an  $F$  distribution to make our decision about convergence. We merely used the statistic as an ad hoc measure of how different the  $k$  Markov chains are.

### Example

#### 12.5.2

**Nursing Homes in New Mexico.** We shall use the data from Sec. 8.6 on the numbers of medical in-patient days in 18 nonrural nursing homes in New Mexico in 1988. There, we modeled the observations as a random sample from the normal distribution with unknown mean  $\mu$  and unknown precision  $\tau$ . We used a natural conjugate prior and found the posterior hyperparameters to be  $\alpha_1 = 11$ ,  $\beta_1 = 50925.37$ ,  $\mu_1 = 183.95$ , and  $\lambda_1 = 20$ . We shall illustrate the above convergence diagnostic for the Gibbs sampling algorithm described in Example 12.5.1. As we found in Example 12.5.1, the conditional distribution of  $\mu$  given  $\tau$  is the normal distribution with mean 183.95 and variance  $(20\tau)^{-1}$ . The conditional distribution of  $\tau$  given  $\mu$  is the gamma distribution with parameters 11.5 and  $50925.37 + 20(\mu - 183.95)^2$ . We shall start with the following  $k = 5$  initial values for  $\mu$ : 182.17, 227, 272, 137, 82. These were chosen by making a crude approximation to the posterior standard deviation of  $\mu$ , namely,  $(\beta_1/[\lambda_1\alpha_1])^{1/2} \approx 15$ , and then using the posterior mean together with values 3 and 6 posterior standard deviations above and below the posterior mean. We have to run the five Markov chains to the  $m = 2$  iteration before we can compute the  $F$  statistics.

In our simulation, at  $m = 2$ , the larger of the two  $F$  statistics was already as low as 0.8862, and it stayed very close to 1 all the way to  $m = 100$ , at which time it seemed clear that we should stop the burn-in.  $\blacktriangleleft$

### Estimation Based on Gibbs Sampling

So far, we have argued (without proof) that if we run the Gibbs sampling algorithm for many iterations (through burn-in), we should start to see pairs  $(X_1^{(i)}, X_2^{(i)})$  whose joint p.d.f. is nearly the function  $f$  from which we wanted to sample. Unfortunately, the successive pairs are not independent of each other even if they do have the same distribution. The law of large numbers does not tell us that the average of dependent random variables with the same distribution converges. However, the type of dependence that we get from a Markov chain is sufficiently regular that there are theorems that guarantee convergence of averages and even that the averages are asymptotically normal. That is, suppose that we wish to estimate the mean  $\mu$  of some function  $h(X_1, X_2)$  based on  $m$  observations from the Markov chain. We can still assume that  $\frac{1}{m} \sum_{i=1}^m h(X_1^{(i)}, X_2^{(i)})$  converges to  $\mu$ , and that it has approximately the normal distribution with mean  $\mu$  and variance  $\sigma^2/m$ . However, the convergence will typically be slower than for i.i.d. samples, and  $\sigma^2$  will be larger than the variance of  $h(X_1, X_2)$ . The reason for this is that the successive values of  $h(X_1^{(i)}, X_2^{(i)})$  are usually positively correlated. The variance of an average of positively correlated identically distributed random variables is higher than the variance of an average of the same number of i.i.d. random variables. (See Exercise 4.)

We shall deal with the problems caused by correlated samples by making use of the same  $k$  independent Markov chains that we used for determining how much burn-in to do. Discard the burn-in and continue to sample each Markov chain for  $m_0$  more iterations. From each Markov chain, we compute our desired estimator, either an average, a sample quantile, a sample variance, or other measure,  $Z_j$  for  $j = 1, \dots, k$ . We then compute  $S$  as in Eq. (12.2.2); that is,

$$S = \left( \frac{1}{k} \sum_{j=1}^k (Z_j - \bar{Z})^2 \right)^{1/2}. \quad (12.5.1)$$

Then  $S^2$  is an estimator of the simulation variance of the  $Z_j$ 's. Write the simulation variance as  $\sigma^2/m_0$  and estimate  $\sigma^2$  by  $\hat{\sigma}^2 = m_0 S^2$  as we did in Example 12.2.9. Also, combine all samples from all  $k$  chains into a single sample, and use this single sample to form the overall estimator  $Z$ . The simulation standard error of our estimator  $Z$  is then  $(\hat{\sigma}^2/(m_0 k))^{1/2} = S/k^{1/2}$ .

In addition, we may wish to determine how many simulations to perform in order to obtain a precise estimator. We can substitute  $\hat{\sigma}$  for  $\sigma$  in Eq. (12.2.5) to get a proposed number of simulations  $v$ . These  $v$  simulations would be divided between the  $k$  Markov chains so that each chain would be run for at least  $v/k$  iterations if  $v/k > m_0$ .

### Some Examples

---

**Example  
12.5.3**

**Nursing Homes in New Mexico.** We actually do not need Gibbs sampling in order to simulate a sample from the posterior distribution in Example 12.5.1. The reason is that we have a closed-form expression for the joint distribution of  $\mu$  and  $\tau$  in that example. Each of the marginal and conditional distributions are known and easy

**Figure 12.7** Quantile plots of  $\mu$  and  $\tau$  values simulated from the posterior distribution in Example 12.5.3. The line on each plot shows the quantiles of the actual posterior distribution as found in Sec. 8.6. The horizontal axis on the left plot is labeled by quantiles of the  $t$  distribution with 22 degrees of freedom. The actual posterior of  $\mu$  is a rescaling and shifting of this  $t$  distribution. The horizontal axis on the right plot is labeled by quantiles of the gamma distribution with parameters 11 and 1. The actual posterior of  $\tau$  is a rescaling of this gamma distribution.

to simulate. Gibbs sampling is most useful when only the conditionals are easy to simulate. However, we can illustrate the use of Gibbs sampling in Example 12.5.1 and compare the simulated results to the known marginal distributions of  $\mu$  and  $\tau$ .

In Example 12.5.2, we started  $k = 5$  Markov chains and burned them in for 100 iterations. Now we wish to produce a sample of  $(\mu, \tau)$  pairs from the joint posterior distribution. After burn-in, we run another  $m_0 = 1000$  iterations for each chain. These iterations produce five correlated sequence of  $(\mu, \tau)$  pairs. The correlations between successive pairs of  $\mu$  values are quite small. The same is true of successive  $\tau$  values. To compare the results with the known posterior distributions found in Sec. 8.6, Fig. 12.7 has a  $t$  quantile plot of the  $\mu$  values and a gamma quantile plot of the  $\tau$  values. (Normal quantile plots were introduced on page 720. Gamma and  $t$  quantile plots are constructed in the same way using gamma and  $t$  quantile functions in place of the standard normal quantile function.) The simulated values seem to lie close to the lines drawn on the plots in Fig. 12.7. (A few points in the tails stray a bit from the lines, but this occurs with virtually all quantile plots.) The lines in Fig. 12.7 show the quantiles of the actual posterior distributions, which are a  $t$  distribution with 22 degrees of freedom multiplied by 15.21 and centered at 183.95 for  $\mu$  and the gamma distribution with parameters 11 and 50925.37 for  $\tau$ .

We can use the sample of  $(\mu, \tau)$  pairs to estimate the posterior mean of an arbitrary function of  $(\mu, \tau)$ . For example, suppose that we are interested in the mean  $\theta$  of  $\mu + 1.645/\tau^{1/2}$ , which is the 0.95 quantile of the unknown distribution of the original observations. The average of our 5000 simulated values of  $\mu + 1.645/\tau^{1/2}$  is  $Z = 299.67$ . The value of  $S$  from Eq. (12.5.1) is 0.4119, giving us a value of  $\hat{\sigma} = 13.03$ . The simulation standard error of  $Z$  is then  $\hat{\sigma}/5000^{1/2} = 0.1842$ . The true posterior mean of  $\mu + 1.645/\tau^{1/2}$  can be computed exactly in this example, and it is

$$\mu_1 + 1.645\beta_1^{1/2} \frac{\Gamma(\alpha_1 - .5)}{\Gamma(\alpha_1)} = 299.88,$$

a bit more than 1 simulation standard error away from our simulated value of  $Z$ . Suppose that we want our estimator of  $\theta$  to be within 0.01 of the true value with

probability 0.99. Substituting these values and  $\hat{\sigma} = 13.03$  into Eq. (12.2.5), we find that we need  $v = 12,358,425$  total simulations. Each of our five Markov chains would have to be run for 2,251,685 iterations.  $\blacktriangleleft$

The true value of Gibbs sampling begins to emerge in problems with more than two parameters. The general Gibbs sampling algorithm for  $p$  random variables  $(X_1, \dots, X_p)$  with p.d.f.  $f(\mathbf{x}) = cg(\mathbf{x})$  is as follows. First, verify that  $g$  looks like an easy-to-simulate p.d.f. as a function of each variable for fixed values of all the others. Then perform these steps:

1. Pick starting values  $x_2^{(0)}, \dots, x_p^{(0)}$  for  $X_2, \dots, X_p$ , and set  $i = 0$ .
2. Simulate a new value  $x_1^{(i+1)}$  from the conditional distribution of  $X_1$  given  $X_2 = x_2^{(i)}, \dots, X_p = x_p^{(i)}$ .
3. Simulate a new value  $x_2^{(i+1)}$  from the conditional distribution of  $X_2$  given  $X_1 = x_1^{(i+1)}, X_3 = x_3^{(i)}, \dots, X_p = x_p^{(i)}$ .  
 $\vdots$
- $p + 1$ . Simulate a new value  $x_p^{(i+1)}$  from the conditional distribution of  $X_p$  given  $X_1 = x_1^{(i+1)}, \dots, X_{p-1} = x_{p-1}^{(i+1)}$ .
- $p + 2$ . Replace  $i$  by  $i + 1$ , and return to step 2.

The sequence of successive  $p$ -tuples of  $(X_1, \dots, X_p)$  values produced by this algorithm is a Markov chain in the same sense as before. The stationary distribution of this Markov chain has the p.d.f.  $f$ , and the distribution of an iteration many steps after the start should be approximately the stationary distribution.

**Example**  
**12.5.4**

**Multiple Regression with an Improper Prior.** Consider a problem in which we observe data consisting of triples  $(Y_i, x_{1i}, x_{2i})$  for  $i = 1, \dots, n$ . We assume that the  $x_{ji}$  values are known, and we model the distribution of  $Y_i$  as the normal distribution with mean  $\beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i}$  and precision  $\tau$ . This is the multiple regression model introduced in Sec. 11.5 with the variance replaced by 1 over the precision. Suppose that we use the improper prior  $\xi(\beta_0, \beta_1, \beta_2, \tau) = 1/\tau$  for the parameters. The posterior p.d.f. of the parameters is then proportional to the likelihood times  $1/\tau$ , which is a constant times

$$\tau^{n/2-1} \exp\left(-\frac{\tau}{2} \sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_{1i} - \beta_2 x_{2i})^2\right). \quad (12.5.2)$$

To simplify the ensuing formulas, we shall define some summaries of the data:

$$\begin{aligned} \bar{x}_1 &= \frac{1}{n} \sum_{i=1}^n x_{1i}, & \bar{x}_2 &= \frac{1}{n} \sum_{i=1}^n x_{2i}, & \bar{y} &= \frac{1}{n} \sum_{i=1}^n y_i, \\ s_{11} &= \sum_{i=1}^n x_{1i}^2, & s_{22} &= \sum_{i=1}^n x_{2i}^2, & s_{12} &= \sum_{i=1}^n x_{1i} x_{2i}, \\ s_{1y} &= \sum_{i=1}^n x_{1i} y_i, & s_{2y} &= \sum_{i=1}^n x_{2i} y_i, & s_{yy} &= \sum_{i=1}^n y_i^2. \end{aligned}$$

Looking at (12.5.2) as a function of  $\tau$  for fixed values of  $\beta_0$ ,  $\beta_1$ , and  $\beta_2$ , it looks like the p.d.f. of the gamma distribution with parameters  $n/2$  and  $\sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_{1i} - \beta_2 x_{2i})^2/2$ . Looking at (12.5.2) as a function of  $\beta_j$  for fixed values of the other parameters, it is  $e$  to the power of a quadratic in  $\beta_j$  with negative coefficient on the

$\beta_j^2$  term. As such, it looks like the p.d.f. of a normal random variable with a mean that depends on the data and the other  $\beta$ 's and a variance that equals  $1/\tau$  times some function of the data. We can be more specific if we complete the square in the expression  $\sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_{1i} - \beta_2 x_{2i})^2$  three times, each time treating a different  $\beta_j$  as the variable of interest. For example, treating  $\beta_0$  as the variable of interest, we get

$$\sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_{1i} - \beta_2 x_{2i})^2 = n (\beta_0 - [\bar{y} - \beta_1 \bar{x}_1 - \beta_2 \bar{x}_2])^2,$$

plus a term that does not depend on  $\beta_0$ . So, the conditional distribution of  $\beta_0$  given the remaining parameters is the normal distribution with mean  $\bar{y} - \beta_1 \bar{x}_1 - \beta_2 \bar{x}_2$  and variance  $1/[n\tau]$ . Treating  $\beta_1$  as the variable of interest, we get

$$\sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_{1i} - \beta_2 x_{2i})^2 = s_{11}(\beta_1 - w_1)^2,$$

plus a term that does not depend on  $\beta_1$ , where

$$w_1 = \frac{1}{s_{11}} (s_{1y} - \beta_0 n \bar{x}_1 - \beta_2 s_{12}).$$

This means that the conditional distribution of  $\beta_1$  given the other parameters is the normal distribution with mean  $w_1$  and variance  $(\tau s_{11})^{-1}$ . Similarly, the conditional distribution of  $\beta_2$  given the other parameters is the normal distribution with mean  $w_2$  and variance  $(\tau s_{22})^{-1}$ , where

$$w_2 = \frac{1}{s_{22}} (s_{2y} - \beta_0 n \bar{x}_2 - \beta_1 s_{12}). \quad \blacktriangleleft$$

### Example 12.5.5

**Unemployment in the 1950s.** In Example 11.5.9, we saw that unemployment data from the years 1951–1959 appeared to satisfy the assumptions of the multiple regression model better than the data that included the year 1950. Let us use just the last nine years of data from this example (in Table 11.12). We shall use an improper prior and Gibbs sampling to obtain samples from the posterior distribution of the parameters. The necessary conditional distributions were all given in Example 12.5.4. We just need the values of the summary statistics and  $n = 9$ :

$$\begin{aligned} \bar{x}_1 &= 140.7778, & \bar{x}_2 &= 6, & \bar{y} &= 2.789, \\ s_{11} &= 179585, & s_{22} &= 384, & s_{12} &= 7837, \\ s_{1y} &= 3580.9, & s_{2y} &= 169.2, & s_{yy} &= 78.29. \end{aligned}$$

Once again, we shall run  $k = 5$  Markov chains. In this problem, there are four coordinates to the parameter:  $\beta_i$  for  $i = 0, 1, 2$  and  $\tau$ . So, we compute four  $F$  statistics and burn-in until the largest  $F$  is less than  $1 + 0.44m$ . Suppose that this occurs at  $m = 4546$ . We then sample 10,000 more iterations from each Markov chain.

Suppose that we want an interval  $[a, b]$  that contains 90 percent of the posterior distribution of  $\beta_1$ . The numbers  $a$  and  $b$  will be the sample 0.05 and 0.95 quantiles. Based on our combined sample of 50,000 values of  $\beta_1$ , the interval is  $[-0.1178, -0.0553]$ . In order to assess the uncertainty in the endpoints, we compute the 0.05 and 0.95 sample quantiles for each of the five Markov chains. Those values are

0.05 quantiles:  $-0.1452, -0.1067, -0.1181, -0.1079, -0.1142$

0.95 quantiles:  $-0.0684, -0.0610, -0.0486, -0.0594, -0.0430$ .

The value of  $S$  based on the sample 0.05 quantiles is 0.01567, and the value of  $S$  based on the sample 0.95 quantiles is 0.01142. To be safe, we shall use the larger of these two to estimate the simulation standard errors of our interval endpoints. Since each chain was run for  $m_0 = 10,000$  iterations, we have  $\hat{\sigma} = Sm_0^{1/2} = 1.567$ . Suppose that we want each endpoint of the interval to be within 0.01 of the corresponding true quantile of the distribution of  $\beta_1$  with probability 0.95. (The probability that both endpoints are within 0.01 would be a bit smaller, but is harder to compute.) We could use Eq. (12.2.5) to compute how many simulations we would need. That equation yields  $v = 94,386$ , which means that each of our five chains would need to be run 18,878 iterations, about twice what we already have. For comparison, a 90 percent confidence interval for  $\beta_1$  constructed using the methods of Sec. 11.3 is  $[-0.1124, -0.0579]$ . This is quite close to the posterior probability interval.  $\blacktriangleleft$

Although we did not do so in this text, we could have found the posterior distribution for Example 12.5.5 in closed form. Indeed, the 90 percent confidence interval calculated at the end of the example contains 90 percent of the posterior distribution in much the same way that coefficient  $1 - \alpha_0$  confidence intervals contain posterior probability  $1 - \alpha_0$  in Sec. 11.4 when we use improper priors. The next example is one in which a closed-form solution is not available.

### Example 12.5.6

**Bayesian Analysis of One-Way Layout with Unequal Variances.** Consider the one-way layout that was introduced in Sec. 11.6. There, we assumed that data would be observed from each of  $p$  normal distributions with possibly different means but the same variance. In order to illustrate the added power of Gibbs sampling, we shall drop the assumption that each normal distribution has the same variance. That is, for  $i = 1, \dots, p$ , we shall assume that  $Y_{i1}, \dots, Y_{in_i}$  have the normal distribution with mean  $\mu_i$  and precision  $\tau_i$ , and all observations are independent conditional on all parameters. Our prior distribution for the parameters will be the following: Let  $\mu_1, \dots, \mu_p$  be conditionally independent given all other parameters with  $\mu_i$  having the normal distribution with mean  $\psi$  and precision  $\lambda_0\tau_i$ . Here,  $\psi$  is another parameter that also needs a distribution. We introduce this parameter  $\psi$  as a way of saying that we think that the  $\mu_i$ 's all come from a common distribution, but we are not willing to say for sure where that distribution is located. We then say that  $\psi$  has the normal distribution with mean  $\psi_0$  and precision  $u_0$ . For an improper prior, we could set  $u_0 = 0$  in what follows, and then  $\psi_0$  would not be needed either. Next, we model  $\tau_1, \dots, \tau_p$  as i.i.d. having the gamma distribution with parameters  $\alpha_0$  and  $\beta_0$ . We model  $\psi$  and the  $\tau_i$ 's as independent. For an improper prior, we could set  $\alpha_0 = \beta_0 = 0$ . The type of model just described is called a *hierarchical model* because of the way that the distributions fall into a hierarchy of levels. Figure 12.8 illustrates the levels of the hierarchy in this example.

**Figure 12.8** Diagram of hierarchical model in Example 12.5.6. The parameter  $\psi$  influences the distributions of the  $\mu_i$ 's, while the  $(\mu_i, \tau_i)$  parameters influence the distributions of the  $Y_{ij}$ 's.

The joint p.d.f. of the observations and the parameters is the product of the likelihood function (the p.d.f. of the observations given the  $\mu_i$ 's and  $\tau_i$ 's) times the product of the conditional prior p.d.f.'s of the  $\mu_i$ 's given the  $\tau_i$ 's and  $\psi$ , times the prior p.d.f.'s of the  $\tau_i$ 's times the prior p.d.f. for  $\psi$ . Aside from constants that depend neither on the data nor on the parameters, this product has the form

$$\exp\left(-\frac{u_0(\psi - \psi_0)^2}{2} - \sum_{i=1}^p \tau_i \left[ \beta_0 + \frac{n_i(\mu_i - \bar{y}_i)^2 + w_i + \lambda_0(\mu_i - \psi)^2}{2} \right]\right) \\ \times \prod_{i=1}^p \tau_i^{\alpha_0 + [n_i + 1]/2 - 1}, \quad (12.5.3)$$

where  $w_i = \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2$  for  $i = 1, \dots, p$ . We have arranged terms in (12.5.3) so that the terms involving each parameter are close together. This will facilitate describing the Gibbs sampling algorithm.

In order to set up Gibbs sampling, we need to examine (12.5.3) as a function of each parameter separately. The parameters are  $\mu_1, \dots, \mu_p; \tau_1, \dots, \tau_p$ ; and  $\psi$ . As a function of  $\tau_i$ , (12.5.3) looks like the p.d.f. of the gamma distribution with parameters  $\alpha_0 + (n_i + 1)/2$  and  $\beta_0 + [n_i(\mu_i - \bar{y}_i)^2 + w_i + \lambda_0(\mu_i - \psi)^2]/2$ . As a function of  $\psi$ , it looks like the p.d.f. of the normal distribution with mean  $[u_0\psi_0 + \lambda_0 \sum_{i=1}^p \tau_i \mu_i]/[u_0 + \lambda_0 \sum_{i=1}^p \tau_i]$  and precision  $u_0 + \lambda_0 \sum_{i=1}^p \tau_i$ . This is obtained by completing the square for all terms involving  $\psi$ . Similarly, by completing the square for all terms involving  $\mu_i$ , we find that (12.5.3) looks like the normal p.d.f. with mean  $[n_i \bar{y}_i + \lambda_0 \psi]/[n_i + \lambda_0]$  and precision  $\tau_i(n_i + \lambda_0)$  as a function of  $\mu_i$ . All of these distributions are easy to simulate.

As an example, use the hot dog calorie data from Example 11.6.2. In this example,  $p = 4$ . We shall use a prior distribution in which  $\lambda_0 = \alpha_0 = 1, \beta_0 = 0.1, u_0 = 0.001$ , and  $\psi_0 = 170$ . We use  $k = 6$  Markov chains and do  $m = 100$  burn-in simulations, which turn out to be more than enough to make the maximum of all nine  $F$  statistics less than  $1 + 0.44m$ . We then run each of the six Markov chains another 10,000 iterations. The samples from the posterior distribution allow us to answer any questions that we might have about the parameters, including some that we would not have been able to answer using the analysis done in Chapter 11. For example, the posterior means and standard deviations of some of the parameters are listed in Table 12.6. To see how different the variances are, we can estimate the probability that the variance of one group is at least 2.25 times as high as that of another group by computing the fraction of iterations  $\ell$  in which at least one  $\tau_i^{(\ell)}/\tau_j^{(\ell)} > 2.25$ . The result is 0.4, indicating that there is some chance that at least some of the variances are different. If the variances are different, the ANOVA calculations in Chapter 11 are not justified.

We can also address the question of how much difference there is between the  $\mu_i$ 's. For comparison, we shall do the same calculations that we did in Example 12.3.7. In 99 percent of the 60,000 simulations, at least one  $|\mu_i^{(\ell)} - \mu_j^{(\ell)}| > 26.35$ . In about one-half of the simulations, all  $|\mu_i^{(\ell)} - \mu_j^{(\ell)}| > 2.224$ . And in 99 percent of the simulations, the average of the differences was at least 13.78. Figure 12.9 contains a plot of the sample c.d.f.'s of the largest, smallest, and average of the six  $|\mu_i - \mu_j|$  differences. Careful examination of the results in this example shows that the four  $\mu_i$ 's appear to be closer together than we would have thought after the analysis of Example 12.3.7. This is typical of what occurs when we use a proper prior in a hierarchical model. In Example 12.3.7, the  $\mu_i$ 's were all independent, and they did not have a common unknown mean in the prior. In Example 12.5.6, the  $\mu_i$ 's all have a common prior distribution with mean  $\psi$ , which is an additional unknown parameter. The estimation

**Table 12.6** Posterior means and standard deviations for some parameters in Example 12.5.6

Type	Beef	Meat	Poultry	Specialty
$i$	1	2	3	4
$E(\mu_i \mathbf{y})$	156.6	158.3	120.5	159.6
$(Var(\mu_i \mathbf{y}))^{1/2}$	4.893	5.825	5.521	7.615
$E(1/\tau_i \mathbf{y})$	495.6	608.5	542.9	568.2
$(Var(1/\tau_i \mathbf{y}))^{1/2}$	166.0	221.2	201.6	307.4
$E(\psi \mathbf{y}) = 151.0$		$(Var(\psi \mathbf{y}))^{1/2} = 11.16$		

**Figure 12.9** Sample c.d.f.'s of the maximum, average, and minimum of the six  $|\mu_i - \mu_j|$  differences for Example 12.5.6.

of this additional parameter allows the posterior distributions of the  $\mu_i$ 's to be pulled toward a location that is near the average of all of the samples. With these data, the overall sample average is 147.60. ◀

## Prediction

All of the calculations done in the examples of this section have concerned functions of the parameters. The sample from the posterior distribution that we obtain from Gibbs sampling can also be used to make predictions and form prediction intervals for future observations. The most straightforward way to make predictions is to simulate the future data conditional on each value of the parameter from the posterior sample. Although there are more efficient methods for predicting, this method is easy to describe and evaluate.

### Example 12.5.7

**Calories in Hot Dogs.** In Example 12.5.6, we might be concerned with how different we should expect the calorie counts of two hot dogs to be. For example, let  $Y_1$  and  $Y_3$  be future calorie counts for hot dogs of the beef and poultry varieties, respectively. We can form a prediction interval for  $D = Y_1 - Y_3$  as follows: For each iteration  $\ell$ , let

the simulated parameter vector be

$$\theta^{(\ell)} = (\mu_1^{(\ell)}, \mu_2^{(\ell)}, \mu_3^{(\ell)}, \mu_4^{(\ell)}, \tau_1^{(\ell)}, \tau_2^{(\ell)}, \tau_3^{(\ell)}, \tau_4^{(\ell)}, \psi^{(\ell)}, \beta^{(\ell)}).$$

For each  $\ell$ , simulate a beef hot dog calorie count  $Y_1^{(\ell)}$  having the normal distribution with mean  $\mu_1^{(\ell)}$  and variance  $1/\tau_1^{(\ell)}$ . Also simulate a poultry hot dog calorie count  $Y_3^{(\ell)}$  having the normal distribution with mean  $\mu_3^{(\ell)}$  and variance  $1/\tau_3^{(\ell)}$ . Then compute  $D^{(\ell)} = Y_1^{(\ell)} - Y_3^{(\ell)}$ . Sample quantiles of the values  $D^{(1)}, \dots, D^{(60,000)}$  can be used to estimate quantiles of the distribution of  $D$ .

For example, suppose that we want a 90 percent prediction interval for  $D$ . We simulate 60,000  $D^{(\ell)}$  values as above and find the 0.05 and 0.95 sample quantiles to be  $-18.49$  and  $90.63$ , which are then the endpoints of our prediction interval. To assess how close the simulation estimators are to the actual quantiles of the distribution of  $D$ , we compute the simulation standard errors of the two endpoints. For the samples from each of the  $k = 6$  Markov chains, we can compute the sample 0.05 quantiles of our  $D$  values. We can then use these values as  $Z_1, \dots, Z_6$  in Eq. (12.5.1) to compute a value  $S$ . Our simulation standard error is then  $S/6^{1/2}$ . We can then repeat this for the sample 0.95 quantiles. For the two endpoints of our interval, the simulation standard errors are  $0.2228$  and  $0.4346$ , respectively. These simulation standard errors are fairly small compared to the length of the prediction interval.  $\blacktriangleleft$

**Example  
12.5.8**

**Censored Arsenic Measurements.** Frey and Edwards (1997) describe the National Arsenic Occurrence Survey (NAOS). Several hundred community water systems submitted samples of their untreated water in an attempt to help characterize the distribution of arsenic across the nation. Arsenic is one of several contaminants that the Environmental Protection Agency (EPA) is required to regulate. One difficulty in modeling the occurrence of a substance like arsenic is that concentrations are often too low to be measured accurately. In such cases, the measurements are censored. That is, we only know that the concentration of arsenic is less than some censoring point, but not how much less. In the NAOS data set, the censoring point is 0.5 microgram per liter. Each concentration less than 0.5 microgram per liter is censored.

Gibbs sampling can help us to estimate the distribution of arsenic in spite of the censored observations. Lockwood et al. (2001) do an extensive analysis of the NAOS and other data and show how the distribution of arsenic differs from one state to the next and from one type of water source to the next. For convenience, let us focus our attention on the 24 observations from one state, Ohio. Of those 24 observations, 11 were taken from groundwater sources (wells). The other 13 came from surface water sources (e.g., rivers and lakes). The following are seven uncensored groundwater observations from Ohio:

$$9.62, 10.50, 2.30, 0.80, 17.04, 9.90, 1.32.$$

The other four groundwater observations were censored.

Suppose that we model groundwater arsenic concentrations in Ohio as having the lognormal distribution with parameters  $\mu$  and  $\sigma^2$ . One popular way to deal with censored observations is to treat them like unknown parameters. That is, let  $Y_1, \dots, Y_4$  be the four unknown concentrations from the four wells where the measurements were censored. Let  $X_1, \dots, X_7$  stand for the seven uncensored values. Suppose that  $\mu$  and  $\tau = 1/\sigma^2$  have the normal-gamma prior distribution with hyperparameters  $\mu_0, \lambda_0, \alpha_0$ , and  $\beta_0$ . The joint p.d.f. of  $X_1, \dots, X_7, Y_1, \dots, Y_4$ , and  $\mu$  and  $\tau$  is proportional to

$$\tau^{\beta_0+(7+4+1)/2-1} \exp\left(-\frac{\tau}{2}\left[\lambda_0(\mu - \mu_0)^2 + \sum_{i=1}^7 (\log(x_i) - \mu)^2 + \sum_{j=1}^4 (\log(y_j) - \mu)^2 + 2\beta_0\right]\right).$$

The observed data consist of the values  $x_1, \dots, x_7$  of  $X_1, \dots, X_7$  together with the fact that  $Y_j \leq 0.5$  for  $j = 1, \dots, 4$ . The conditional distributions of  $\mu$  and  $\tau$  given the data and the other parameters are just like what we obtained in Example 12.5.1. To be precise,  $\mu$  has the normal distribution with mean

$$\frac{\lambda_0\mu_0 + \sum_{i=1}^7 \log(x_i) + \sum_{j=1}^4 \log(y_j)}{\lambda_0 + 11}$$

and precision  $\tau(\lambda_0 + 11)$  conditional on  $\tau$ , the  $Y_j$ 's, and the data. Also,  $\tau$  has the gamma distribution with parameters  $\alpha_0 + (11 + 1)/2$  and

$$\beta_0 + \frac{1}{2} \left( \sum_{i=1}^7 (\log(x_i) - \mu)^2 + \sum_{j=1}^4 (\log(y_j) - \mu)^2 + \lambda_0(\mu - \mu_0)^2 \right),$$

conditional on  $\mu$ , the  $Y_j$ 's, and the data. The conditional distribution of the  $Y_j$ 's given  $\mu$ ,  $\tau$ , and the data is that of i.i.d. random variables with the lognormal distribution having parameters  $\mu$  and  $1/\tau$  but conditional on  $Y_j < 0.5$ . That is, the conditional c.d.f. of each  $Y_j$  is

$$F(y) = \frac{\Phi([\log(y) - \mu]\tau^{1/2})}{\Phi([\log(0.5) - \mu]\tau^{1/2})}, \text{ for } y < 0.5.$$

We can simulate random variables with c.d.f.  $F$  so long as we can compute the standard normal c.d.f. and quantile function. Let  $U$  have the uniform distribution on the interval  $[0, 1]$ . Then

$$Y = \exp(\mu + \tau^{-1/2}\Phi^{-1}[U\Phi([\log(0.5) - \mu]\tau^{1/2})])$$

has the desired c.d.f.,  $F$ .

One example of the type of inference that is needed in an analysis of this sort is to predict arsenic concentrations for different water systems. Knowing the likely sizes of arsenic measurements can help water systems choose economical treatments that will meet the standards set by the EPA. For simplicity, we shall simulate one arsenic concentration at each iteration of the Markov chain. For example, suppose that  $(\mu^{(i)}, \tau^{(i)})$  are the simulated values of  $\mu$  and  $\tau$  at the  $i$ th iteration of the Markov chain. Then we can simulate  $Y^{(i)} = \exp(\mu^{(i)} + Z(\tau^{(i)})^{-1/2})$ , where  $Z$  is a standard normal random variable. Figure 12.10 shows a histogram of the simulated  $\log(Y^{(i)})$  values from 10 Markov chains of length 10,000 each. The proportion of predicted values that are below the censoring point of  $\log(0.5)$  is 0.335, with a simulation standard error of 0.001. The median predicted value on the logarithmic scale is 0.208 with a simulation standard error of 0.007. We can transform this back to the original scale of measurement using the delta method as described in Example 12.2.8. The median predicted arsenic concentration is  $\exp(0.208) = 1.231$  micrograms per liter with a simulation standard error of 0.007  $\exp(0.208) = 0.009$ .  $\blacktriangleleft$

**Note: There Are More-General Markov Chain Monte Carlo Algorithms.** Gibbs sampling requires a special structure for the distribution we wish to simulate. We need to be able to simulate the conditional distribution of each coordinate given the other coordinates. In many problems, this is not possible for at least some, if not all, of the coordinates. If only one coordinate is difficult to simulate, one might try using an acceptance/rejection simulator for that one coordinate. If even this does not work,

**Figure 12.10** Histogram of simulated log(arsenic) values for 10,000 iterations from each of 10 Markov chains in Example 12.5.8. The vertical line is at the censoring point,  $\log(0.5)$ .

there are more-general Markov chain Monte Carlo algorithms that can be used. The simplest of these is the *Metropolis algorithm* introduced by Metropolis et al. (1953). An introduction to the Metropolis algorithm can be found in chapter 11 of Gelman et al. (1995) together with a further generalization due to Hastings (1970).

## Summary

We introduced the Gibbs sampling algorithm that produces a Markov chain of observations from a joint distribution of interest. The joint distribution must have a special form. As a function of each variable, the joint p.d.f. must look like a p.d.f. from which it is easy to simulate pseudo-random variables. The Gibbs sampling algorithm cycles through the coordinates, simulating each one conditional on the values of the others. The algorithm requires a burn-in period during which the distribution of states in the Markov chain converges to the desired distribution. Assessing convergence and computing simulation standard errors of simulated values are both facilitated by running several independent Markov chains simultaneously.

## Exercises

1. Let  $f(x_1, x_2) = cg(x_1, x_2)$  be a joint p.d.f. for  $(X_1, X_2)$ . For each  $x_2$ , let  $h_2(x_1) = g(x_1, x_2)$ . That is,  $h_2$  is what we get by considering  $g(x_1, x_2)$  as a function of  $x_1$  for fixed  $x_2$ . Show that there is a multiplicative factor  $c_2$  that does not depend on  $x_1$  such that  $h_2(x_1)c_2$  is the conditional p.d.f. of  $X_1$  given  $X_2 = x_2$ .

2. Let  $f(x_1, x_2)$  be a joint p.d.f. Suppose that  $(X_1^{(i)}, X_2^{(i)})$  has the joint p.d.f.  $f$ . Let  $(X_1^{(i+1)}, X_2^{(i+1)})$  be the result of applying steps 2 and 3 of the Gibbs sampling algorithm on page 824. Prove that  $(X_1^{(i+1)}, X_2^{(i)})$  and  $(X_1^{(i+1)}, X_2^{(i+1)})$  also have the joint p.d.f.  $f$ .

3. Let  $Z_1, Z_2, \dots$  form a Markov chain, and assume that the distribution of  $Z_1$  is the stationary distribution. Show that the joint distribution of  $(Z_1, Z_2)$  is the same as the

joint distribution of  $(Z_i, Z_{i+1})$  for all  $i > 1$ . For convenience, you may assume that the Markov chain has finite state space, but the result holds in general.

4. Let  $X_1, \dots, X_n$  be uncorrelated, each with variance  $\sigma^2$ . Let  $Y_1, \dots, Y_n$  be positively correlated, each with variance  $\sigma^2$ . Prove that the variance of  $\bar{X}$  is smaller than the variance of  $\bar{Y}$ .

5. Use the data consisting of 30 lactic acid concentrations in cheese, 10 from Example 8.5.4 and 20 from Exercise 16 in Sec. 8.6. Fit the same model used in Example 8.6.2 with the same prior distribution, but this time use the Gibbs sampling algorithm described in Example 12.5.1. Simulate 10,000 pairs of  $(\mu, \tau)$  parameters. Estimate the posterior mean of  $(\sqrt{\tau}\mu)^{-1}$ , and compute the simulation standard error of the estimator.

**6.** Use the data on dishwasher shipments in Table 11.13 on page 744. Suppose that we wish to fit a multiple linear regression model for predicting dishwasher shipments from time (year minus 1960) and private residential investment. Suppose that the parameters have the improper prior proportional to  $1/\tau$ . Use the Gibbs sampling algorithm to obtain a sample of size 10,000 from the joint posterior distribution of the parameters.

- a. Let  $\beta_1$  be the coefficient of time. Draw a plot of the sample c.d.f. of  $|\beta_1|$  using your posterior sample.
- b. We are interested in predicting dishwasher shipments for 1986.
  - i. Draw a histogram of the values of  $\beta_0 + 26\beta_1 + 67.2\beta_2$  from your posterior distribution.
  - ii. For each of your simulated parameters, simulate a dishwasher sales figure for 1986 (time = 26 and private residential investment = 67.2). Compute a 90 percent prediction interval from the simulated values and compare it to the interval found in Example 11.5.7.
  - iii. Draw a histogram of the simulated 1986 sales figures, and compare it to the histogram in part i. Can you explain why one sample seems to have larger variance than the other?

**7.** Use the data in Table 11.19 on page 762. This time fit the model developed in Example 12.5.6. Use the prior hyperparameters  $\lambda_0 = \alpha_0 = 1$ ,  $\beta_0 = 0.1$ ,  $u_0 = 0.001$ , and  $\psi_0 = 800$ . Obtain a sample of 10,000 from the posterior joint distribution of the parameters. Estimate the posterior means of the three parameters  $\mu_1$ ,  $\mu_2$ , and  $\mu_3$ .

**8.** In this problem, we shall outline a form of robust linear regression. Assume throughout the exercise that the data consist of pairs  $(Y_i, x_i)$  for  $i = 1, \dots, n$ . Assume also that the  $x_i$ 's are all known and the  $Y_i$ 's are independent random variables. We shall only deal with simple regression here, but the method easily extends to multiple regression.

- a. Let  $\beta_0$ ,  $\beta_1$ , and  $\sigma$  stand for unknown parameters, and let  $a$  be a known positive constant. Prove that the following two models are equivalent. That is, prove that the joint distribution of  $(Y_1, \dots, Y_n)$  is the same in both models.

*Model 1:* For each  $i$ ,  $[Y_i - (\beta_0 + \beta_1 x_i)]/\sigma$  has the  $t$  distribution with  $a$  degrees of freedom.

*Model 2:* For each  $i$ ,  $Y_i$  has the normal distribution with mean  $\beta_0 + \beta_1 x_i$  and variance  $1/\tau_i$  conditional on  $\tau_i$ . Also,  $\tau_1, \dots, \tau_n$  are i.i.d. having the gamma distribution with parameters  $a/2$  and  $a\sigma^2/2$ .

*Hint:* Use the same argument that produced the marginal distribution of  $\mu$  in Sec. 8.6 when  $\mu$  and  $\tau$  had a normal-gamma distribution.

- b. Now consider Model 2 from part (a). Let  $\eta = \sigma^2$ , and assume that  $\eta$  has a prior distribution that is the gamma distribution with parameters  $b/2$  and  $f/2$ ,

where  $b$  and  $f$  are known constants. Assume that the parameters  $\beta_0$  and  $\beta_1$  have an improper prior with “p.d.f.” 1. Show that the product of likelihood and prior “p.d.f.” is a constant times

$$\eta^{(na+b)/2-1} \prod_{i=1}^n \tau_i^{(a+1)/2-1} \exp\left(-\frac{1}{2} [f\eta + \sum_{i=1}^n \tau_i \{a\eta + (y_i - \beta_0 - \beta_1 x_i)^2\}]\right). \quad (12.5.4)$$

- c. Consider (12.5.4) as a function of each parameter for fixed values of the others. Show that Table 12.7 specifies the appropriate conditional distribution for each parameter given all of the others.

**Table 12.7** Parameters and conditional distributions for Exercise 8

Parameter	(12.5.4) looks like the p.d.f. of this distribution
$\eta$	gamma distribution with parameters $(na+b)/2$ and $(f + a \sum_{i=1}^n \tau_i)/2$
$\tau_i$	gamma distribution with parameters $(a+1)/2$ and $[a\eta + (y_i - \beta_0 - \beta_1 x_i)^2]/2$
$\beta_0$	normal distribution with mean $\sum_{i=1}^n \tau_i (y_i - \beta_1 x_i) / \sum_{i=1}^n \tau_i$ and precision $\sum_{i=1}^n \tau_i$
$\beta_1$	normal distribution with mean $\sum_{i=1}^n \tau_i x_i (y_i - \beta_0) / \sum_{i=1}^n \tau_i x_i^2$ and precision $\sum_{i=1}^n \tau_i x_i^2$

- 9. Use the data in Table 11.5 on page 699. Suppose that  $Y_i$  is the logarithm of pressure and  $x_i$  is the boiling point for the  $i$ th observation,  $i = 1, \dots, 17$ . Use the robust regression scheme described in Exercise 8 with  $a = 5$ ,  $b = 0.1$ , and  $f = 0.1$ . Estimate the posterior means and standard deviations of the parameters  $\beta_0$ ,  $\beta_1$ , and  $\eta$ .

- 10. In this problem, we shall outline a Bayesian solution to the problem described in Example 7.5.10 on page 423. Let  $\tau = 1/\sigma^2$  and use a proper normal-gamma prior of the form described in Sec. 8.6. In addition to the two parameters  $\mu$  and  $\tau$ , introduce  $n$  additional parameters.

For  $i = 1, \dots, n$ , let  $Y_i = 1$  if  $X_i$  came from the normal distribution with mean  $\mu$  and precision  $\tau$ , and let  $Y_i = 0$  if  $X_i$  came from the standard normal distribution.

- a. Find the conditional distribution of  $\mu$  given  $\tau$ ;  $Y_1, \dots, Y_n$ ; and  $X_1, \dots, X_n$ .
- b. Find the conditional distribution of  $\tau$  given  $\mu$ ;  $Y_1, \dots, Y_n$ ; and  $X_1, \dots, X_n$ .
- c. Find the conditional distribution of  $Y_i$  given  $\mu$ ;  $\tau$ ;  $X_1, \dots, X_n$ ; and the other  $Y_j$ 's.

- d.** Describe how to find the posterior distribution of  $\mu$  and  $\tau$  using Gibbs sampling.
- e.** Prove that the posterior mean of  $Y_i$  is the posterior probability that  $X_i$  came from the normal distribution with unknown mean and variance.
- 11.** Consider, once again, the model described in Example 7.5.10. Assume that  $n = 10$  and the observed values of  $X_1, \dots, X_{10}$  are
- $$-0.92, -0.33, -0.09, 0.27, 0.50, -0.60, 1.66, -1.86, 3.29, 2.30.$$
- a.** Fit the model to the observed data using the Gibbs sampling algorithm developed in Exercise 10. Use the following prior hyperparameters:  $\alpha_0 = 1$ ,  $\beta_0 = 1$ ,  $\mu_0 = 0$ , and  $\lambda_0 = 1$ .
- b.** For each  $i$ , estimate the posterior probability that  $X_i$  came from the normal distribution with unknown mean and variance.
- 12.** Let  $X_1, \dots, X_n$  be i.i.d. with the normal distribution having mean  $\mu$  and precision  $\tau$ . Gibbs sampling allows one to use a prior distribution for  $(\mu, \tau)$  in which  $\mu$  and  $\tau$  are independent. Let the prior distribution of  $\mu$  be the normal distribution with mean  $\mu_0$  and precision  $\gamma_0$ . Let the prior distribution of  $\tau$  be the gamma distribution with parameters  $\alpha_0$  and  $\beta_0$ .
- a.** Show that Table 12.8 specifies the appropriate conditional distribution for each parameter given the other.
- b.** Use the New Mexico nursing home data (Examples 12.5.2 and 12.5.3). Let the prior hyperparameters be  $\alpha_0 = 2$ ,  $\beta_0 = 6300$ ,  $\mu_0 = 200$ , and  $\gamma_0 = 6.35 \times 10^{-4}$ . Implement a Gibbs sampler to find the posterior distribution of  $(\mu, \tau)$ . In particular, calculate an interval containing 95 percent of the posterior distribution of  $\mu$ .
- Table 12.8** Parameters and conditional distributions for Exercise 12
- | Parameter | Prior times likelihood looks like the p.d.f. of this distribution                                                                |
|-----------|----------------------------------------------------------------------------------------------------------------------------------|
| $\tau$    | gamma distribution with parameters $\alpha_0 + n/2$ and $\beta_0 + 0.5 \sum_{i=1}^n (x_i - \bar{x})^2 + 0.5n(\bar{x} - \mu)^2$ , |
| $\mu$     | normal distribution with mean $(\gamma_0 \mu_0 + n\tau \bar{x}) / (\gamma_0 + n\tau)$ and precision $\gamma_0 + n\tau$ .         |
- 13.** Consider again the situation described in Exercise 12. This time, we shall let the prior distribution of  $\mu$  be more like it was in the conjugate prior. Introduce another parameter  $\gamma$ , whose prior distribution is the gamma distribution with parameters  $a_0$  and  $b_0$ . Let the prior distribution of  $\mu$  conditional on  $\gamma$  be the normal distribution with mean  $\mu_0$  and precision  $\gamma$ .
- a.** Prove that the marginal prior distribution of  $\mu$  specifies that
- $$\left( \frac{b_0}{a_0} \right)^{-1/2} (\mu - \mu_0) \text{ has the } t \text{ distribution with } 2a_0 \text{ degrees of freedom.}$$
- Hint:* Look at the derivation of the marginal distribution of  $\mu$  in Sec. 8.6.
- b.** Suppose that we want the marginal prior distributions of both  $\mu$  and  $\tau$  to be the same as they were with the conjugate prior in Sec. 8.6. How must the prior hyperparameters be related in order to make this happen?
- c.** Show that Table 12.9 specifies the appropriate conditional distribution for each parameter given the others.
- Table 12.9** Parameters and conditional distributions for Exercise 13
- | Parameter | Prior times likelihood looks like the p.d.f. of this distribution                                                                |
|-----------|----------------------------------------------------------------------------------------------------------------------------------|
| $\tau$    | gamma distribution with parameters $\alpha_0 + n/2$ and $\beta_0 + 0.5 \sum_{i=1}^n (x_i - \bar{x})^2 + 0.5n(\bar{x} - \mu)^2$ , |
| $\mu$     | normal distribution with mean $(\gamma_0 \mu_0 + n\tau \bar{x}) / (\gamma_0 + n\tau)$ and precision $\gamma_0 + n\tau$ ,         |
| $\gamma$  | gamma distribution with parameters $a_0 + 1/2$ and $b_0 + 0.5(\mu - \mu_0)^2$ .                                                  |
- d.** Use the New Mexico nursing home data (Examples 12.5.2 and 12.5.3). Let the prior hyperparameters be  $\alpha_0 = 2$ ,  $\beta_0 = 6300$ ,  $\mu_0 = 200$ ,  $a_0 = 2$ , and  $b_0 = 3150$ . Implement a Gibbs sampler to find the posterior distribution of  $(\mu, \tau, \gamma)$ . In particular, calculate an interval containing 95 percent of the posterior distribution of  $\mu$ .
- 14.** Consider the situation described in Example 12.5.8. In addition to the 11 groundwater sources, there are 13 observations taken from surface water sources in Ohio. Of the 13 surface water measurements, only one was censored. The 12 uncensored surface water arsenic concentrations from Ohio are
- $$1.93, 0.99, 2.21, 2.29, 1.15, 1.81, 2.26, 3.10, 1.18, 1.00, 2.67, 2.15.$$
- Let the prior hyperparameters be  $\alpha_0 = 0.5$ ,  $\mu_0 = 0$ ,  $\lambda_0 = 1$ , and  $\beta_0 = 0.5$ .
- a.** Fit the same model as described in Example 12.5.8, and predict a logarithm of surface water concentration for each iteration of the Markov chain.

- b.** Compare a histogram of your predicted measurements to the histogram of the underground well predictions in Fig. 12.10. Describe the main differences.
- c.** Estimate the median of the distribution of predicted surface water arsenic concentration and compare it to the median of the distribution of predicted groundwater concentration.
- 15.** Let  $X_1, \dots, X_{n+m}$  be a random sample from the exponential distribution with parameter  $\theta$ . Suppose that  $\theta$  has the gamma prior distribution with known parameters  $\alpha$  and  $\beta$ . Assume that we get to observe  $X_1, \dots, X_n$ , but  $X_{n+1}, \dots, X_{n+m}$  are censored.
- a.** First, suppose that the censoring works as follows: For  $i = 1, \dots, m$ , we learn only that  $X_{n+i} \leq c$ , but not the precise value of  $X_{n+i}$ . Set up a Gibbs sampling algorithm that will allow us to simulate the posterior distribution of  $\theta$  in spite of the censoring.
- b.** Next, suppose that the censoring works as follows: For  $i = 1, \dots, m$ , we learn only that  $X_{n+i} \geq c$ , but not the precise value of  $X_{n+i}$ . Set up a Gibbs sampling algorithm that will allow us to simulate the posterior distribution of  $\theta$  in spite of the censoring.
- 16.** Suppose that the time to complete a task is the sum of two parts  $X$  and  $Y$ . Let  $(X_i, Y_i)$  for  $i = 1, \dots, n$  be a random sample of the times to complete the two parts of the task. However, for some observations, we get to observe only  $Z_i = X_i + Y_i$ . To be precise, suppose that we observe  $(X_i, Y_i)$  for  $i = 1, \dots, k$  and we observe  $Z_i$  for  $i = k+1, \dots, n$ . Suppose that all  $X_i$  and  $Y_j$  are independent with every  $X_i$  having the exponential distribution with parameter  $\lambda$  and every  $Y_j$  having the exponential distribution with parameter  $\mu$ .
- a.** Prove that the conditional distribution of  $X_i$  given  $Z_i = z$  has the c.d.f.
- $$G(x|z) = \frac{1 - \exp(-x[\lambda - \mu])}{1 - \exp(-z[\lambda - \mu])}, \quad \text{for } 0 < x < z.$$
- b.** Suppose that the prior distribution of  $(\lambda, \mu)$  is as follows: The two parameters are independent with  $\lambda$  having the gamma distribution with parameters  $a$  and  $b$ , and  $\mu$  having the gamma distribution with parameters  $c$  and  $d$ . The four numbers  $a, b, c$ , and  $d$  are all known constants. Set up a Gibbs sampling algorithm that allows us to simulate the posterior distribution of  $(\lambda, \mu)$ .

## 12.6 The Bootstrap

The parametric and nonparametric bootstraps are methods for replacing an unknown distribution  $F$  with a known distribution in a probability calculation. If we have a sample of data from the distribution  $F$ , we first approximate  $F$  by  $\hat{F}$  and then perform the desired calculation. If  $\hat{F}$  is a good approximation to  $F$ , the bootstrap can be successful. If the desired calculation is sufficiently difficult, we typically resort to simulation.

### Introduction

Assume that we have a sample  $\mathbf{X} = (X_1, \dots, X_n)$  of data from some unknown distribution  $F$ . Suppose that we are interested in some quantity that involves both  $F$  and  $\mathbf{X}$ , for example, the bias of a statistic  $g(\mathbf{X})$  as an estimator of the median of  $F$ . The main idea behind bootstrap analysis in the simplest cases is the following: First, replace the unknown distribution  $F$  with a known distribution  $\hat{F}$ . Next, let  $\mathbf{X}^*$  be a sample from the distribution  $\hat{F}$ . Finally, compute the quantity of interest based on  $\hat{F}$  and  $\mathbf{X}^*$ , for example, the bias of  $g(\mathbf{X}^*)$  as an estimator of the median of  $\hat{F}$ . Consider the following overly simple example.

---

**Example**  
**12.6.1**

**The Variance of the Sample Mean.** Let  $\mathbf{X} = (X_1, \dots, X_n)$  be a random sample from a distribution with a continuous c.d.f.  $F$ . For the moment, we shall assume nothing more about  $F$  than that it has finite mean  $\mu$  and finite variance  $\sigma^2$ . Suppose that we are interested in the variance of the sample mean  $\bar{X}$ . We already know that this variance equals  $\sigma^2/n$ , but we do not know  $\sigma^2$ . In order to estimate  $\sigma^2/n$ , the bootstrap replaces

the unknown distribution  $F$  with a known distribution  $\hat{F}$ , which also has finite mean  $\hat{\mu}$  and finite variance  $\hat{\sigma}^2$ . If  $X^* = (X_1^*, \dots, X_n^*)$  is a random sample from  $\hat{F}$ , then the variance of the sample mean  $\bar{X}^* = \frac{1}{n} \sum_{i=1}^n X_i^*$  is  $\hat{\sigma}^2/n$ . Since the distribution  $\hat{F}$  is known, we should be able to compute  $\hat{\sigma}^2/n$ , and we can then use this value to estimate  $\sigma^2/n$ .

One popular choice of known distribution  $\hat{F}$  is the sample c.d.f.  $F_n$  defined in Sec. 10.6. This sample c.d.f. is the discrete c.d.f. that has jumps of size  $1/n$  at each of the observed values  $x_1, \dots, x_n$  of the random sample  $X_1, \dots, X_n$ . So, if  $X^* = (X_1^*, \dots, X_n^*)$  is a random sample from  $\hat{F}$ , then each  $X_i^*$  is a discrete random variable with the p.f.

$$f(x) = \begin{cases} \frac{1}{n} & \text{if } x \in \{x_1, \dots, x_n\}, \\ 0 & \text{otherwise.} \end{cases}$$

It is relatively simple to compute the variance  $\hat{\sigma}^2$  of a random variable  $X_i^*$  whose p.f. is  $f$ . The variance is

$$\hat{\sigma}^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2,$$

where  $\bar{x}$  is the average of the observed values  $x_1, \dots, x_n$ . Thus, our bootstrap estimate of the variance of  $\bar{X}$  is  $\hat{\sigma}^2/n$ .  $\blacktriangleleft$

The key step in a bootstrap analysis is the choice of the known distribution  $\hat{F}$ . The particular choice made in Example 12.6.1, namely, the sample c.d.f., leads to what is commonly called the *nonparametric bootstrap*. The reason for this name is that we do not assume that the distribution belongs to a parametric family when choosing  $\hat{F} = F_n$ . If we are willing to assume that  $F$  belongs to a parametric family, then we can choose  $\hat{F}$  to be a member of that family and perform a *parametric bootstrap* analysis as illustrated next.

### Example 12.6.2

**The Variance of the Sample Mean.** Let  $X = (X_1, \dots, X_n)$  be a random sample from the normal distribution with mean  $\mu$  and variance  $\sigma^2$ . Suppose, as in Example 12.6.1, that we are interested in estimating  $\sigma^2/n$ , the variance of the sample mean  $\bar{X}$ . To apply the parametric bootstrap, we replace  $F$  by  $\hat{F}$ , a member of the family of normal distributions. For this example, we shall choose  $\hat{F}$  to be the normal distribution with mean and variance equal to the M.L.E.'s  $\bar{x}$  and  $\hat{\sigma}^2$ , respectively, although other choices could be made. We then estimate  $\sigma^2/n$  by the variance of the sample mean  $\bar{X}^*$  of a random sample from the distribution  $\hat{F}$ . The variance of  $\bar{X}^*$  is easily computed as  $\hat{\sigma}^2/n$ . In this case, the parametric bootstrap yields precisely the same answer as the nonparametric bootstrap.  $\blacktriangleleft$

In Examples 12.6.1 and 12.6.2, it was very simple to compute the variance of the sample mean of a random sample from the distribution  $\hat{F}$ . In typical applications of the bootstrap, it is not so simple to compute the quantity of interest. For example, there is no simple formula for the variance of the sample median of a sample  $X^*$  from  $\hat{F}$  in Examples 12.6.1 and 12.6.2. In such cases, one resorts to simulation techniques in order to approximate the desired calculation. Before presenting examples of the use of simulation in the bootstrap, we shall first describe the general class of situations in which bootstrap analysis is used.

**Table 12.10** Correspondence between statistical model and bootstrap analysis

	Statistical model	Bootstrap
Distribution	Unknown $F$	Known $\hat{F}$
Data	i.i.d. sample $\mathbf{X}$ from $F$	i.i.d. sample $\mathbf{X}^*$ from $\hat{F}$
Function of interest	$\eta(\mathbf{X}, F)$	$\eta(\mathbf{X}^*, \hat{F})$
Parameter/estimate	Mean, median, variance, etc. of $\eta(\mathbf{X}, F)$	Mean, median, variance, etc. of $\eta(\mathbf{X}^*, \hat{F})$

## The Bootstrap in General

Let  $\eta(\mathbf{X}, F)$  be a quantity of interest that possibly depends on both a distribution  $F$  and a sample  $\mathbf{X}$  drawn from  $F$ . For example, if the distribution  $F$  has the p.d.f.  $f$ , we might be interested in

$$\eta(\mathbf{X}, F) = \left[ \frac{1}{n} \sum_{i=1}^n X_i - \int x f(x) dx \right]^2. \quad (12.6.1)$$

In Examples 12.6.1 and 12.6.2, we wanted the variance of the sample average, which equals the mean of the quantity in Eq. (12.6.1). In general, we might wish to estimate the mean or a quantile or some other probabilistic feature of  $\eta(\mathbf{X}, F)$ . The bootstrap estimates the mean or a quantile or some other feature of  $\eta(\mathbf{X}, F)$  by the mean or quantile or the other feature of  $\eta(\mathbf{X}^*, \hat{F})$ , where  $\mathbf{X}^*$  is a random sample drawn from the distribution  $\hat{F}$ , and  $\hat{F}$  is some distribution that we hope is close to  $F$ . Table 12.10 shows the correspondence between the original statistical model for the data and the quantities that are involved in a bootstrap analysis. The function  $\eta$  of interest must be something that exists for all distributions under consideration and all samples from those distributions. Other quantities that might be of interest include the quantiles of the distribution of a statistic, the M.A.E. or M.S.E. of an estimator, the bias of an estimator, probabilities that statistics lie in various intervals, and the like.

In the simple examples considered so far, the distribution of  $\eta(\mathbf{X}^*, \hat{F})$  was both known and easy to compute. It will often be the case that the distribution of  $\eta(\mathbf{X}^*, \hat{F})$  is too complicated to allow analytic computation of its features. In such cases, one approximates the bootstrap estimate using simulation. First, draw a large number (say,  $v$ ) of random samples  $\mathbf{X}^{*(1)}, \dots, \mathbf{X}^{*(v)}$  from the distribution  $\hat{F}$  and then compute  $T^{(i)} = \eta(\mathbf{X}^{*(i)}, \hat{F})$  for  $i = 1, \dots, v$ . Finally, compute the desired feature of the sample c.d.f. of the values  $T^{(1)}, \dots, T^{(v)}$ .

### Example 12.6.3

**The M.S.E. of the Sample Median.** Suppose that we model our data  $\mathbf{X} = (X_1, \dots, X_n)$  as coming from some continuous distribution with the c.d.f.  $F$  having median  $\theta$ . Suppose also that we are interested in using the sample median  $M$  as an estimator of  $\theta$ . We would like to estimate the M.S.E. of  $M$  as an estimator of  $\theta$ . That is, let  $\eta(\mathbf{X}, F) = (M - \theta)^2$ , and try to estimate the mean of  $\eta(\mathbf{X}, F)$ . Let  $\hat{F}$  be a known distribution that we hope is similar to  $F$ , and let  $\mathbf{X}^*$  be a random sample of size  $n$  from  $\hat{F}$ . Regardless of what distribution  $\hat{F}$  we choose, it is very difficult to compute the bootstrap estimate, the mean of  $\eta(\mathbf{X}^*, \hat{F})$ . Instead, we would simulate a large number  $v$  of samples  $\mathbf{X}^{*(1)}, \dots, \mathbf{X}^{*(v)}$  with the distribution  $\hat{F}$  and then compute the sample

**Figure 12.11** Sample medians of 10,000 bootstrap samples in Example 12.6.3.

median of each sample  $M^{(1)}, \dots, M^{(v)}$ . Then we compute  $T^{(i)} = (M^{(i)} - \hat{\theta})^2$  for  $i = 1, \dots, v$ , where  $\hat{\theta}$  is the median of the distribution  $\hat{F}$ . Our simulation approximation to the bootstrap estimate is then the average of the values  $T^{(1)}, \dots, T^{(v)}$ .

As an example, suppose that our sample consists of the  $n = 25$  values  $y_1, \dots, y_{25}$  listed in Table 10.33 on page 662. For a nonparametric bootstrap analysis, we would use  $\hat{F} = F_n$ , which is also listed in Table 10.33. Notice that the median of the distribution  $\hat{F}$  is the sample median of the original sample,  $\hat{\theta} = 0.40$ . Next, we simulate  $v = 10,000$  random samples of size 25 from the distribution  $\hat{F}$ . This is done by selecting 25 numbers *with replacement* from the  $y_i$  values and repeating for a total of 10,000 samples of size 25. (Solve Exercise 2 to show why this provides the desired samples  $\mathbf{X}^{*(1)}, \dots, \mathbf{X}^{*(v)}$ .) For example, here is one of the 10,000 bootstrap samples:

1.64	0.88	0.70	-1.23	-0.15	1.40	-0.07	-2.46	-2.46	-0.10
-0.15	1.62	0.27	0.44	-0.42	-2.46	1.40	-0.10	0.88	0.44
-1.23	1.07	0.81	-0.02	1.62					

If we sort the numbers in this sample, we find that the sample median is 0.27. In fact, there were 1485 bootstrap samples out of 10,000 that had sample median equal to 0.27. Figure 12.11 contains a histogram of all 10,000 sample medians from the bootstrap samples. The four largest and four smallest observations in the original sample never appeared as sample medians in the 10,000 bootstrap samples. For each of the 10,000 bootstrap samples  $i$ , we compute the sample median  $M^{(i)}$  and its squared error  $T^{(i)} = (M^{(i)} - \hat{\theta})^2$ , where  $\hat{\theta} = 0.40$  is the median of the distribution  $\hat{F}$ . We then average all of these values over the 10,000 samples and obtain the value 0.0887. This is our simulation approximation to the nonparametric bootstrap estimate of the M.S.E. of the sample median. The sample variance of the simulated  $T^{(i)}$  values is  $\hat{\sigma}^2 = 0.0135$ , and the simulation standard error of the bootstrap estimate is  $\hat{\sigma}/\sqrt{10,000} = 1.163 \times 10^{-3}$ .  $\blacktriangleleft$

**Note: Simulation Approximation of Bootstrap Estimates.** The bootstrap is an estimation technique. As such, it produces estimates of parameters of interest. When a bootstrap estimate is too difficult to compute, we resort to simulation. Simulation provides an estimator of the bootstrap estimate. In this text, we shall refer to the simulation estimator of a bootstrap estimate as an *approximation*. We do this merely to avoid having to refer to estimators of estimates.

The bootstrap was introduced by Efron (1979), and there have been many applications since then. Readers interested in more detail about the bootstrap should see Efron and Tibshirani (1993) or Davison and Hinkley (1997). Young (1994) gives a review of much of the literature on the bootstrap and contains many useful references. In the remainder of this section, we shall present several examples of both the parametric and nonparametric bootstraps and illustrate how simulation is used to approximate the desired bootstrap estimates.

## The Nonparametric Bootstrap

---

**Example**  
**12.6.4**

**Confidence Interval for the Interquartile Range.** The interquartile range (IQR) of a distribution was introduced in Definition 4.3.2. It is defined to be the difference between the upper and lower quartiles, the 0.75 and 0.25 quantiles. The central 50 percent of the distribution lies between the lower and upper quartiles, so the IQR is the length of the interval that contains the middle half of the distribution. For example, if  $F$  is the normal distribution with variance  $\sigma^2$ , then the IQR is  $1.35\sigma$ .

Suppose that we desire a 90 percent confidence interval for the IQR  $\theta$  of the unknown distribution  $F$  from which we have a random sample  $X_1, \dots, X_n$ . There are many ways to form confidence intervals, so we shall restrict attention to those that are based on the relationship between  $\theta$  and the sample IQR  $\hat{\theta}$ . Since the IQR is a scale feature, it might be reasonable to base our confidence interval on the distribution of  $\hat{\theta}/\theta$ . That is, let the 0.05 and 0.95 quantiles of the distribution of  $\hat{\theta}/\theta$  be  $a$  and  $b$ , so that

$$\Pr\left(a \leq \frac{\hat{\theta}}{\theta} \leq b\right) = 0.9.$$

Because  $a \leq \hat{\theta}/\theta \leq b$  is equivalent to  $\hat{\theta}/b \leq \theta \leq \hat{\theta}/a$ , we conclude that  $(\hat{\theta}/b, \hat{\theta}/a)$  is a 90 percent confidence interval for  $\theta$ . The nonparametric bootstrap can be used to estimate the quantiles  $a$  and  $b$  as follows: Let  $\eta(X, F) = \hat{\theta}/\theta$  be the ratio of the sample IQR of the sample  $X$  to the IQR of the distribution  $F$ . Let  $\hat{F} = F_n$ , and notice that the IQR of  $\hat{F}$  is  $\hat{\theta}$ , the sample IQR. Next, let  $X^*$  be a sample of size  $n$  from  $\hat{F}$ . Let  $\hat{\theta}^*$  be the sample IQR calculated from  $X^*$ , so that  $\eta(X^*, \hat{F}) = \hat{\theta}^*/\hat{\theta}$ . The 0.05 and 0.95 quantiles of the distribution of  $\eta(X, F)$  are estimated by the 0.05 and 0.95 quantiles of the distribution of  $\eta(X^*, \hat{F})$ . These last quantiles, in turn, are typically approximated by simulation. We simulate a large number, say,  $v$ , of bootstrap samples  $X^{*(i)}$  for  $i = 1, \dots, v$ . For each bootstrap sample  $i$ , we compute the sample IQR  $\hat{\theta}^{*(i)}$  and divide it by  $\hat{\theta}$ . Call the ratio  $T^{(i)}$ . The  $q$  quantile of  $\hat{\theta}^*/\hat{\theta}$  is approximated by the sample  $q$  quantile of the sample  $T^{(1)}, \dots, T^{(v)}$ . The confidence interval constructed by this method is called a *percentile bootstrap confidence interval*.

We can illustrate this with the data in Table 10.33 on page 662. The IQR of the distribution  $F_n$  is 1.46, the difference between the 19th and 6th observations. We simulate 10,000 random samples of size 25 from the distribution  $F_n$ . For the  $i$ th sample, we compute the sample IQR  $\hat{\theta}^{*(i)}$  and divide it by 1.46 to obtain  $T^{(i)}$ . The 500th and 9500th ordered values from  $T^{(1)}, \dots, T^{(10,000)}$  are 0.5822 and 1.6301. We then compute the percentile bootstrap confidence interval  $(1.46/1.6301, 1.46/0.5822) = (0.8956, 2.5077)$ .  $\blacktriangleleft$

---

**Example**  
**12.6.5**

**Confidence Interval for a Location Parameter.** Let  $X_1, \dots, X_n$  be a random sample from the distribution  $F$ . Suppose that we want a confidence interval for the median  $\theta$  of  $F$ . We can base a confidence interval on the sample median  $M$ . For example,

our interval could be of the form  $[M - c_1, M + c_2]$ . Since  $M - c_1 \leq \theta \leq M + c_2$  is equivalent to  $-c_2 \leq M - \theta \leq c_1$ , we might want  $-c_2$  and  $c_1$  to be quantiles of the distribution of  $M - \theta$ . Without making assumptions about the distribution  $F$ , it might be very difficult to approximate quantiles of the distribution of  $M - \theta$ . To compute a percentile bootstrap confidence interval, let  $\eta(\mathbf{X}, F) = M - \theta$  and then approximate quantiles (such as  $\alpha_0/2$  and  $1 - \alpha_0/2$ ) of the distribution of  $\eta(\mathbf{X}, F)$  by the corresponding quantiles of  $\eta(\mathbf{X}^*, \hat{F})$ . Here,  $\hat{F}$  is the sample c.d.f.,  $F_n$ , whose median is  $M$ , and  $\mathbf{X}^*$  is a random sample from  $\hat{F}$ . We then choose a large number  $v$  and simulate many samples  $\mathbf{X}^{*(i)}$  for  $i = 1, \dots, v$ . For each sample, we compute the sample median  $M^{*(i)}$  and then find the sample quantiles of the values  $M^{*(i)} - M$  for  $i = 1, \dots, v$ .  $\blacktriangleleft$

How well the percentile bootstrap interval performs in Example 12.6.5 depends on how closely the distribution of  $M^* - M$  approximates the distribution of  $M - \theta$ . (Here,  $M^*$  is the median of a sample  $\mathbf{X}^*$  of size  $n$  from  $\hat{F}$ .) The situation of Example 12.6.5 is one in which there is a possible improvement to the approximation. One thing that can make the distribution of  $M^* - M$  different from the distribution of  $M - \theta$  is that one of these distributions is more or less spread out than the other. We can use a different bootstrap approximation that suffers less from differences in spread. Instead of constructing an interval of the form  $[M - c_1, M + c_2]$ , we could let our interval be  $[M - d_1Y, M + d_2Y]$ , where  $Y$  is a statistic that measures the spread of the data. One possibility for  $Y$  is the sample IQR. Another possible spread measure is the sample median absolute deviation (the sample median of the values  $|X_1 - M|, \dots, |X_n - M|$ ). Now, we see that  $M - d_1Y \leq \theta \leq M + d_2Y$  is equivalent to

$$-d_2 \leq \frac{M - \theta}{Y} \leq d_1.$$

So, we want  $-d_2$  and  $d_1$  to be quantiles of the distribution of  $(M - \theta)/Y$ . This type of interval resembles the  $t$  confidence interval developed in Sec. 8.5. Indeed, the interval we are constructing is called a *percentile-t bootstrap confidence interval*. To construct the percentile- $t$  bootstrap confidence interval, we would use each bootstrap sample  $\mathbf{X}^*$  as follows: Compute the sample median  $M^*$  and the scale statistic  $Y^*$  from the bootstrap sample  $\mathbf{X}^*$ . Then calculate  $T = (M^* - M)/Y^*$ . Repeat this procedure many times producing  $T^{(1)}, \dots, T^{(v)}$  from a large number  $v$  of bootstrap samples. Then let  $-d_2$  and  $d_1$  be sample quantiles (such as  $\alpha_0/2$  and  $1 - \alpha_0/2$ ) of the  $T^{(i)}$  values.

### Example 12.6.6

**Percentile- $t$  Confidence Interval for a Median.** Consider the  $n = 10$  lactic acid concentrations in cheese from Example 8.5.4. We shall do  $v = 10,000$  bootstrap simulations to find a coefficient  $1 - \alpha_0 = 0.90$  confidence interval for the median lactic acid concentration  $\theta$ . The median of the sample values is  $M = 1.41$ , and the median absolute deviation is  $Y = 0.245$ . The 0.05 and 0.95 sample quantiles of the  $(M^{*(i)} - M)/Y^{*(i)}$  values are  $-2.133$  and  $1.581$ . This makes the percentile- $t$  bootstrap confidence interval  $(1.41 - 1.581 \times 0.245, 1.41 + 2.133 \times 0.245) = (1.023, 1.933)$ . For comparison, the 0.05 and 0.95 sample quantiles of the values of  $M^{*(i)} - M$  are  $-0.32$  and  $0.16$ , respectively. This makes the percentile bootstrap interval equal to  $(1.41 - 0.16, 1.41 + 0.32) = (1.25, 1.73)$ .  $\blacktriangleleft$

The percentile- $t$  interval in Example 11.5.6 is considerably wider than the percentile interval. This reflects the fact that the  $Y^*$  values from the bootstrap samples are quite spread out. This in turn suggests that the spread that we should expect to see in a sample has substantial variability. Hence, it is probably not a good idea to assume that the spread of the distribution of  $M^* - M$  is the same as the spread of

the distribution of  $M - \theta$ . The percentile- $t$  bootstrap interval is generally preferred to the percentile bootstrap interval when both are available. This is due to the fact that the distribution of  $(M^* - M)/Y^*$  depends less on  $\hat{F}$  than does the distribution of  $M^* - M$ . In particular,  $(M^* - M)/Y^*$  does not depend on any scale parameter of the distribution  $\hat{F}$ . For this reason, we expect more similarity between the distributions of  $(M^* - M)/Y^*$  and  $(M - \theta)/Y$  than we expect between the distributions of  $M^* - M$  and  $M - \theta$ .

**Example  
12.6.7**

**Features of the Distribution of a Sample Correlation.** Let  $(X, Y)$  have a bivariate joint distribution  $F$  with finite variances for both coordinates, so that it makes sense to talk about correlation. Suppose that we observe a random sample  $(X_1, Y_1), \dots, (X_n, Y_n)$  from the distribution  $F$ . Suppose further that we are interested in the distribution of the sample correlation:

$$R = \frac{\sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y})}{\left( \left[ \sum_{i=1}^n (X_i - \bar{X})^2 \right] \left[ \sum_{i=1}^n (Y_i - \bar{Y})^2 \right] \right)^{1/2}}. \quad (12.6.2)$$

We might be interested in the variance of  $R$ , or the bias of  $R$ , or some other feature of  $R$  as an estimator of the correlation  $\rho$  between  $X$  and  $Y$ . Whatever our goal is, we can make use of the nonparametric bootstrap. For example, consider the bias of  $R$  as an estimator of  $\rho$ . This bias equals the mean of  $\eta(X, F) = R - \rho$ . We begin by replacing the joint distribution  $F$  by the sample distribution  $F_n$  of the observed pairs. This  $F_n$  is a discrete joint distribution on pairs of real numbers, and it assigns probability  $1/n$  to each of the  $n$  observed sample pairs. If  $(X^*, Y^*)$  has the distribution  $F_n$ , it is easy to check (see Exercise 8) that the correlation between  $X^*$  and  $Y^*$  is  $R$ . We then choose a large number  $v$  and simulate  $v$  samples of size  $n$  from  $F_n$ . For each  $i$ , we compute the sample correlation  $R^{(i)}$  by plugging the  $i$ th bootstrap sample into Eq. (12.6.2). For each  $i$ , we compute  $T^{(i)} = R^{(i)} - R$ , and we estimate the mean of  $R - \rho$  by the average  $\frac{1}{v} \sum_{i=1}^v T^{(i)}$ .

As a numerical example, consider the flea beetle data from Example 5.10.2. The sample correlation is  $R = 0.6401$ . We sample  $v = 10,000$  bootstrap samples of size  $n = 31$ . The average sample correlation in the 10,000 bootstrap samples is 0.6354 with a simulation standard error of 0.001. We then estimate the bias of the sample correlation to be  $0.6354 - 0.6401 = -0.0047$ . ◀

## The Parametric Bootstrap

**Example  
12.6.8**

**Correcting the Bias in the Coefficient of Variation.** The coefficient of variation of a distribution is the ratio of the standard deviation to the mean. (Typically, people only compute the coefficient of variation for distributions of positive random variables.) If we believe that our data  $X_1, \dots, X_n$  come from a lognormal distribution with parameters  $\mu$  and  $\sigma^2$ , then the coefficient of variation is  $\theta = (e^{\sigma^2} - 1)^{1/2}$ . The M.L.E. of the coefficient of variation is  $\hat{\theta} = (e^{\hat{\sigma}^2} - 1)^{1/2}$ , where  $\hat{\sigma}$  is the M.L.E. of  $\sigma$ . We expect the M.L.E. of the coefficient of variation to be a biased estimator because it is nonlinear. Computing the bias is a difficult task. However, we can use the parametric bootstrap to estimate the bias. The M.L.E.  $\hat{\sigma}$  of  $\sigma$  is the square root of the sample variance of  $\log(X_1), \dots, \log(X_n)$ . The M.L.E.  $\hat{\mu}$  of  $\mu$  is the sample average of  $\log(X_1), \dots, \log(X_n)$ . We can simulate a large number of random samples of size  $n$  from the lognormal distribution with parameters  $\hat{\mu}$  and  $\hat{\sigma}^2$ . For each  $i$ , we compute

$\hat{\sigma}^{*(i)}$ , the sample standard deviation of the  $i$ th bootstrap sample. We estimate the bias of  $\hat{\theta}$  by the sample average of the values  $T^{(i)} = (e^{[\hat{\sigma}^{*(i)}]^2} - 1)^{1/2} - \hat{\theta}$ .

As an example, consider the failure times of ball bearings introduced in Example 5.6.9. If we model these data as lognormal, the M.L.E.'s of the parameters are  $\hat{\mu} = 4.150$  and  $\hat{\sigma} = 0.5217$ . The M.L.E. of  $\theta$  is  $\hat{\theta} = 0.5593$ . We could draw 10,000 random samples of size 23 from a lognormal distribution and compute the sample variances of the logarithms. However, there is an easier way to do this simulation. The distribution of  $[\hat{\theta}^{*(i)}]^2$  is that of a  $\chi^2$  random variable with 22 degrees of freedom times  $0.5217^2/23$ . Hence, we shall just sample 10,000  $\chi^2$  random variables with 22 degrees of freedom, multiply each one by  $0.5217^2/23$ , and call the  $i$ th one  $[\hat{\sigma}^{*(i)}]^2$ . After doing this, the sample average of the 10,000  $T^{(i)}$  values is  $-0.01825$ , which is our parametric bootstrap estimate of the bias of  $\hat{\theta}$ . (The simulation standard error is  $9.47 \times 10^{-4}$ .) Because our estimate of the bias is negative, this means that we expect  $\hat{\theta}$  to be smaller than  $\theta$ . To "correct" the bias, we could add 0.01825 to our original estimate  $\hat{\theta}$  and produce the new estimate  $0.5593 + 0.01825 = 0.5776$ .  $\blacktriangleleft$

**Example  
12.6.9**

**Estimating the Standard Deviation of a Statistic.** Suppose that  $X_1, \dots, X_n$  is a random sample from the normal distribution with mean  $\mu$  and variance  $\sigma^2$ . We are interested in the probability that a random variable having this same distribution is at most  $c$ . That is, we are interested in estimating  $\theta = \Phi([c - \mu]/\sigma)$ . The M.L.E. of  $\theta$  is  $\hat{\theta} = \Phi([c - \bar{X}]/\hat{\sigma})$ . It is not easy to calculate the standard deviation of  $\hat{\theta}$  in closed form. However, we can draw many, say,  $v$ , bootstrap samples of size  $n$  from the normal distribution with mean  $\bar{x}$  and variance  $\hat{\sigma}^2$ . For the  $i$ th bootstrap sample, we compute a sample average  $\bar{x}^{*(i)}$ , a sample standard deviation  $\hat{\sigma}^{*(i)}$ , and, finally,  $\hat{\theta}^{*(i)} = \Phi([c - \bar{x}^{*(i)}]/\hat{\sigma}^{*(i)})$ . We estimate the mean of  $\hat{\theta}$  by

$$\bar{\theta}^* = \frac{1}{v} \sum_{i=1}^v \hat{\theta}^{*(i)}.$$

(This can also be used, as in Example 12.6.8, to estimate the bias of  $\hat{\theta}$ .) The standard deviation of  $\hat{\theta}$  can then be estimated by the sample standard deviation of the  $\hat{\theta}^{*(i)}$  values,

$$Z = \left( \frac{1}{v} \sum_{i=1}^v (\hat{\theta}^{*(i)} - \bar{\theta}^*)^2 \right)^{1/2}.$$

For example, we can use the nursing home data from Sec. 8.6. There are  $n = 18$  observations, and we might be interested in  $\Phi([200 - \mu]/\sigma)$ . The M.L.E.'s of  $\mu$  and  $\sigma$  are  $\hat{\mu} = 182.17$  and  $\hat{\sigma} = 72.22$ . The observed value of  $\hat{\theta}$  is  $\Phi([200 - 182.17]/72.22) = 0.5975$ . We simulate 10,000 samples of size 18 from the normal distribution with mean 182.17 and variance  $(72.22)^2$ . For the  $i$ th sample, we find the value  $\hat{\theta}^{*(i)}$  for  $i = 1, \dots, 10,000$ , and the average of these is  $\bar{\theta}^* = 0.6020$  with sample standard deviation  $Z = 0.09768$ .

We can compute the simulation standard error of the approximation to the bootstrap estimate in two steps. First, apply the method of Example 12.2.10. This gives the simulation standard error of  $Z^2$ , the sample variance of the  $\hat{\theta}^{*(i)}$ 's. In our example, this yields the value  $1.365 \times 10^{-4}$ . Second, use the delta method, as in Example 12.2.8, to find the simulation standard error of the square root of  $Z^2$ . In our example, this second step yields the value  $6.986 \times 10^{-4}$ .  $\blacktriangleleft$

**Example  
12.6.10**

**Comparing Means When Variances Are Unequal.** Suppose that we have two samples  $X_1, \dots, X_m$  and  $Y_1, \dots, Y_n$  from two possibly different normal distributions. That is,  $X_1, \dots, X_m$  are i.i.d. from the normal distribution with mean  $\mu_1$  and variance  $\sigma_1^2$ , while  $Y_1, \dots, Y_n$  are i.i.d. from the normal distribution with mean  $\mu_2$  and variance  $\sigma_2^2$ . In Sec. 9.6, we saw how to test the null hypothesis  $H_0: \mu_1 = \mu_2$  versus the alternative hypothesis  $H_1: \mu_1 \neq \mu_2$  if we are willing to assume that we know the ratio  $k = \sigma_2^2/\sigma_1^2$ . If we are not willing to assume that we know the ratio  $k$ , we have seen only approximate tests.

Suppose that we choose to use the usual two-sample  $t$  test even though we do not claim to know  $k$ . That is, suppose that we choose to reject  $H_0$  when  $|U| > c$ , where  $U$  is the statistic defined in Eq. (9.6.3) and  $c$  is the  $1 - \alpha_0/2$  quantile of the  $t$  distribution with  $m + n - 2$  degrees of freedom. This test will not necessarily have level  $\alpha_0$  if  $k \neq 1$ . We can use the parametric bootstrap to try to compute the level of this test. In fact, we can use the parametric bootstrap to help us choose a different critical value  $c^*$  for the test so that we at least estimate the type I error probability to be  $\alpha_0$ .

As an example, we shall use the data from Example 9.6.5 again. The M.L.E.'s of the variances of the two distributions were  $\hat{\sigma}_1^2 = 0.04$  (for the  $X$  data) and  $\hat{\sigma}_2^2 = 0.022$  (for the  $Y$  data). The probability of type I error is the probability of rejecting the null hypothesis given that the null hypothesis is true, that is, given that  $\mu_1 = \mu_2$ . Hence, we must simulate bootstrap samples in which the  $X$  data and  $Y$  data have the same mean. Since the sample averages of the  $X$  and  $Y$  data are subtracted from each other in the calculation of  $U$ , it will not matter what common mean we choose for the two samples.

So, the parametric bootstrap can proceed as follows: First, choose a large number  $v$ , and for  $i = 1, \dots, v$ , simulate  $(\bar{X}^{*(i)}, \bar{Y}^{*(i)}, S_X^{2*(i)}, S_Y^{2*(i)})$  where all four random variables are independent with the following distributions:

- $\bar{X}^{*(i)}$  has the normal distribution with mean 0 and variance  $\hat{\sigma}_1^2/m$ .
- $\bar{Y}^{*(i)}$  has the normal distribution with mean 0 and variance  $\hat{\sigma}_2^2/n$ .
- $S_X^{2*(i)}$  is  $\hat{\sigma}_1^2$  times a random variable having the  $\chi^2$  distribution with  $m - 1$  degrees of freedom.
- $S_Y^{2*(i)}$  is  $\hat{\sigma}_2^2$  times a random variable having the  $\chi^2$  distribution with  $n - 1$  degrees of freedom.

Then compute

$$U^{(i)} = \frac{(m+n-2)^{1/2}(\bar{X}^{*(i)} - \bar{Y}^{*(i)})}{\left(\frac{1}{m} + \frac{1}{n}\right)^{1/2} \left(S_X^{2*(i)} + S_Y^{2*(i)}\right)^{1/2}}$$

for each  $i$ . Our simulation approximation to the bootstrap estimate of the probability of type I error for the usual two-sample  $t$  test would be the proportion of simulations in which  $|U^{(i)}| > c$ .

With  $v = 10,000$ , we shall perform the analysis described above for several different  $c$  values. We set  $c$  equal to the  $1 - \alpha_0/2$  quantile of the  $t$  distribution with 16 degrees of freedom with  $\alpha_0 = j/1000$  for each  $j = 1, \dots, 999$ . Figure 12.12 shows a plot of the simulation approximation to the bootstrap estimate of the type I error probability against the nominal level  $\alpha_0$  of the test. There is remarkably close agreement between the two, although the bootstrap estimate is generally slightly larger. For example, when  $\alpha_0 = 0.05$ , the bootstrap estimate is 0.065.

**Figure 12.12** Plots of bootstrap estimated type I error probability of  $t$  test versus nominal type I error probability in Example 12.6.10. The dashed line is the diagonal along which the two error probabilities would be equal.

Next, we use the bootstrap analysis to correct the level of the two-sample  $t$  test in this example. To do this, let  $Z$  be the sample  $1 - \alpha_0$  quantile of our simulated  $|U^{(i)}|$  values. If we want a level  $\alpha_0$  test, we can replace the critical value  $c$  in the two-sample  $t$  test with  $Z$  and reject the null hypothesis if  $|U| > Z$ . For example, with  $\alpha_0 = 0.05$ , the 0.975 quantile of the  $t$  distribution is 2.12, while in our simulation  $Z = 2.277$ . The simulation standard error of  $Z$  (based on splitting the 10,000 bootstrap samples into 10 subsamples of 1000 each) is 0.0089. ◀

### Example 12.6.11

**The Bias of the Sample Correlation.** In Example 12.6.7, we made no assumptions about the distribution  $F$  of  $(X, Y)$  except that  $X$  and  $Y$  have finite variances. Now suppose that we also assume that  $(X, Y)$  has a bivariate normal distribution. We can compute the M.L.E.'s of all of the parameters as in Exercise 24 in Sec. 7.6. We could then simulate  $v$  samples of size  $n$  from the bivariate normal distribution with parameters equal to the M.L.E.'s, as in Example 12.3.6. For sample  $i$  for  $i = 1, \dots, v$ , we could compute the sample correlation  $R^{(i)}$  by substituting the  $i$ th sample into Eq. (12.6.2). Our estimate of the bias would be  $\bar{R} - \hat{\rho}$ . Note that  $\hat{\rho}$ , the M.L.E. of  $\rho$ , is the same as  $R$ .

As a numerical example, consider the flea beetle data from Example 5.10.2. The sample correlation is  $R = 0.6401$ . We construct  $v = 10,000$  samples of size  $n = 31$  from a bivariate normal distribution with correlation 0.6401. The means and variances do not affect the distribution of  $R$ . (See Exercise 12.) The average sample correlation in the 10,000 bootstrap samples is 0.6352 with a simulation standard error of 0.001. We then estimate the bias of the sample correlation to be  $0.6352 - 0.6401 = -0.0049$ . This is pretty much the same as we obtained using the nonparametric bootstrap in Example 12.6.7. ◀

### Summary

The bootstrap is a method for estimating probabilistic features of a function  $\eta$  of our data  $\mathbf{X}$  and their unknown distribution  $F$ . That is, suppose that we are interested in the mean, a quantile, or some other feature of  $\eta(\mathbf{X}, F)$ . The first step in the bootstrap is to replace  $F$  by a known distribution  $\hat{F}$  that is like  $F$  in some way. Next, replace  $\mathbf{X}$  by data  $\mathbf{X}^*$  sampled from  $\hat{F}$ . Finally, compute the mean, quantile, or other feature of  $\eta(\mathbf{X}^*, \hat{F})$  as the bootstrap estimate. This last step generally requires simulation except in the simplest examples. There are two varieties of bootstrap that differ by

how  $\hat{F}$  is chosen. In the nonparametric bootstrap, the sample c.d.f. is used as  $\hat{F}$ . In the parametric bootstrap,  $F$  is assumed to be a member of some parametric family and  $\hat{F}$  is chosen by replacing the unknown parameter by its M.L.E. or some other estimate.

## Exercises

---

1. Suppose that  $X_1, \dots, X_n$  form a random sample from an exponential distribution with parameter  $\theta$ . Explain how to use the parametric bootstrap to estimate the variance of the sample average  $\bar{X}$ . (No simulation is required.)
2. Let  $x_1, \dots, x_n$  be the observed values of a random sample  $\mathbf{X} = (X_1, \dots, X_n)$ . Let  $F_n$  be the sample c.d.f. Let  $J_1, \dots, J_n$  be a random sample with replacement from the numbers  $\{1, \dots, n\}$ . Define  $X_i^* = x_{J_i}$  for  $i = 1, \dots, n$ . Show that  $\mathbf{X}^* = (X_1^*, \dots, X_n^*)$  is an i.i.d. sample from the distribution  $F_n$ .
3. Let  $n$  be odd, and let  $\mathbf{X} = (X_1, \dots, X_n)$  be a sample of size  $n$  from some distribution. Suppose that we wish to use the nonparametric bootstrap to estimate some feature of the sample median. Compute the probability that the sample median of a nonparametric bootstrap sample will be the smallest observation from the original data  $\mathbf{X}$ .
4. Use the data in the first column of Table 11.5 on page 699. These data give the boiling points of water at 17 different locations from Forbes' experiment. Let  $F$  be the distribution from which these boiling points were drawn. We might not be willing to make many assumptions about  $F$ . Suppose that we are interested in the bias of the sample median as an estimator of the median of the distribution  $F$ . Use the nonparametric bootstrap to estimate this bias. First, do a pilot run to compute the simulation standard error of the simulation approximation, and then see how many bootstrap samples you need in order for your bias estimate (for distribution  $\hat{F}$ ) to be within 0.02 of the true bias (for distribution  $\hat{F}$ ) with probability at least 0.9.
5. Use the data in Table 10.6 on page 640. We are interested in the bias of the sample median as an estimator of the median of the distribution.
  - a. Use the nonparametric bootstrap to estimate this bias.
  - b. How many bootstrap samples does it appear that you need in order to estimate the bias to within .05 with probability 0.99?
6. Use the data in Exercise 16 of Sec. 10.7.
  - a. Use the nonparametric bootstrap to estimate the variance of the sample median.
  - b. How many bootstrap samples does it appear that you need in order to estimate the variance to within .005 with probability 0.95?
7. Use the blood pressure data in Table 9.2 that was described in Exercise 10 of Sec. 9.6. Suppose now that we are not confident that the variances are the same for the two treatment groups. Perform a parametric bootstrap analysis of the sort done in Example 12.6.10. Use  $v = 10,000$  bootstrap simulations.
  - a. Estimate the probability of type I error for a two-sample  $t$  test whose nominal level is  $\alpha_0 = 0.1$ .
  - b. Correct the level of the two-sample  $t$  test by computing the appropriate quantile of the bootstrap distribution of  $|U^{(i)}|$ .
  - c. Compute the simulation standard error for the quantile in part (b).
8. In Example 12.6.7, let  $(X^*, Y^*)$  be a random draw from the sample distribution  $F_n$ . Prove that the correlation between  $X^*$  and  $Y^*$  is  $R$  in Eq. (12.6.2).
9. Use the data on fish prices in Table 11.6 on page 707. Suppose that we assume only that the distribution of fish prices in 1970 and 1980 is a continuous joint distribution with finite variances. We are interested in the properties of the sample correlation coefficient. Construct 1000 nonparametric bootstrap samples for solving this exercise.
  - a. Approximate the bootstrap estimate of the variance of the sample correlation.
  - b. Approximate the bootstrap estimate of the bias of the sample correlation.
  - c. Compute simulation standard errors of each of the above bootstrap estimates.
10. Use the beef hot dog data in Exercise 7 of Sec. 8.5. Form 10,000 nonparametric bootstrap samples to solve this exercise.
  - a. Approximate a 90 percent percentile bootstrap confidence interval for the median calorie count in beef hot dogs.
  - b. Approximate a 90 percent percentile- $t$  bootstrap confidence interval for the median calorie count in beef hot dogs.
  - c. Compare these intervals to the 90 percent interval formed using the assumption that the data came from a normal distribution.

- 11.** The skewness of a random variable was defined in Definition 4.4.1. Suppose that  $X_1, \dots, X_n$  form a random sample from a distribution  $F$ . The sample skewness is defined as

$$M_3 = \frac{\frac{1}{n} \sum_{i=1}^n (X_i - \bar{X})^3}{\left[ \frac{1}{n} \sum_{i=1}^n (X_i - \bar{X})^2 \right]^{3/2}}.$$

One might use  $M_3$  as an estimator of the skewness  $\theta$  of the distribution  $F$ . The bootstrap can be used to estimate the bias and standard deviation of the sample skewness as an estimator of  $\theta$ .

- a.** Prove that  $M_3$  is the skewness of the sample distribution  $F_n$ .

- b.** Use the 1970 fish price data in Table 11.6 on page 707. Compute the sample skewness, and then simulate 1000 bootstrap samples. Use the bootstrap samples to estimate the bias and standard deviation of the sample skewness.

- 12.** Suppose that  $(X_1, Y_1), \dots, (X_n, Y_n)$  form a random sample from a bivariate normal distribution with means  $\mu_x$  and  $\mu_y$ , variances  $\sigma_x^2$  and  $\sigma_y^2$ , and correlation  $\rho$ . Let  $R$  be the sample correlation. Prove that the distribution of  $R$  depends only on  $\rho$ , not on  $\mu_x, \mu_y, \sigma_x^2$ , or  $\sigma_y^2$ .

## 12.7 Supplementary Exercises

- 1.** Test the standard normal pseudo-random number generator on your computer by generating a sample of size 10,000 and drawing a normal quantile plot. How straight does the plot appear to be?

- 2.** Test the gamma pseudo-random number generator on your computer. Simulate 10,000 gamma pseudo-random variables with parameters  $a$  and 1 for  $a = 0.5, 1, 1.5, 2, 5, 10$ . Then draw gamma quantile plots.

- 3.** Test the  $t$  pseudo-random number generator on your computer. Simulate 10,000  $t$  pseudo-random variables with  $m$  degrees of freedom for  $m = 1, 2, 5, 10, 20$ . Then draw  $t$  quantile plots.

- 4.** Let  $X$  and  $Y$  be independent random variables with  $X$  having the  $t$  distribution with five degrees of freedom and  $Y$  having the  $t$  distribution with three degrees of freedom. We are interested in  $E(|X - Y|)$ .

- a.** Simulate 1000 pairs of  $(X_i, Y_i)$  each with the above joint distribution and estimate  $E(|X - Y|)$ .
- b.** Use your 1000 simulated pairs to estimate the variance of  $|X - Y|$  also.
- c.** Based on your estimated variance, how many simulations would you need to be 99 percent confident that your estimator of  $E(|X - Y|)$  is within 0.01 of the actual mean?

- 5.** Consider the power calculation done in Example 9.5.5.

- a.** Simulate  $v_0 = 1000$  i.i.d. noncentral  $t$  pseudo-random variables with 14 degrees of freedom and noncentrality parameter 1.936.
- b.** Estimate the probability that a noncentral  $t$  random variable with 14 degrees of freedom and noncentrality parameter 1.936 is at least 1.761. Also, compute the simulation standard error.
- c.** Suppose that we want our estimator of the noncentral  $t$  probability in part (b) to be closer than 0.01 to

the true value with probability 0.99. How many noncentral  $t$  random variables do we need to simulate?

- 6.** The  $\chi^2$  goodness-of-fit test (see Chapter 10) is based on an asymptotic approximation to the distribution of the test statistic. For small to medium samples, the asymptotic approximation might not be very good. Simulation can be used to assess how good the approximation is. Simulation can also be used to estimate the power function of a goodness-of-fit test. For this exercise, assume that we are performing the test that was done in Example 10.1.6. The idea illustrated in this exercise applies in all such problems.

- a.** Simulate  $v = 10,000$  samples of size  $n = 23$  from the normal distribution with mean 3.912 and variance 0.25. For each sample, compute the  $\chi^2$  goodness-of-fit statistic  $Q$  using the same four intervals that were used in Example 10.1.6. Use the simulations to estimate the probability that  $Q$  is greater than or equal to the 0.9, 0.95, and 0.99 quantiles of the  $\chi^2$  distribution with three degrees of freedom.
- b.** Suppose that we are interested in the power function of a  $\chi^2$  goodness-of-fit test when the actual distribution of the data is the normal distribution with mean 4.2 and variance 0.8. Use simulation to estimate the power function of the level 0.1, 0.05, and 0.01 tests at the alternative specified.

- 7.** In Sec. 10.2, we discussed  $\chi^2$  goodness-of-fit tests for composite hypotheses. These tests required computing M.L.E.'s based on the numbers of observations that fell into the different intervals used for the test. Suppose instead that we use the M.L.E.'s based on the original observations. In this case, we claimed that the asymptotic distribution of the  $\chi^2$  test statistic was somewhere between two different  $\chi^2$  distributions. We can use simulation to better approximate the distribution of the test statistic. In this exercise, assume that we are trying to test

the same hypotheses as in Example 10.2.5, although the methods will apply in all such cases.

- a. Simulate  $v = 1000$  samples of size  $n = 23$  from each of 10 different normal distributions. Let the normal distributions have means of 3.8, 3.9, 4.0, 4.1, and 4.2. Let the distributions have variances of 0.25 and 0.8. Use all 10 combinations of mean and variance. For each simulated sample, compute the  $\chi^2$  statistic  $Q$  using the usual M.L.E.'s of  $\mu$  and  $\sigma^2$ . For each of the 10 normal distributions, estimate the 0.9, 0.95, and 0.99 quantiles of the distribution of  $Q$ .
  - b. Do the quantiles change much as the distribution of the data changes?
  - c. Consider the test that rejects the null hypothesis if  $Q \geq 5.2$ . Use simulation to estimate the power function of this test at the following alternative: For each  $i$ ,  $(X_i - 3.912)/0.5$  has the  $t$  distribution with five degrees of freedom.
- 8.** In Example 12.5.6, we used a hierarchical model. In that model, the parameters  $\mu_1, \dots, \mu_p$  were independent random variables with  $\mu_i$  having the normal distribution with mean  $\psi$  and precision  $\lambda_0 \tau_i$  conditional on  $\psi$  and  $\tau_1, \dots, \tau_p$ . To make the model more general, we could also replace  $\lambda_0$  by an unknown parameter  $\lambda$ . That is, let the  $\mu_i$ 's be independent with  $\mu_i$  having the normal distribution with mean  $\psi$  and precision  $\lambda \tau_i$  conditional on  $\psi$ ,  $\lambda$ , and  $\tau_1, \dots, \tau_p$ . Let  $\lambda$  have the gamma distribution with parameters  $\gamma_0$  and  $\delta_0$ , and let  $\lambda$  be independent of  $\psi$  and  $\tau_1, \dots, \tau_p$ . The remaining parameters have the prior distributions stated in Example 12.5.6.

- a. Write the product of the likelihood and the prior as a function of the parameters  $\mu_1, \dots, \mu_p, \tau_1, \dots, \tau_p, \psi$ , and  $\lambda$ .
- b. Find the conditional distributions of each parameter given all of the others. Hint: For all the parameters besides  $\lambda$ , the distributions should be almost identical to those given in Example 12.5.6. Wherever  $\lambda_0$  appears, of course, something will have to change.
- c. Use a prior distribution in which  $\alpha_0 = 1$ ,  $\beta_0 = 0.1$ ,  $u_0 = 0.001$ ,  $\gamma_0 = \delta_0 = 1$ , and  $\psi_0 = 170$ . Fit the model to the hot dog calorie data from Example 11.6.2. Compute the posterior means of the four  $\mu_i$ 's and  $1/\tau_i$ 's.

- 9.** In Example 12.5.6, we modeled the parameters  $\tau_1, \dots, \tau_p$  as i.i.d. having the gamma distribution with parameters  $\alpha_0$  and  $\beta_0$ . We could have added a level to the hierarchical model that would allow the  $\tau_i$ 's to come from a distribution with an unknown parameter. For example, suppose that we model the  $\tau_i$ 's as conditionally independent having the gamma distribution with parameters  $\alpha_0$  and  $\beta$  given  $\beta$ . Let  $\beta$  be independent of  $\psi$  and  $\mu_1, \dots, \mu_p$  with  $\beta$  having the gamma distribution with parameters  $\epsilon_0$  and  $\phi_0$ . The rest of the prior distributions are as specified in Example 12.5.6.

- a. Write the product of the likelihood and the prior as a function of the parameters  $\mu_1, \dots, \mu_p, \tau_1, \dots, \tau_p, \psi$ , and  $\beta$ .

- b. Find the conditional distributions of each parameter given all of the others. Hint: For all the parameters besides  $\beta$ , the distributions should be almost identical to those given in Example 12.5.6. Wherever  $\beta_0$  appears, of course, something will have to change.
- c. Use a prior distribution in which  $\alpha_0 = \lambda_0 = 1$ ,  $u_0 = 0.001$ ,  $\epsilon_0 = 0.3$ ,  $\phi_0 = 3.0$ , and  $\psi_0 = 170$ . Fit the model to the hot dog calorie data from Example 11.6.2. Compute the posterior means of the four  $\mu_i$ 's and  $1/\tau_i$ 's.

- 10.** Let  $X_1, \dots, X_k$  be independent random variables such that  $X_i$  has the binomial distribution with parameters  $n_i$  and  $p_i$ . We wish to test the null hypothesis  $H_0: p_1 = \dots = p_k$  versus the alternative hypothesis  $H_1$  that  $H_0$  is false. Assume that the numbers  $n_1, \dots, n_k$  are known constants.

- a. Show that the likelihood ratio test procedure is to reject  $H_0$  if the following statistic is greater than or equal to some constant  $c$ :

$$\frac{\prod_{i=1}^k [X_i^{X_i} (n_i - X_i)^{n_i - X_i}]}{\left(\sum_{j=1}^k X_j\right)^{\sum_{j=1}^k X_j} \left[\sum_{j=1}^k (n_j - X_j)\right]^{\sum_{j=1}^k (n_j - X_j)}}.$$

- b. Describe how you could use simulation techniques to estimate the constant  $c$  in order to make the likelihood ratio test have a desired level of significance  $\alpha_0$ . (Assume that you can simulate as many binomial pseudo-random variables as you wish.)
- c. Consider the depression study in Example 2.1.4. Let  $p_i$  stand for the probability of success (no relapse) for the subjects in group  $i$  of Table 2.1 on page 57, where  $i = 1$  means imipramine,  $i = 2$  means lithium,  $i = 3$  means combination, and  $i = 4$  means placebo. Test the null hypothesis that  $p_1 = p_2 = p_3 = p_4$  by computing the  $p$ -value for the likelihood ratio test.

- 11.** Consider the problem of testing the equality of two normal means when the variances are unequal. This problem was introduced on page 593 in Sec. 9.6. The data are two independent samples  $X_1, \dots, X_m$  and  $Y_1, \dots, Y_n$ . The  $X_i$ 's are i.i.d. having the normal distribution with mean  $\mu_1$  and variance  $\sigma_1^2$ , while the  $Y_j$ 's are i.i.d. having the normal distribution with mean  $\mu_2$  and variance  $\sigma_2^2$ .

- a. Assume that  $\mu_1 = \mu_2$ . Prove that the random variable  $V$  in Eq. (9.6.14) has a distribution that depends on the parameters only through the ratio  $\sigma_2/\sigma_1$ .
- b. Let  $v$  be the approximate degrees of freedom for Welch's procedure from Eq. (9.6.17). Prove that the distribution of  $v$  depends on the parameters only through the ratio  $\sigma_2/\sigma_1$ .

- c. Use simulation to assess the approximation in Welch's procedure. In particular, set the ratio  $\sigma_2/\sigma_1$  equal to each of the numbers 1, 1.5, 2, 3, 5, and 10 in succession. For each value of the ratio, simulate 10,000 samples of sizes  $n = 11$  and  $m = 10$  (or the appropriate summary statistics). For each simulated sample, compute the test statistic  $V$  and the 0.9, 0.95, and 0.99 quantiles of the approximate  $t$  distribution that corresponds to the data in that simulation. Keep track of the proportion of simulations in which  $V$  is greater than each of the three quantiles. How do these proportions compare to the nominal values 0.1, 0.05, and 0.01?
12. Consider again the situation described in Exercise 11. This time, use simulation to assess the performance of the usual two-sample  $t$  test. That is, use the same simulations as in part (c) of Exercise 11 (or ones just like them if you do not have the same simulations). This time, for each simulated sample compute the statistic  $U$  in Eq. (9.6.3) and keep track of the proportion of simulations in which  $U$  is greater than each of the nominal  $t$  quantiles,  $T_{19}^{-1}(1 - \alpha_0)$  for  $\alpha_0 = 0.1, 0.05$ , and 0.01. How do these proportions compare to the nominal  $\alpha_0$  values?
13. Suppose that our data comprise a set of pairs  $(Y_i, x_i)$ , for  $i = 1, \dots, n$ . Here, each  $Y_i$  is a random variable and each  $x_i$  is a known constant. Suppose that we use a simple linear regression model in which  $E(Y_i) = \beta_0 + \beta_1 x_i$ . Let  $\hat{\beta}_1$  stand for the least squares estimator of  $\beta_1$ . Suppose, however, that the  $Y_i$ 's are actually random variables with translated and scaled  $t$  distributions. In particular, suppose that  $(Y_i - \beta_0 - \beta_1 x_i)/\sigma$  are i.i.d. having the  $t$  distribution with  $k \geq 5$  degrees of freedom for  $i = 1, \dots, n$ . We can use simulation to estimate the standard deviation of the sampling distribution of  $\hat{\beta}_1$ .
- a. Prove that the variance of the sampling distribution of  $\hat{\beta}_1$  does not depend on the values of the parameters  $\beta_0$  and  $\beta_1$ .
  - b. Prove that the variance of the sampling distribution of  $\hat{\beta}_1$  is equal to  $v\sigma^2$ , where  $v$  does not depend on any of the parameters  $\beta_0$ ,  $\beta_1$ , and  $\sigma$ .
- c. Describe a simulation scheme to estimate the value  $v$  from part (b).
14. Use the simulation scheme developed in Exercise 13 and the data in Table 11.5 on page 699. Suppose that we think that the logarithms of pressure are linearly related to boiling point, but that the logarithms of pressure have translated and scaled  $t$  distributions with  $k = 5$  degrees of freedom. Estimate the value  $v$  from part (b) of Exercise 13 using simulation.
15. In Sec. 7.4, we introduced Bayes estimators. For simple loss functions, such as squared error and absolute error, we were able to derive general forms for Bayes estimators. In many real problems, loss functions are not so simple. Simulation can often be used to approximate Bayes estimators. Suppose that we are able to simulate a sample  $\theta^{(1)}, \dots, \theta^{(v)}$  (either directly or by Gibbs sampling) from the posterior distribution of some parameter  $\theta$  given some observed data  $X = x$ . Here,  $\theta$  can be real valued or multidimensional. Suppose that we have a loss function  $L(\theta, a)$ , and we want to choose  $a$  so as to minimize the posterior mean  $E[L(\theta, a)|x]$ .
- a. Describe a general method for approximating the Bayes estimate in the situation described above.
  - b. Suppose that the simulation variance of the approximation to the Bayes estimate is proportional to 1 over the size of the simulation. How could one compute a simulation standard error for the approximation to the Bayes estimate?
16. In Example 12.5.2, suppose that the State of New Mexico wishes to estimate the mean number  $\mu$  of medical in-patient days in nonrural nursing homes. The parameter is  $\theta = (\mu, \tau)$ . The loss function will be asymmetric to reflect different costs of underestimating and overestimating. Suppose that the loss function is
- $$L(\theta, a) = \begin{cases} 30(a - \mu) & \text{if } a \geq \mu, \\ (\mu - a)^2 & \text{if } \mu > a. \end{cases}$$
- Use the method developed in your solution to Exercise 15 to approximate the Bayes estimate and compute a simulation standard error.

## Table of Poisson Probabilities

$$\Pr(X = k) = \frac{e^{-\lambda} \lambda^k}{k!}$$

**Table of the  $\chi^2$  Distribution**

If  $X$  has a  $\chi^2$  distribution with  $m$  degrees of freedom, this table gives the value of  $x$  such that  $\Pr(X \leq x) = p$ , the  $p$  quantile of  $X$ .

$m$	$p$								
	.005	.01	.025	.05	.10	.20	.25	.30	.40

**Table of the *t* Distribution**

If  $X$  has a  $t$  distribution with  $m$  degrees of freedom, the table gives the value of  $x$  such that  $\Pr(X \leq x) = p$ .

$m$	$p = .55$	.60	.65	.70	.75	.80	.85	.90	.95	.975	.99	.995

"Table of the Standard Normal Distribution Function" from HANDBOOK OF STATISTICAL TABLES by Donald B. Owen. © 1962 by Addison-Wesley.

**Table of the 0.95 Quantile of the *F* Distribution**

If  $X$  has an *F* distribution with  $m$  and  $n$  degrees of freedom, the table gives the value of  $x$  such that  $\Pr(X \leq x) = 0.95$ .

<i>n</i>	1	2	3	4	5	6	7	8	9	10	15	20	30	40	60	120	<i>m</i>

# ANSWERS TO ODD-NUMBERED EXERCISES

---

Note: Answers are not provided for exercises that request a proof, a derivation, or a graph.

## Chapter 1

### Section 1.4

7. (a)  $\{x: x < 1 \text{ or } x > 5\}$ ; (b)  $\{x: 1 \leq x \leq 7\}$ ; (c)  $B$ ; (d)  $\{x: 0 < x < 1 \text{ or } x > 7\}$ ; (e)  $\emptyset$ .    11. (a)  $S = \{(x, y) : 0 \leq x \leq 5 \text{ and } 0 \leq y \leq 5\}$ . (b)  $A = \{(x, y) \in S : x + y \geq 6\}$ ,  $B = \{(x, y) \in S : x = y\}$ ,  $C = \{(x, y) \in S : x > y\}$ ,  $D = \{(x, y) \in S : x + y < 6\}$ . (c)  $A^c \cap D^c \cap B$ . (d)  $A^c \cap B^c \cap C^c$ .

### Section 1.5

1.  $\frac{2}{5}$ .    3. (a)  $\frac{1}{2}$ ; (b)  $\frac{1}{6}$ ; (c)  $\frac{3}{8}$ .    5. 0.4.    7. 0.4 if  $A \subset B$  and 0.1 if  $\Pr(A \cup B) = 1$ .    11. (a)  $1 - \frac{\pi}{4}$ ; (b)  $\frac{3}{4}$ ; (c)  $\frac{2}{3}$ ; (d) 0.

### Section 1.6

1.  $\frac{1}{2}$ .    3.  $\frac{2}{3}$ .    5.  $\frac{4}{7}$ .    7.  $\Pr(Aa) = \Pr(aa) = \frac{1}{2}$ .

### Section 1.7

1. 14.    3. 5!.    5.  $\frac{5}{18}$ .    7.  $\frac{20!}{8!20!^2}$ .    9.  $\frac{(3!)^2}{6!}$ .

### Section 1.8

1.  $\binom{20}{10}$ .    3. They are equal.    5. This number is  $\binom{4251}{97}$ , and therefore it must be an integer.    7.  $\frac{n+1-k}{\binom{n}{k}}$ .    9.  $\frac{n+1}{\binom{2n}{n}}$ .  
11.  $\frac{\binom{98}{10}}{\binom{100}{12}}$ .    13.  $\frac{\binom{20}{6} + \binom{20}{10}}{\binom{24}{10}}$ .    17.  $\frac{4\binom{13}{4}}{\binom{3^2}{4}}$ .    21.  $\binom{365+k}{k}$ .

### Section 1.9

1.  $\binom{21}{7, 7, 7}$ .    3.  $\binom{300}{5, 8, 287}$ .    5.  $\frac{1}{6^6} \binom{n}{n_1, n_2, \dots, n_6}$ .    7.  $\frac{\binom{12}{6, 2, 4} \binom{13}{4, 6, 3}}{\binom{25}{10, 8, 7}}$ .    9.  $\frac{4!}{\binom{52}{13, 13, 13, 13}}$ .

### Section 1.10

1.  $3 \frac{\binom{4}{2} \binom{48}{3}}{\binom{52}{5}} - 3 \frac{\binom{4}{2} \cdot \binom{48}{3, 3, 42}}{\binom{52}{5, 5, 42}}$ .    3. 45 percent.    5.  $\frac{3}{8}$ .    7.  $1 - \frac{1}{\binom{100}{15}} \left\{ \left[ \binom{90}{15} + \binom{80}{15} + \binom{70}{15} + \binom{60}{15} \right] - \left[ \binom{70}{15} + \binom{60}{15} + \binom{50}{15} + \binom{40}{15} + \binom{30}{15} \right] + \left[ \binom{40}{15} + \binom{30}{15} + \binom{20}{15} \right] \right\}$ .    9.  $n = 10$ .    11.  $\frac{\binom{5}{r} \binom{5}{5-r}}{\binom{10}{5}}$ , where  $r = \frac{x}{2}$  and  $x = 0, 2, \dots, 10$ .

### Section 1.12

1. No.    3.  $\frac{\binom{250}{18} \cdot \binom{100}{12}}{\binom{350}{30}}$ .    5. 0.3120.    7.  $\frac{1}{(r+w)^r}$ .    9.  $\frac{\binom{7}{j} \binom{3}{5-j}}{\binom{10}{5}}$ , where  $k = 2j - 2$  and  $j = 2, 3, 4, 5$ .    13. (d)  $\frac{\binom{n-k+1}{k}}{\binom{n}{k}}$ .

## Chapter 2

### Section 2.1

1.  $\Pr(A)/\Pr(B)$ .    3.  $\Pr(A)$ .    5.  $\frac{r(r+k)(r+2k)b}{(r+b)(r+b+k)(r+b+2k)(r+b+3k)}$ .    7.  $\frac{1}{3}$ .    9. (a)  $\frac{3}{4}$ ; (b)  $\frac{3}{5}$ .    13. 0.44.    15. 0.47.

### Section 2.2

1.  $\Pr(A^c)$ .    5.  $1 - \frac{1}{10^6}$ .    7. (a) 0.92; (b) 0.8696.    9.  $\frac{1}{7}$ .    11. (a) 0.2617.    13.  $10(0.01)(0.99)^9$ .    15.  $n > \frac{\log(0.2)}{\log(0.99)}$ .  
17.  $\frac{1}{12}$ .    19.  $[(0.8)^{10} + (0.7)^{10}] - [(0.2)^{10} + (0.3)^{10}]$ .    23. (a) 0.2215; (b) 0.0234.

### Section 2.3

3. 0.301.    5.  $\frac{18}{59}$ .    7. (a) 0,  $\frac{1}{10}, \frac{2}{10}, \frac{3}{10}, \frac{4}{10}$ ; (b)  $\frac{3}{4}$ ; (c)  $\frac{1}{4}$ .    11. 1/4.    13. (a) 1/9; (b) 1.    15. 0.274.

**Section 2.4**

3. Condition (a).    5.  $i \geq 198$ .    9.  $\frac{2}{3}$ .

**Section 2.5**

3.  $\frac{11}{12}$ .    5.  $\frac{1}{(\frac{10}{3})}$ .    7. Always.    9.  $\frac{1}{6}$ .    11.  $1 - \left(\frac{49}{50}\right)^{50}$ .    13. (a) 0.93; (b) 0.38.    15.  $\frac{4}{81}$ .    17. 0.067.

19.  $p_1 + p_2 + p_3 - p_1p_2 - p_2p_3 - p_1p_3 + p_1p_2p_3$ , where

$$p_1 = \frac{\binom{6}{1}}{\binom{8}{3}}, \quad p_2 = \frac{\binom{6}{2}}{\binom{8}{4}}, \quad p_3 = \frac{\binom{6}{3}}{\binom{8}{5}}.$$

21.  $\Pr(A \text{ wins}) = \frac{4}{7}$ ;  $\Pr(B \text{ wins}) = \frac{2}{7}$ ;  $\Pr(C \text{ wins}) = \frac{1}{7}$ .    23. 0.372.    25. (a) 0.659; (b) 0.051.    27.  $\frac{1 - \left(\frac{1}{2}\right)^{n-1}}{1 - \left(\frac{1}{2}\right)^n}$ .  
 29. (a)  $\frac{1-p_0-p_1}{1-p_0}$ , where  $p_0 = \frac{\binom{48}{13}}{\binom{52}{13}}$  and  $p_1 = \frac{4\binom{48}{12}}{\binom{52}{13}}$ . (b)  $1 - p_1$ . Also,  $\frac{\binom{3}{1}\binom{48}{11} + \binom{3}{2}\binom{48}{10} + \binom{48}{9}}{\binom{51}{12}} = 0.5612$ .    33.  $\frac{7}{9}$ .    35. (a) The second condition; (b) The first condition; (c) Equal probability under both conditions.

**Chapter 3****Section 3.1**

1.  $\frac{6}{11}$ .    3.  $f(0) = \frac{1}{6}$ ,  $f(1) = \frac{5}{18}$ ,  $f(2) = \frac{2}{9}$ ,  $f(3) = \frac{1}{6}$ ,  $f(4) = \frac{1}{9}$ ,  $f(5) = \frac{1}{18}$ .    5.  $f(x) = \begin{cases} \frac{7}{x}(5-x) & \text{for } x = 2, 3, 4, 5, \\ 0 & \text{otherwise} \end{cases}$   
 7. 0.806.    9. 1/2.

1.  $f(x) = 1/(n+1)$  for  $x = 0, \dots, n$ .    3. 0.0404.    7.  $3\mu\sigma^2 + \mu^3$ .    9. 0.8152.    11.  $\frac{15}{7}$ .    13. 0.2202.
15. (a) Exponential, parameter  $\beta = 5$ ; (b) Gamma, parameters  $\alpha = k$  and  $\beta = 5$ ; (c)  $e^{-5(k-1)/3}$ .    23. (a)  $\rho(X_i, X_j) = -\left(\frac{p_i}{1-p_i} \cdot \frac{p_j}{1-p_j}\right)^{1/2}$ , where  $p_i$  is the proportion of students in class  $i$ ; (b)  $i = 1, j = 2$ ; (c)  $i = 3, j = 4$ .    25. Normal with  $\mu = -3$  and  $\sigma^2 = 16$ ;  $\rho(X, Y) = \frac{1}{2}$ .

**Chapter 6****Section 6.1**

1.  $4x$  if  $0 < x \leq 1/2$ ,  $4 - 4x$  if  $1/2 < x < 1$ , and 0 otherwise; 0.36; 0.2; look at where each p.d.f. is higher than the other.  
3. 0.9964. The probability looks like it might be increasing to 1.

**Section 6.2**

5. 25.    13. (a) Yes; (b) No.    17. (b)  $np(1-p)$  and  $knp(1-p/k)$ .    21. (a)  $[u \exp(1-u)]^n$ ; (b) Useless bound.

**Section 6.3**

1. 0.001    3. 0.9938    5.  $n \geq 542$ .    7. 0.7385.    9. (a) 0.36; (b) 0.7887.    11. 0.9938.    13. Normal with mean  $\theta^3$  and variance  $\frac{9\theta^4\sigma^2}{n}$ .    15. (c)  $n(Y_n^2 - \theta^2)/[2\theta]$  has approximately c.d.f.  $F^*$ .

**Section 6.4**

1. 0.8169.    3. 0.0012.    5. 0.9938.    7. 0.7539.

**Section 6.5**

1. 8.00.    3. Without continuity correction, 0.473; with continuity correction, 0.571; exact probability, 0.571.  
5.  $\arcsin(\sqrt{\bar{X}_n})$ .    9. 0.1587.    11. (b) Normal with mean  $n/3$  and variance  $n/9$ .

**Chapter 7****Section 7.1**

1.  $X_1, X_2, \dots, P$ ; the  $X_i$  are i.i.d. Bernoulli with parameter  $p$  given  $P = p$ .    3.  $Z_1, Z_2, \dots$  times of hits, parameter  $\beta$ ,  $Y_k = Z_k - Z_{k-1}$  for  $k \geq 2$ .    5.  $(\bar{X}_n - 0.98, \bar{X}_n + 0.98)$  has probability 0.95 of containing  $\mu$ .    7.  $Y$  Poisson with mean  $\lambda t$ , parameters  $\lambda$  and  $p$ ,  $X_1, \dots, X_y$  i.i.d. Bernoulli with parameter  $p$  given  $Y = y$ ,  $X = X_1 + \dots + X_y$  (observable).

**Section 7.2**

1. 0.4516.    3.  $\xi(1.0|X=3) = 0.2456$ ;  $\xi(1.5|X=3) = 0.7544$ .    5. The p.d.f. of the beta distribution with parameters  $\alpha = 3$  and  $\beta = 6$ .    7. Beta distribution with parameters  $\alpha = 4$  and  $\beta = 7$ .    9. Beta distribution with parameters  $\alpha = 4$  and  $\beta = 6$ .    11. Uniform distribution on the interval [11.2, 11.4].

**Section 7.3**

1. 120.    3. Beta distribution with parameters  $\alpha = 5$  and  $\beta = 297$ .    5. Gamma distribution with parameters  $\alpha = 16$  and  $\beta = 6$ .    7. Normal distribution with mean 69.07 and variance 0.286.    9. Normal distribution with mean 0 and variance  $\frac{1}{5}$ .    13.  $n \geq 100$ .    17.  $\xi(\theta|x) = \begin{cases} \frac{6(8^6)}{\theta^7} & \text{for } \theta > 8, \\ 0 & \text{for } \theta \leq 8. \end{cases}$     19.  $\frac{\alpha+n}{\beta - \sum_{i=1}^n \log x_i}$  and  $\frac{\alpha+n}{(\beta - \sum_{i=1}^n \log x_i)^2}$ .    21. Gamma distribution with parameters  $n$  and  $n\bar{x}_n$ .

**Section 7.4**

1. 2/3 and  $2^{-1/2}$ .    3. (a) 12 or 13; (b) 0.    5.  $\frac{8}{3}$ .    9.  $n \geq 396$ .    13.  $\frac{\alpha+n}{\alpha+n-1} \max(x_0, X_1, \dots, X_n)$ .

**Section 7.5**

3.  $\frac{2}{3}$ .    5. (a)  $\hat{\theta} = \bar{x}_n$ .    7.  $\hat{\beta} = \frac{1}{\bar{X}_n}$ .    9.  $\hat{\theta} = -\frac{n}{\sum_{i=1}^n \log X_i}$ .    11.  $\hat{\theta}_1 = \min(X_1, \dots, X_n)$ ;  $\hat{\theta}_2 = \max(X_1, \dots, X_n)$ .  
 13.  $\hat{\mu}_1 = \bar{X}_n$ ;  $\hat{\mu}_2 = \bar{Y}_n$ .

**Section 7.6**

1.  $(\prod_{i=1}^n X_i)^{1/n}$ .    3.  $\hat{m} = \bar{X}_n \log 2$ .    5.  $\hat{\mu} = \frac{1}{2}[\min\{X_1, \dots, X_n\} + \max\{X_1, \dots, X_n\}]$ .    7.  $\hat{v} = \Phi\left(\frac{\hat{\mu}-2}{\hat{\sigma}}\right)$ .  
 9.  $\bar{X}_n$ .    15.  $\hat{\mu} = 6.75$ .    17.  $\hat{p} = \frac{2}{5}$ .    23. (a)  $\hat{\alpha} = [\bar{x}_n(\bar{x}_n - \bar{x}_{n-1}^2)]/[\bar{x}_{n-1}^2 - \bar{x}_n^2]$ ,  $\hat{\beta} = [(1 - \bar{x}_n)(\bar{x}_n - \bar{x}_{n-1}^2)]/[\bar{x}_{n-1}^2 - \bar{x}_n^2]$ .  
 25.  $\hat{\mu}_1 = \bar{X}_n$ ,  $\hat{\sigma}_1^2 = \frac{1}{n} \sum_{i=1}^n (X_i - \bar{X}_n)^2$ ,  $\hat{\mu}_2 = \hat{\alpha} + \hat{\beta}\hat{\mu}_1$ ,  $\hat{\sigma}_2^2 = \hat{\sigma}_{2,1}^2 + \hat{\beta}^2\hat{\sigma}_1^2$ ,  $\hat{\rho} = \hat{\beta}\hat{\sigma}_1/\hat{\sigma}_2$ , where  $\hat{\beta} = \sum_{i=1}^{n-k} (Y_i - \bar{Y}_{n-k})(X_i - \bar{X}_{n-k}) / \sum_{i=1}^{n-k} (X_i - \bar{X}_{n-k})^2$ ,  $\hat{\alpha} = \bar{Y}_{n-k} - \hat{\beta}\hat{\mu}_1$ , and  $\hat{\sigma}_{2,1}^2 = \frac{1}{n-k} \sum_{i=1}^{n-k} (Y_i - \hat{\alpha} - \hat{\beta}X_i)^2$ .

**Section 7.8**

9. Yes.    11. No.    13. Yes.    15. Yes.    17. Yes.

**Section 7.9**

3.  $R(\theta, \delta_1) = \frac{\theta^2}{3n}$ .    5.  $c^* = \frac{n+2}{n+1}$ .    7. (a)  $R(\beta, \delta) = (\beta - 3)^2$ .    11.  $\hat{\theta} = \delta_0$ .    13.  $\left(\frac{n-1}{n}\right)^T$ .    15.  $\exp(\bar{X}_n + 0.125)$ ,  $c = 0.125(1 - 3/n)$ .

**Section 7.10**

1. (a) Beta distribution with parameters 11 and 16; (b) 11/27.    3.  $\frac{6}{17}$ .    5.  $\frac{\sigma_2^2 b_1 x_1 + \sigma_1^2 b_2 x_2}{\sigma_2^2 b_1^2 + \sigma_1^2 b_2^2}$ .  
 7. (a)  $\frac{1}{3}(X_1 + \frac{1}{2}X_2 + \frac{1}{3}X_3)$ ; (b) Gamma distribution, parameters  $\alpha + 3$  and  $\beta + x_1 + \frac{1}{2}x_2 + \frac{1}{3}x_3$ .    9. (a)  $x + 1$ .  
 (b)  $x + \log 2$ .    11.  $\hat{p} = 2(\hat{\theta} - \frac{1}{4})$ , where

$$\hat{\theta} = \begin{cases} \frac{X}{n} & \text{if } \frac{1}{4} \leq \frac{X}{n} \leq \frac{3}{4}, \\ \frac{1}{4} & \text{if } \frac{X}{n} < \frac{1}{4}, \\ \frac{3}{4} & \text{if } \frac{X}{n} > \frac{3}{4}. \end{cases}$$

13.  $2^{1/5}$ .    15.  $\min(X_1, \dots, X_n)$ .    17.  $\hat{x}_0 = \min(X_1, \dots, X_n)$ , and  $\hat{\alpha} = \left(\frac{1}{n} \sum_{i=1}^n \log x_i - \log \hat{x}_0\right)^{-1}$ .    19. The smallest integer greater than  $\frac{x}{p} - 1$ . If  $\frac{x}{p} - 1$  is itself an integer, both  $\frac{x}{p} - 1$  and  $\frac{x}{p}$  are M.L.E.'s.    21. 16.

**Chapter 8****Section 8.1**

1.  $n \geq 29$ .    3.  $n \geq 255$ .    5.  $n = 10$ .    7.  $n \geq 16$ .    9.  $1 - G(n/t)$ , where  $G(\cdot)$  is the c.d.f. of the gamma distribution with parameters  $n$  and  $\theta$ .

**Section 8.2**

1. 0.1278.    5. 0.20.    9.  $\chi^2$  distribution with one degree of freedom.    11.  $\frac{2^{1/2} \Gamma[(m+1)/2]}{\Gamma(m/2)}$ .

**Section 8.3**

7. (a)  $n = 21$ ; (b)  $n = 13$ .    9. The same for both samples.

**Section 8.4**

3.  $c = \sqrt{3/2}$ .    5. 0.70.

**Section 8.5**

3. (a)  $6.16\sigma^2$ ; (b)  $2.05\sigma^2$ ; (c)  $0.56\sigma^2$ ; (d)  $1.80\sigma^2$ ; (e)  $2.80\sigma^2$ ; (f)  $6.12\sigma^2$ .  
 7. (148.1, 165.6).    9. (a) (4.7, 5.3); (b) (4.8, 5.2); (d) 0.6; (e) 0.5.  
 11. Endpoints are  $\sin^2(\arcsin \sqrt{\bar{x}_n} \pm n^{-1/2} \Phi^{-1}([1 + \gamma]/2))$ , unless one of the numbers  $\arcsin \sqrt{\bar{x}_n} \pm n^{-1/2} \Phi^{-1}([1 +$

$\gamma]/2)$  lies outside of the interval  $[0, \pi/2]$ .

### Section 8.6

5.  $\mu_0 = -5$ ;  $\lambda_0 = 4$ ;  $\alpha_0 = 2$ ;  $\beta_0 = 4$ .    7. The conditions imply that  $\alpha_0 = \frac{1}{4}$ , and  $E(\mu)$  exists only for  $\alpha_0 > \frac{1}{2}$ .  
 9. (a) (157.83, 210.07); (b) (152.55, 211.79).    11. (0.446, 1.530).    13. (0.724, 3.336).    15. (a)  $\alpha_1 = 7.5$ ,  $\beta_1 = 22.73$ ,  $\lambda_1 = 13$ ,  $\mu_1 = 6.631$ ; (b) (5.602, 7.660).    17.  $\alpha_1 = 4.5$ ,  $\beta_1 = 0.4831$ ,  $\lambda_1 = 10$ ,  $\mu_1 = 1.379$ .    19. (a) Normal-gamma with hyperparameters  $\alpha_1 = 11$ ,  $\beta_1 = 4885.7$ ,  $\lambda_1 = 20.5$ ,  $\mu_1 = 156.7$ ; (b) (148.7, 164.7).

### Section 8.7

1. (a)  $g(\theta) = \theta$ ; (b)  $\bar{X}_n$ .    3.  $\frac{1}{n} \sum_{i=1}^n X_i^2 - \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X}_n)^2$ .    5.  $\delta(X) = 2^X$ .    11. (a) All values; (b)  $\alpha = \frac{m}{m+4n}$ .  
 15. (c)  $c_0 = \frac{1}{3}(1 + \theta_0)$ .

### Section 8.8

3.  $I(\theta) = \frac{1}{\theta}$ .    5.  $I(\sigma^2) = \frac{1}{2\sigma^4}$ .    9.  $\sqrt{\pi/2}|X|$ ,  $(\pi/2 - 1)\sigma^2$ .

### Section 8.9

7. (a) For  $\alpha(m-1) + 2\beta(n-1) = 1$ . (b)  $\alpha = \frac{1}{m+n-2}$ ,  $\beta = \frac{1}{2(m+n-2)}$ .    9.  $\frac{Y}{2 \left[ \frac{s_n^2}{n-1} \right]^{1/2}}$ .    11.  $\bar{X}_n - c \left[ \frac{s_n^2}{n(n-1)} \right]^{1/2}$ , where  $c$  is the 0.99 quantile of the  $t$  distribution with  $n-1$  degrees of freedom.    13. (a)  $(\mu_1 - 1.96v_1, \mu_1 + 1.96v_1)$ , where  $\mu_1$  and  $v_1$  are given by Eqs. (7.3.1) and (7.3.2).    15. Normal with mean  $\theta$  and variance  $\theta^2/n$ .    21. (c) Normal with mean  $1/\theta$  and variance  $1/[n\theta^3]$ .

## Chapter 9

### Section 9.1

1. (a)  $\pi(\beta|\delta) = e^{-\beta}$ ; (b)  $e^{-1}$ .  
 3. (a)  $\pi(0) = 1$ ,  $\pi(0.1) = 0.3941$ ,  $\pi(0.2) = 0.1558$ ,  $\pi(0.3) = 0.3996$ ,  $\pi(0.4) = 0.7505$ ,  $\pi(0.5) = 0.9423$ ,  $\pi(0.6) = 0.9935$ ,  $\pi(0.7) = 0.9998$ ,  $\pi(0.8) = 1.0000$ ,  $\pi(0.9) = 1.0000$ ,  $\pi(1) = 1.0000$ ; (b) 0.1558.    5. (a) Simple; (b) Composite; (c) Composite; (d) Composite.    9.  $T = \mu_0 - \bar{X}_n$ .    11. (a)  $c_1 < 0$ ,  $c_2 = 6$ ; (b) 0.0994.    13. 3    15.  $1-x$ , if  $0 \leq x \leq 1$ ; 0, if  $x > 1$ .    19.  $(-\infty, \bar{x}_n + \sigma' n^{-1/2} T_{n-1}^{-1} (1 - \alpha_0))$ .

### Section 9.2

1. Reject  $H_0$  if  $X = 1$ ; don't reject  $H_0$  if  $X = 0$ .    3. (b) 1.    5. (a) Reject  $H_0$  when  $\bar{X}_n > 5 - 1.645n^{-1/2}$ ; (b)  $\alpha(\delta) = 0.0877$ .  
 7. (b)  $c = 31.02$ .    9.  $\beta(\delta) = \left(\frac{1}{2}\right)^n$ .    11. (a) 0.6170; (b) 0.3173; (c) 0.0455; (d) 0.0027.    13. (a) Reject  $H_0$  if  $\exp(-T/2)/4 < 4/(2+T)^3$ ; (b) Do not reject  $H_0$ ; (d) Reject  $H_0$  if  $T > 13.28$ ; (e) Do not reject  $H_0$ .

### Section 9.3

7. The power function is 0.05 for every value of  $\theta$ .    9.  $c = 36.62$ .    13. (a) Reject  $H_0$  if  $\bar{X}_n \leq 9.359$ ; (b) 0.7636; (c) 0.9995.

### Section 9.4

1.  $c_1 = \mu_0 - 1.645n^{-1/2}$  and  $c_2 = \mu_0 + 1.645n^{-1/2}$ .    3.  $n = 11$ .    5.  $c_1 = -0.424$  and  $c_2 = 0.531$ .    11.  $c_1 = \mu_0 - 1.645n^{-1/2}$  and  $c_2 = \mu_0 + 1.645n^{-1/2}$ .

### Section 9.5

1. (a) Don't reject  $H_0$ ; (b) 0.0591.    3.  $U = -1.809$ ; do not reject the claim.    5. Don't reject  $H_0$ .    9. Since  $\frac{s_n^2}{4} < 16.92$ , don't reject  $H_0$ .    13.  $U = \frac{26}{3}$ ; the corresponding tail area is very small.    15.  $U = \frac{13}{3}$ ; the corresponding tail area is very small.

**Section 9.6**

1. Don't reject  $H_0$ .    3.  $c_1 = -1.782$  and  $c_2 = 1.782$ ;  $H_0$  will not be rejected.    5. Since  $U = -1.672$ , reject  $H_0$ .  
 7.  $-0.320 < \mu_1 - \mu_2 < 0.008$ .    11. (a) Do not reject  $H_0$ ; (b) Do not reject  $H_0$ .

**Section 9.7**

1. Reject the null hypothesis.    3.  $c = 1.228$ .    5. 1.    7. (a)  $\hat{\sigma}_1^2 = 7.625$  and  $\hat{\sigma}_2^2 = 3.96$ ; (b) Don't reject  $H_0$ .  
 9.  $c_1 = 0.321$  and  $c_2 = 3.77$ .    11.  $0.265V < r < 3.12V$ .    15. 0.8971.    19. (a) 0.0503; (b) 0.0498.

**Section 9.8**

1.  $X > 50.653$ .    3. Decide that failure was caused by a major defect if  $\sum_{i=1}^n X_i > \frac{4n + \log(0.64)}{\log(7/3)}$ .    11. (a) For the first choice,  $w_0 = w'$ ,  $w_1 = w''$ ,  $d_0 = d'$ ,  $d_1 = d''$ ,  $\Omega_0 = \Omega'$ , and  $\Omega_1 = \Omega''$ . Switch them all for the other case.

**Section 9.9**

1. (a)  $c = 1.96$ .    3. 0.0013.    5. (a) 1.681, 0.3021, 0.25; (b) 0.0464, 0.00126,  
 $3 \times 10^{-138}$ .

**Section 9.10**

1. Reject  $H_0$  if  $X \geq 2$ ,  $\alpha(\delta) = 0.5$ ,  $\beta(\delta) = 0.1563$ .    3. Reject  $H_0$  for  $X \leq 6$ .    5. Reject  $H_0$  for  $X > 1 - \alpha^{1/2}$ ,  
 $\beta(\delta) = (1 - \alpha^{1/2})^2$ .    7. Reject  $H_0$  for  $X \leq \frac{1}{2}[(1.4)^{1/2} - 1]$ .    9. Reject  $H_0$  for  $X \leq 0.01$  or  $X \geq 1$ ; power is 0.6627.  
 11. 0.0093.    17. (a) 1; (b)  $\frac{1}{\alpha}$ .    23. (a) Reject  $H_0$  if the measurement is at least  $5 + 0.1 \times \text{variance} \times \log(w_0 \xi_0 / [w_1 \xi_1])$ .

**Chapter 10****Section 10.1**

7.  $Q = 11.5$ ; reject the hypothesis.    9. (a)  $Q = 5.4$  and corresponding tail area is 0.25; (b)  $Q = 8.8$  and corresponding tail area is between 0.4 and 0.5.

**Section 10.2**

1. The results will depend on how one divides the real line into intervals, but the  $p$ -values for part (b) should be noticeably larger than the  $p$ -values for part (a).    3. (a)  $\hat{\theta}_1 = \frac{2N_1 + N_4 + N_5}{2n}$  and  $\hat{\theta}_2 = \frac{2N_2 + N_4 + N_6}{2n}$ . (b)  $Q = 4.37$  and corresponding tail area is 0.226.    5.  $\hat{\theta} = 1.5$  and  $Q = 7.56$ ; corresponding tail area lies between 0.1 and 0.2.

**Section 10.3**

1.  $Q = 21.5$ ; corresponding tail area is  $2.2 \times 10^{-5}$ .    5.  $Q = 8.6$ ; corresponding tail area lies between 0.025 and 0.05.

**Section 10.4**

1.  $Q = 18.8$ ; corresponding tail area is  $8.5 \times 10^{-4}$ .    3.  $Q = 18.9$ ; corresponding tail area is between 0.1 and 0.05.    5. Correct value of  $Q$  is 7.2, for which the corresponding tail area is less than 0.05.

**Section 10.5**

7. (b)

		<b>Proportion helped</b>
	Older subjects	Younger subjects
Treatment I	0.433	0.700
Treatment II	0.400	0.667

(c)

<b>Proportion helped</b>	
All subjects	
Treatment I	0.500
Treatment II	0.600

**Section 10.6**

3.  $D_n^* = 0.25$ ; corresponding tail area is 0.11.      5.  $D_n^* = 0.15$ ; corresponding tail area is 0.63.      7.  $D_n^* = 0.065$ ; corresponding tail area is approximately 0.98.      9.  $D_{mn} = 0.27$ ; corresponding tail area is 0.39.      11.  $D_{mn} = 0.50$ ; corresponding tail area is 0.008.

**Section 10.7**

1. (a) 22.17; (b) 20.57, 22.02, 22.00, 22.00; (c) 22.10; (d) 22.00.      3. 0.575.      5. M.S.E.  $(\bar{X}_n) = 0.025$  and M.S.E.  $(\tilde{X}_n) = 0.028$ .      13. 1.      17. Normal, with mean equal to the IQR of the distribution  $(\theta_{3/4} - \theta_{1/4})$  and variance  $[4nf(\theta_{1/4})^2]^{-1}$ .

**Section 10.8**

3.  $U = 3.447$ ; corresponding (two-sided) tail area is 0.003.      5.  $D_{mn} = 0.5333$ ; corresponding tail area is 0.010.

**Section 10.9**

1. (141, 175).      3. Any level greater than 0.005, the smallest probability given in the table in this book.      5. Do not reject the hypothesis.      9.  $|a| > \frac{1}{2}(6.635n)^{1/\theta}$ .      15. Normal, with mean  $\left(\frac{1}{2}\right)^{1/\theta}$  and variance  $\frac{1}{n\theta^2 24^{1/\theta}}$ .      17. (a)  $0.031 < \alpha < 0.994$ . (b)  $\sigma < 0.447$  or  $\sigma > 2.237$ .      19. Uniform on the interval  $[y_1, y_3]$ .

**Chapter 11****Section 11.1**

5.  $y = -1.670 + 1.064x$ .      7. (a)  $y = 40.893 + 0.548x$ ; (b)  $y = 38.483 + 3.440x - 0.643x^2$ .      9.  $y = 3.7148 + 1.1013x_1 + 1.8517x_2$ .      11. The sum of the squares of the deviations of the observed values from the fitted curve is smaller in Exercise 10.

**Section 11.2**

7. (a)  $-0.7861, 0.6850, 0.9377$ ; (b)  $0.2505\sigma^2, 0.0277\sigma^2$ ; (c)  $-0.775$       9.  $c_1 = 3\bar{x}_n = 6.99$ .      11.  $x = \bar{x}_n = 2.33$ .      13.  $-0.891$ .      15.  $c_1 = -\bar{x}_n = -2.25$ .      17.  $x = \bar{x}_n = 2.25$ .

**Section 11.3**

1. Since  $U_0 = -6.695$ , reject  $H_0$ .      3. Since  $U_1 = -6.894$ , reject  $H_0$ .      5. Since  $|U_{01}| = 0.664$ , don't reject  $H_0$ .      9. Since  $U^2 = 24.48$ , reject  $H_0$ .      11.  $0.246 < \beta_2 < 0.624$ .      13.  $0.284 < y < 0.880$ .      17.  $10(\beta_1 - 0.147)^2 + 10.16(\beta_2 - 0.435)^2 + 8.4(\beta_1 - 0.147)(\beta_2 - 0.435) < 0.503$ .      19.  $C = 1/(n - 2)$ .      25. (a)  $\beta_0 + \beta_1 x_i \pm T_{n-2}^{-1}(1 - \alpha_0/4)\sigma' \left[ \frac{1}{n} + \frac{(x_i - \bar{x}_n)^2}{s_x^2} \right]^{1/2}$ ; (b)  $\alpha(x) = \frac{x - x_1}{x_0 - x_1}$ .

**Section 11.4**

5. (a)  $12.21(\beta_1 - 0.4352)$  has the  $t$  distribution with eight degrees of freedom;  
(b)  $11.25(\beta_0 + \beta_1 - 0.5824)$  has the  $t$  distribution with eight degrees of freedom.

**Section 11.5**

5.  $\hat{\beta} = 5.126$ ,  $\hat{\sigma}^2 = 16.994$ , and  $\text{Var}(\hat{\beta}) = 0.0150\sigma^2$ .    7.  $\hat{\beta}_0 = -0.744$ ,  $\hat{\beta}_1 = 0.616$ ,  $\hat{\beta}_2 = 0.013$ ,  $\hat{\sigma}^2 = 0.937$ .    9.  $U_3 = 0.095$ ; corresponding tail area is greater than 0.90.    11.  $R^2 = 0.644$ .    13.  $\text{Var}(\hat{\beta}_0) = 222.7\sigma^2$ ,  $\text{Var}(\hat{\beta}_1) = 0.1355\sigma^2$ ,  $\text{Var}(\hat{\beta}_2) = 0.0582\sigma^2$ ,  $\text{Cov}(\hat{\beta}_0, \hat{\beta}_1) = 4.832\sigma^2$ ,  $\text{Cov}(\hat{\beta}_0, \hat{\beta}_2) = -3.598\sigma^2$ ,  $\text{Cov}(\hat{\beta}_1, \hat{\beta}_2) = -0.0792\sigma^2$ .    15.  $U_2 = 4.319$ ; corresponding tail area is less than 0.01.    21. The value of the  $F$  statistic with two and seven degrees of freedom is 1.615; corresponding tail area is greater than 0.05.    25. 87.    29. 0.893.

**Section 11.6**

5.  $U^2 = 13.09$ ; corresponding tail area is less than 0.025.

**Section 11.7**

5.  $\mu = 3.25$ ,  $\alpha_1 = -2$ ,  $\alpha_2 = 3$ ,  $\alpha_3 = -1$ ,  $\beta_1 = 1.75$ ,  $\beta_2 = -2.25$ ,  $\beta_3 = -1.25$ ,  $\beta_4 = 1.75$ .    13.  $\hat{\sigma}^2 = 1.9647$ .    15.  $U_B^2 = 4.664$ ; corresponding tail area is between 0.05 and 0.025.

**Section 11.8**

3. (a)  $\mu = 9$ ,  $\alpha_1 = -3$ ,  $\alpha_2 = 3$ ,  $\beta_1 = -1.5$ ,  $\beta_2 = 1.5$ ,  $\gamma_{11} = \gamma_{22} = \frac{1}{2}$ ,  $\gamma_{12} = \gamma_{21} = -\frac{1}{2}$ ; (b)  $\mu = 5$ ,  $\alpha_1 = -\frac{1}{2}$ ,  $\alpha_2 = \frac{1}{2}$ ,  $\beta_1 = -\frac{3}{2}$ ,  $\beta_2 = \frac{3}{2}$ ,  $\gamma_{11} = \gamma_{12} = \gamma_{21} = \gamma_{22} = 0$ ; (c)  $\mu = 3\frac{1}{4}$ ,  $\alpha_1 = -2$ ,  $\alpha_2 = 3$ ,  $\alpha_3 = -1$ ,  $\beta_1 = 1\frac{3}{4}$ ,  $\beta_2 = -2\frac{1}{4}$ ,  $\beta_3 = -1\frac{1}{4}$ ,  $\beta_4 = 1\frac{3}{4}$ ,  $\gamma_{ij} = 0$  for all values of  $i$  and  $j$ ; (d)  $\mu = 5$ ,  $\alpha_1 = -2\frac{1}{2}$ ,  $\alpha_2 = 0$ ,  $\alpha_3 = 2\frac{1}{2}$ ,  $\beta_1 = -3$ ,  $\beta_2 = -1$ ,  $\beta_3 = 1$ ,  $\beta_4 = 3$ ,  $\gamma_{11} = 1\frac{1}{2}$ ,  $\gamma_{12} = \frac{1}{2}$ ,  $\gamma_{13} = -\frac{1}{2}$ ,  $\gamma_{14} = -1\frac{1}{2}$ ,  $\gamma_{21} = \gamma_{22} = \gamma_{23} = \gamma_{24} = 0$ ,  $\gamma_{31} = -1\frac{1}{2}$ ,  $\gamma_{32} = -\frac{1}{2}$ ,  $\gamma_{33} = \frac{1}{2}$ ,  $\gamma_{34} = 1\frac{1}{2}$ .    11.  $U_{AB}^2 = 0.7047$ ; corresponding tail area is much larger than 0.05.    13.  $U_B^2 = 9.0657$ ; corresponding tail area is less than 0.025.    15. The value of the appropriate statistic having the  $t$  distribution with 12 degrees of freedom is 2.8673; the corresponding tail area is between 0.01 and 0.005.    19.  $\alpha_0 + (1 - \alpha_0)\beta_0$ .

**Section 11.9**

1. (a) (0.01996, 0.02129); (b) Reject the null hypothesis; (c) (25.35, 26.16).    3.  $E(T) = \frac{\rho\sigma_2}{\sigma_1}$ ;  $\text{Var}(T) = \frac{(1-\rho^2)\sigma_2^2}{\sum_{i=1}^n(x_i - \bar{x}_n)^2}$ .

7.  $\beta_2 = \frac{\sum_{i=1}^n(y'_i - x'_i) \pm \left\{ \left[ \sum_{i=1}^n(y'_i - x'_i)^2 \right]^2 + 4\left( \sum_{i=1}^n x'_i y'_i \right)^2 \right\}^{1/2}}{2 \sum_{i=1}^n x'_i y'_i}$ ,  $\beta_1 = \bar{y}_n - \beta_2 \bar{x}_n$ , where  $x'_i = x_i - \bar{x}_n$  and  $y'_i = y_i - \bar{y}_n$ . Either the plus sign or the minus sign in  $\beta_2$  should be used, depending on whether the optimal line has a positive or a negative slope.    9.  $\frac{1}{n} \sum_{i=1}^k n_i \left[ v_i^2 + (\bar{x}_{i+} - \bar{x}_{++})^2 \right]$ .

11.  $\frac{1}{IJ(K-1)} \sum_{i,j,k} (Y_{ijk} - \bar{Y}_{ijk})^2$ .    13. Let  $U = \frac{IJ(K-1)(S_A^2 + S_B^2 + S_{AB}^2)}{(IJ-1)S_{\text{Resid}}^2}$ . Reject  $H_0$  if  $U \geq c$ . Under  $H_0$ ,  $U$  has an  $F$  distribution with  $IJ - 1$  and  $IJ(K - 1)$  degrees of freedom.    15.  $\hat{\theta}_1 = \frac{1}{4}(Y_1 + Y_2) + \frac{1}{2}Y_3$ ,  $\hat{\theta}_2 = \frac{1}{4}(Y_1 + Y_2) - \frac{1}{2}Y_3$ ,  $\hat{\sigma}^2 = \frac{1}{3}[(Y_1 - \hat{\theta}_1 - \hat{\theta}_2)^2 + (Y_2 - \hat{\theta}_1 - \hat{\theta}_2)^2 + (Y_3 - \hat{\theta}_1 + \hat{\theta}_2)^2]$ , where  $Y_1 = W_1$ ,  $Y_2 = W_2 - 5$ ,  $Y_3 = \frac{1}{2}W_3$ ;  $(\hat{\theta}_1, \hat{\theta}_2)$  and  $\hat{\sigma}^2$  are independent;  $(\hat{\theta}_1, \hat{\theta}_2)$  has a bivariate normal distribution with mean vector  $(\theta_1, \theta_2)$  and covariance matrix  $\begin{bmatrix} \frac{3}{8} & -\frac{1}{8} \\ \frac{1}{8} & \frac{3}{8} \end{bmatrix} \sigma^2$ ;

$\frac{3\hat{\sigma}^2}{\sigma^2}$  has the  $\chi^2$  distribution with one degree of freedom.    17.  $\text{Var}(\epsilon_i) = \left[ 1 - \frac{1}{n} - \frac{(x_i - \bar{x}_n)^2}{\sum_{j=1}^n(x_j - \bar{x}_n)^2} \right] \sigma^2$ .    19.  $\mu = \bar{\theta} + \bar{\psi}$ ;

$\alpha_i = \theta_i - \bar{\theta}$ ; and  $\beta_j = \psi_j - \bar{\psi}$ , where  $\bar{\theta} = \frac{\sum_{i=1}^I v_i \theta_i}{v_+}$  and  $\bar{\psi} = \frac{\sum_{j=1}^J w_j \psi_j}{w_+}$ .

23.

$$\begin{aligned}
\mu &= \bar{\theta}_{+++}, \\
\alpha_i^A &= \bar{\theta}_{i++} - \bar{\theta}_{+++}, \\
\alpha_j^B &= \bar{\theta}_{+j+} - \bar{\theta}_{+++}, \\
\alpha_k^C &= \bar{\theta}_{++k} - \bar{\theta}_{+++}, \\
\beta_{ij}^{AB} &= \bar{\theta}_{ij+} - \bar{\theta}_{i++} - \bar{\theta}_{+j+} + \bar{\theta}_{+++}, \\
\beta_{ik}^{AC} &= \bar{\theta}_{i+k} - \bar{\theta}_{i++} - \bar{\theta}_{++k} + \bar{\theta}_{+++}, \\
\beta_{jk}^{BC} &= \bar{\theta}_{+jk} - \bar{\theta}_{+j+} - \bar{\theta}_{++k} + \bar{\theta}_{+++}, \\
\gamma_{ijk} &= \theta_{ijk} - \bar{\theta}_{ij+} - \bar{\theta}_{i+k} - \bar{\theta}_{+jk} + \bar{\theta}_{i++} + \bar{\theta}_{+j+} + \bar{\theta}_{++k} - \bar{\theta}_{+++}.
\end{aligned}$$

## Chapter 12

*Note: Answers to exercises that involve simulation are themselves only simulation approximations. Your answers will be different.*

### Section 12.1

5. (c)  $f(x, y) = 0.4^3 x \exp(-0.4[x + y])$  for  $x, y > 0$ ,  $\int_0^\infty \int_x^\infty 0.4^3 x \exp(-0.4[x + y]) dy dx$ .

### Section 12.2

5. (b) The  $k = 2$  trimmed mean probably has the smallest M.S.E.    9. 0.2599.    11.  $(\lambda_{x1}\alpha_{x1}/\beta_{x1})^{1/2}(\mu_x - \mu_{x1})$  has the  $t$  distribution with  $2\alpha_{x1}$  degrees of freedom, and similarly for  $\mu_y$ .    15. (a)  $r - [\log \psi(1)]/u$ .

### Section 12.3

1. (a) Approximation = 0.0475, sim. std. err. = 0.0018; (b)  $v = 484$ .    11.  $\chi^2$  distribution with  $n - p$  degrees of freedom divided by  $S_{\text{Resid}}^2$ .

### Section 12.4

7. (a)  $Z = 0.8343$ , sim. std. err. = 0.00372; (b)  $Z' = 0.8386$ , sim. std. err. = 0.00003.    17. Look at Exercises 3, 4, 6, and 10.

### Section 12.5

5. Approximation = 0.2542, sim. std. err. =  $4.71 \times 10^{-4}$ .    7. 826.8, 843.3, 783.3.    9. Means: -0.965,  $0.02059$ ,  $1.199 \times 10^{-5}$ ; std. devs.:  $2.448 \times 10^{-2}$ ,  $1.207 \times 10^{-4}$ ,  $8.381 \times 10^{-6}$ .    11. 0.33, 0.29, 0.30, 0.31, 0.34, 0.30, 0.62, 0.51, 0.98, 0.83.    13. (b) Both  $\alpha_0$  and  $\beta_0$  must be the same in both priors. In addition,  $b_0 = \beta_0/\lambda_0$  and  $a_0 = \alpha_0$ ; (d) Approximation = (154.67, 215.79), sim. std. err. of endpoints =  $10.8v^{-1/2}$  (based on 10 Markov chains of length  $v$  each).    15. (a) Conditional on everything else  $X_{n+i}$  has the d.f.  $F(x) = [1 - e^{-\theta x}]/[1 - e^{-\theta c}]$ , for  $0 < x \leq c$ ; (b) Conditional on everything else  $X_{n+i}$  has the d.f.  $F(x) = 1 - e^{-\theta(x-c)}$ , for  $x \geq c$ .

### Section 12.6

3.  $\sum_{i=(n+1)/2}^n \binom{n}{i} (\ell/n)^n (1 - \ell/n)^{n-i}$ , where  $\ell$  is the number of observations in the original sample that equal the smallest value.    5. (a) -1.684; (b) About 50,000.    7. (a) 0.107; (b) 1.763; (c) 0.0183.    9. (a)  $4.868 \times 10^{-4}$ ; (b) -0.0023; (c)  $2.423 \times 10^{-5}$  and  $6.920 \times 10^{-4}$ .    11. (b) -0.2694 and 0.5458.

**Section 12.7**

5. (b) Approximation = 0.581, sim. std. err. = 0.0156; (c) 16,200.     7. (a) 0.9 quantiles around 4.0, 0.95 quantiles around 5.2, 0.99 quantiles around 8; (b) The differences are on the same order of magnitude as Monte Carlo variability; (c) 0.123.
9. (a)  $\exp\left(-\beta\phi_0 - \frac{u_0(\psi-\psi_0)^2}{2} - \sum_{i=1}^p \tau_i \left[\beta + \frac{n_i(\mu_i-\bar{y}_i)^2+w_i+\lambda_0(\mu_i-\psi)^2}{2}\right]\right)$   
 $\times \beta^{p\alpha_0+\epsilon_0-1} \prod_{i=1}^p \tau_i^{\alpha_0+[n_i+1]/2-1}$ ; (b)  $\beta$  has a gamma distribution with parameters  $p\alpha_0 + \epsilon_0$  and  $\phi_0 + \sum_{i=1}^p \tau_i$ ; (c) Very close to the values in Table 12.6.
11. (c) The proportions are rather close to the nominal values.

## Discrete Distributions

	Bernoulli with parameter $p$	Binomial with parameters $n$ and $p$
<b>p.f.</b>	$f(x) = p^x(1-p)^{1-x}$ , for $x = 0, 1$	$f(x) = \binom{n}{x} p^x(1-p)^{n-x}$ , for $x = 0, \dots, n$
<b>Mean</b>	$p$	$np$
<b>Variance</b>	$p(1-p)$	$np(1-p)$
<b>m.g.f.</b>	$\psi(t) = pe^t + 1 - p$	$\psi(t) = (pe^t + 1 - p)^n$

	Uniform on the integers $a, \dots, b$	Hypergeometric with parameters $A, B$ , and $n$
<b>p.f.</b>	$f(x) = \frac{1}{b-a+1}$ , for $x = a, \dots, b$	$f(x) = \frac{\binom{A}{x}\binom{B}{n-x}}{\binom{A+B}{n}}$ , for $x = \max\{0, n-b\}, \dots, \min\{n, A\}$
<b>Mean</b>	$\frac{b+a}{2}$	$\frac{nA}{A+B}$
<b>Variance</b>	$\frac{(b-a)(b-a+2)}{12}$	$\frac{nAB}{(A+B)^2} \frac{A+B-n}{A+B-1}$
<b>m.g.f.</b>	$\psi(t) = \frac{e^{(b+1)t} - e^{at}}{(e^t - 1)(b-a+1)}$	Nothing simpler than $\psi(t) = \sum_x f(x)e^{tx}$

	Geometric with parameter $p$	Negative binomial with parameters $r$ and $p$
<b>p.f.</b>	$f(x) = p(1-p)^x$ , for $x = 0, 1, \dots$	$f(x) = \binom{r+x-1}{x} p^r (1-p)^x$ , for $x = 0, 1, \dots$
<b>Mean</b>	$\frac{1-p}{p}$	$\frac{r(1-p)}{p}$
<b>Variance</b>	$\frac{1-p}{p^2}$	$\frac{r(1-p)}{p^2}$
<b>m.g.f.</b>	$\psi(t) = \frac{p}{1-(1-p)e^t}$ , for $t < \log(1/[1-p])$	$\psi(t) = \left(\frac{p}{1-(1-p)e^t}\right)^r$ , for $t < \log(1/[1-p])$

	Poisson with mean $\lambda$	Multinomial with parameters $n$ and $(p_1, \dots, p_k)$
<b>p.f.</b>	$f(x) = e^{-\lambda} \frac{\lambda^x}{x!}$ , for $x = 0, 1, \dots$	$f(x_1, \dots, x_k) = \binom{n}{x_1, \dots, x_k} p_1^{x_1} \cdots p_k^{x_k}$ , for $x_1 + \cdots + x_k = n$ and all $x_i \geq 0$
<b>Mean</b>	$\lambda$	$E(X_i) = np_i$ , for $i = 1, \dots, k$
<b>Variance</b>	$\lambda$	$\text{Var}(X_i) = np_i(1-p_i)$ , $\text{Cov}(X_i, X_j) = -np_i p_j$ , for $i, j = 1, \dots, k$
<b>m.g.f.</b>	$\psi(t) = e^{\lambda(e^t - 1)}$	Multivariate m.g.f. can be defined, but is not defined in this text.

## Continuous Distributions

	Beta with parameters $\alpha$ and $\beta$	Uniform on the interval $[a, b]$
<b>p.d.f.</b>	$f(x) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)}x^{\alpha-1}(1-x)^{\beta-1}$ , for $0 < x < 1$	$f(x) = \frac{1}{b-a}$ , for $a < x < b$
<b>Mean</b>	$\frac{\alpha}{\alpha+\beta}$	$\frac{a+b}{2}$
<b>Variance</b>	$\frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)}$	$\frac{(b-a)^2}{12}$
<b>m.g.f.</b>	Not available in simple form	$\psi(t) = \frac{e^{-at}-e^{-bt}}{t(b-a)}$

	Exponential with parameter $\beta$	Gamma with parameters $\alpha$ and $\beta$
<b>p.d.f.</b>	$f(x) = \beta e^{-\beta x}$ , for $x > 0$	$f(x) = \frac{\beta^\alpha}{\Gamma(\alpha)} x^{\alpha-1} e^{-\beta x}$ , for $x > 0$
<b>Mean</b>	$\frac{1}{\beta}$	$\frac{\alpha}{\beta}$
<b>Variance</b>	$\frac{1}{\beta^2}$	$\frac{\alpha}{\beta^2}$
<b>m.g.f.</b>	$\psi(t) = \frac{\beta}{\beta-t}$ , for $t < \beta$	$\psi(t) = \left(\frac{\beta}{\beta-t}\right)^\alpha$ , for $t < \beta$

	Normal with mean $\mu$ and variance $\sigma^2$	Bivariate normal with means $\mu_1$ and $\mu_2$ , variances $\sigma_1^2$ and $\sigma_2^2$ , and correlation $\rho$
<b>p.d.f.</b>	$f(x) = \frac{1}{(2\pi)^{1/2}\sigma} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right)$	Formula is too large to print here. See Eq. (5.10.2) on page 338.
<b>Mean</b>	$\mu$	$E(X_i) = \mu_i$ , for $i = 1, 2$
<b>Variance</b>	$\sigma^2$	Covariance matrix: $\begin{pmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{pmatrix}$
<b>m.g.f.</b>	$\psi(t) = \exp\left(\mu t + \frac{t^2\sigma^2}{2}\right)$	Bivariate m.g.f. can be defined, but is not defined in this text.

## Continuous Distributions

	Lognormal with parameters $\mu$ and $\sigma^2$	$F$ with $m$ and $n$ degrees of freedom
<b>p.d.f.</b>	$f(x) = \frac{1}{(2\pi)^{1/2}\sigma_x} \exp\left(-\frac{(\log(x)-\mu)^2}{2\sigma^2}\right),$ for $x > 0$	$f(x) = \frac{\Gamma\left[\frac{1}{2}(m+n)\right]m^{m/2}n^{n/2}}{\Gamma\left(\frac{1}{2}m\right)\Gamma\left(\frac{1}{2}n\right)} \cdot \frac{x^{(m/2)-1}}{(mx+n)^{(m+n)/2}},$ for $x > 0$
<b>Mean</b>	$e^{\mu+\sigma^2/2}$	$\frac{n}{n-2}$ , if $n > 2$
<b>Variance</b>	$e^{2\mu+\sigma^2}[e^{\sigma^2}-1]$	$\frac{2n^2(m+n-2)}{m(n-2)^2(n-4)}$ , if $n > 4$
<b>m.g.f.</b>	Not finite for $t > 0$	Not finite for $t > 0$

	$t$ with $m$ degrees of freedom	$\chi^2$ with $m$ degrees of freedom
<b>p.d.f.</b>	$f(x) = \frac{\Gamma\left(\frac{m+1}{2}\right)}{(m\pi)^{1/2}\Gamma\left(\frac{m}{2}\right)} \left(1 + \frac{x^2}{m}\right)^{-(m+1)/2}$	$f(x) = \frac{1}{2^{m/2}\Gamma(m/2)}x^{(m/2)-1}e^{-x/2}$ , for $x > 0$
<b>Mean</b>	0, if $m > 1$	$m$
<b>Variance</b>	$\frac{m}{m-2}$ , if $m > 2$	$2m$
<b>m.g.f.</b>	Not finite for $t \neq 0$	$\psi(t) = (1-2t)^{-m/2},$ for $t < 1/2$

	Cauchy centered at $\mu$	Pareto with parameters $x_0$ and $\alpha_0$
<b>p.d.f.</b>	$f(x) = \frac{1}{\pi(1+[x-\mu]^2)}$	$f(x) = \frac{\alpha x_0^\alpha}{x^{\alpha+1}}$ , for $x > x_0$
<b>Mean</b>	Does not exist	$\frac{\alpha x_0}{\alpha-1}$ , if $\alpha > 1$
<b>Variance</b>	Does not exist	$\frac{\alpha x_0^2}{(\alpha-1)^2(\alpha-2)}$ , if $\alpha > 2$
<b>m.g.f.</b>	Not finite for $t \neq 0$	Not finite for $t > 0$

## Corrections to *Probability and Statistics* (Fourth Edition)

- p. 401, last displayed equation: “0.1154” should read “0.1154” (11/15/10)
- p. 401, last displayed equation: “(1.12)” should read “(0.4116)” (11/15/10)
- p. 536, next line after (9.1.8) “Example 6.5.15” should read “Example 7.5.7” (11/15/10)
- p. 549 Exercise 11: “ $\delta_c$ ” should read “ $\delta$ ” at the ends of parts b and c.
- p. 591, Example 9.6.4, line 2: “ $\psi =$ ” should read “ $|\psi| =$ ”. (11/15/10)
- p. 612, 2 and 4 lines after (9.8.16): In both places, “ $T_{n-1}^{-1}(1 - \alpha_0)$ ” should read “ $-T_{n-1}^{-1}(1 - \alpha_0)$ ” (11/15/10)
- p. 682, first line of “Ties” section: “signed ranks test” should read “ranks test”. (11/15/10)
- p. 683, Eq. (10.8.6): The correct formula is

$$\begin{aligned}\text{Var}(S) &= mn \left( \Pr(X_1 \geq Y_1) - (m+n-1) \Pr(X_1 \geq Y_1)^2 \right. \\ &\quad \left. + (n-1) \Pr(X_1 \geq Y_1, X_1 \geq Y_2) + (m-1) \Pr(X_1 \geq Y_1, X_2 \geq Y_1) \right).\end{aligned}$$

- p. 685, Exercise 15: There are a few errors in the statement of the problem. The corrected exercise is given here:

15. Consider again the conditions of Exercise 1. This time, let  $D_i = X_i - Y_i$ . Wilcoxon (1945) developed the following test of the hypotheses (10.8.7). Order the absolute values  $|D_1|, \dots, |D_n|$  from smallest to largest, and assign ranks from 1 to  $n$  to the values. Then  $S_W$  is set equal to the sum of all the ranks of those  $|D_i|$  such that  $D_i > 0$ . If the distribution of  $D_i$  is symmetric around 0, then the mean and variance of  $S_W$  are

$$E(S_W) = \frac{n(n+1)}{4}, \tag{10.8.8}$$

$$\text{Var}(S_W) = \frac{n(n+1)(2n+1)}{24}. \tag{10.8.9}$$

The test rejects  $H_0$  if  $S_W \geq c$ , where  $c$  is chosen to make the test have level of significance  $\alpha_0$ . This test is called the *Wilcoxon signed ranks test*. If  $n$  is large, a normal distribution approximation allows us to use  $c = E(S_W) + \Phi^{-1}(1 - \alpha_0)\text{Var}(S_W)^{1/2}$ .

- a. Let  $W_i = 1$  if the  $|D_j|$  that gets rank  $i$  has  $D_j > 0$  and  $W_i = 0$  if not. Show that  $S_W = \sum_{i=1}^n iW_i$ .

- b.** Prove that  $E(S_W)$  is as stated in Eq. (10.8.8) under the assumption that the distribution of  $D_i$  is symmetric around 0. *Hint:* You may wish to use Eq. (4.7.13).
- c.** Prove that  $\text{Var}(S_W)$  is as stated in Eq. (10.8.9) under the assumption that the distribution of  $D_i$  is symmetric around 0. *Hint:* You may wish to use Eq. (4.7.14).
  
- p. 703, 3rd displayed equation: “0.382” should read “−0.382” (11/15/10)
  - p. 704, Example 11.2.5, line 3: “−81.049” should read “−81.06” (11/15/10)
  - p. 708, first line after (11.3.2): “ $\sum_{j=1} a_{1j}a_{2j}$ ” should read “ $\sum_{j=1}^n a_{1j}a_{2j}$ ”. (11/15/10)
  - p. 722, Eq. (11.3.30), end of first line: “ $\beta_{\beta_1}^*$ ” should read “ $\beta_1^*$ ”. (11/15/10)
  - p. 728, Exercise 22: The problem should have asked for the regression of logarithm of 1980 price on the logarithm of 1970 price. It can be solved either as stated here or as stated in the text, but the regression on logarithm of 1970 price makes more sense. (11/15/10)
  
- p. 731, end of first displayed equation: “ $-\frac{n\bar{x}_n s_x^2}{\tau \sum_{i=1}^n x_i^2}$ ” should read “ $-\frac{\tau n\bar{x}_n s_x^2}{\sum_{i=1}^n x_i^2}$ ”. (11/15/10)
  - p. 731, two lines after (11.4.6): “ $-\tau^2/2$ ” should read “ $-\tau/2$ ”. (11/15/10)
  - p. 732, first line after (11.4.7): “15” should read “14”. (11/15/03)
  - p. 734, Example 11.4.4, line 6: “7.191” should read “7.181”. (11/15/10)
  - p. 741, Example 11.5.3, end of first displayed equation: “144.1” should read “172.3”. (11/15/10)
  - p. 743, first line after the end of Theorem 11.5.3: “ $j = 1, \dots, n$ ” should read “ $j = 0, \dots, p - 1$ ”. (11/15/10)
  - p. 749, first displayed equation: “ $z_{i0}\beta_0 - \dots - z_{ip-1}\beta_{p-1}$ ” should read “ $z_{i0}\hat{\beta}_0 - \dots - z_{ip-1}\hat{\beta}_{p-1}$ ”. (11/15/10)
  - p. 752, second line of “Summary” section: “ $z_{i0}\hat{\beta}_0 + \dots + z_{ip-1}\hat{\beta}_{p-1}$ ” should read “ $z_{i0}\beta_0 + \dots + z_{ip-1}\beta_{p-1}$ ”. (11/15/10)
  - p. 752, Exercise 2, line 2: “ $S^2$  has the  $\chi^2$ ” should be “ $S^2/\sigma^2$  has the  $\chi^2$ ”. (11/15/10)
  - p. 758, line 5: “Eq. (11.6.8) has the” should read “Eq. (11.6.8), when divided by  $\sigma^2$ , has the”. (11/15/10)
  - p. 761, Exercise 2, displayed equation: Both places where  $\sigma^2$  appears in a denominator should be  $\sigma$ . (11/15/10)
  - p. 763, Exercise 14(a): “ $\sum_{i=1}^p \alpha_i$ ” should be “ $\sum_{i=1}^p n_i \alpha_i$ ” (11/15/10)

- p. 805, Example 12.3.2, first row of last displayed equation: “ $f(\exp[(y_1^2 + y_2^2)/2])$ ,” should read “ $f(\exp[-(y_1^2 + y_2^2)/2])$ ,”. (11/15/10)
- p. 812, Example 12.3.10, last line: “is” should read “if”. (11/15/10)
- p. 832–834, the numerical part of Example 12.5.6 suffered from an error in the input data. The correct analysis changes the conclusions stated in the text. Corrected text can be found by following the link to more extensive corrections at the top of the web page.
- p. 838, Exercise 12, line 5: “variance  $\gamma_0$ ” should read “precision  $\gamma_0$ ” (11/15/10)
- p. 838, Exercise 13(a): The “1/2” exponent should be “−1/2” in the displayed formula. (11/15/10)
- p. 838–839, Exercise 14: Add the text “The prior hyperparameters are  $\alpha_0 = 0.5$ ,  $\mu_0 = 0$ ,  $\lambda_0 = 1$ , and  $\beta_0 = 0.5$ . (11/15/10)
- p. 839, Exercise 15 part a line 2: Delete the text “if  $X_{n+i} \leq c$ , then” (11/15/10)
- p. 839, Exercise 15 part b line 2: Delete the text “if  $X_{n+i} \geq c$ , then” (11/15/10)

As an example, use the hot dog calorie data from Example 11.6.2. In this example,  $p = 4$ . We shall use a prior distribution in which  $\lambda_0 = \alpha_0 = 1$ ,  $\beta_0 = 0.1$ ,  $u_0 = 0.001$ , and  $\psi_0 = 170$ . We use  $k = 6$  Markov chains and do  $m = 100$  burn-in simulations, which turn out to be more than enough to make the maximum of all nine  $F$  statistics less than  $1 + 0.44m$ . We then run each of the six Markov chains another 10,000 iterations. The samples from the posterior distribution allow us to answer any questions that we might have about the parameters, including some that we would not have been able to answer using the analysis done in Chapter 11. For example, the posterior means and standard deviations of some of the parameters are listed in Table 12.6. To see how different the variances are, we can estimate the probability that the variance of one group is at least 2.25 times as high as that of another group by computing the fraction of iterations  $\ell$  in which at least one  $\tau_i^{(\ell)}/\tau_j^{(\ell)} > 2.25$ . The result is 0.4, indicating that there is some chance that at least some of the variances are different. If the variances are different, the ANOVA calculations in Chapter 11 are not justified.

We can also address the question of how much difference there is between the  $\mu_i$ 's. For comparison, we shall do the same calculations that we did in Example 12.3.7. In 99 percent of the 60,000 simulations, at least one  $|\mu_i^{(\ell)} - \mu_j^{(\ell)}| > 26.35$ . In about one-half of the simulations, all  $|\mu_i^{(\ell)} - \mu_j^{(\ell)}| > 2.224$ . And in 99 percent of the simulations, the average of the differences was at least 13.78. Figure 12.9 contains a plot of the sample c.d.f.'s of the largest, smallest, and average of the six  $|\mu_i - \mu_j|$  differences. Careful examination of the results in this example shows that the four  $\mu_i$ 's appear to be closer together than we would have thought after the analysis of Example 12.3.7. This is typical of what occurs when we use a proper prior in a hierarchical model. In Example 12.3.7, the  $\mu_i$ 's were all independent, and they did not have a common unknown mean in the prior. In Example 12.5.6, the  $\mu_i$ 's all have a common prior distribution with mean  $\psi$ , which is an additional unknown parameter. The estimation of this additional parameter allows the posterior distributions of the  $\mu_i$ 's to be pulled toward a

Table 12.6 Posterior means and standard deviations for some parameters in Example 12.5.6

Type	<i>Beef</i>	<i>Meat</i>	<i>Poultry</i>	<i>Specialty</i>
$i$	1	2	3	4
$E(\mu_i \mathbf{y})$	156.6	158.3	120.5	159.6
$(Var(\mu_i \mathbf{y}))^{1/2}$	4.893	5.825	5.521	7.615
$E(1/\tau_i \mathbf{y})$	495.6	608.5	542.9	568.2
$(Var(1/\tau_i \mathbf{y}))^{1/2}$	166.0	221.2	201.6	307.4
$E(\psi \mathbf{y}) = 151.0$		$(Var(\psi \mathbf{y}))^{1/2} = 11.16$		

Figure 12.9 Sample c.d.f.'s of the maximum, average, and minimum of the six  $|\mu_i - \mu_j|$  differences for Example 12.5.6.

location that is near the average of all of the samples. With these data, the overall sample average is 147.60.  $\blacktriangleleft$

## Prediction

All of the calculations done in the examples of this section have concerned functions of the parameters. The sample from the posterior distribution that we obtain from Gibbs sampling can also be used to make predictions and form prediction intervals for future observations. The most straightforward way to make predictions is to simulate the future data conditional on each value of the parameter from the posterior sample. Although there are more efficient methods for predicting, this method is easy to describe and evaluate.

**Example 12.5.7 Calories in Hot Dogs.** In Example 12.5.6, we might be concerned with how different we should expect the calorie counts of two hot dogs to be. For example, let  $Y_1$  and  $Y_3$  be future calorie counts for hot dogs of the beef and poultry varieties, respectively. We can form a prediction interval for  $D = Y_1 - Y_3$  as follows. For each iteration  $\ell$ , let the simulated parameter vector be

$$\theta^{(\ell)} = (\mu_1^{(\ell)}, \mu_2^{(\ell)}, \mu_3^{(\ell)}, \mu_4^{(\ell)}, \tau_1^{(\ell)}, \tau_2^{(\ell)}, \tau_3^{(\ell)}, \tau_4^{(\ell)}, \psi^{(\ell)}, \beta^{(\ell)}).$$

For each  $\ell$ , simulate a beef hot dog calorie count  $Y_1^{(\ell)}$  having the normal distribution with mean  $\mu_1^{(\ell)}$  and variance  $1/\tau_1^{(\ell)}$ . Also simulate a poultry hot dog calorie count  $Y_3^{(\ell)}$  having the normal distribution with mean  $\mu_3^{(\ell)}$  and variance  $1/\tau_3^{(\ell)}$ . Then compute  $D^{(\ell)} = Y_1^{(\ell)} - Y_3^{(\ell)}$ . Sample quantiles of the values  $D^{(1)}, \dots, D^{(60000)}$  can be used to estimate quantiles of the distribution of  $D$ .

For example, suppose that we want a 90 percent prediction interval for  $D$ . We simulate 60,000  $D^{(\ell)}$  values as above and find the 0.05 and 0.95 sample quantiles to be  $-18.49$  and  $90.63$ , which are then the endpoints of our prediction interval. To assess how close the simulation estimators are to the actual quantiles of the distribution of  $D$ , we compute the simulation standard errors of the two endpoints. For the samples from each of the  $k = 6$  Markov chains, we can compute the sample 0.05 quantiles of our  $D$  values. We can then use these values as  $Z_1, \dots, Z_6$  in Eq. (12.5.1) to compute a value  $S$ . Our simulation standard error is then  $S/6^{1/2}$ . We can then repeat this for the sample 0.95 quantiles. For the two endpoints of our interval, the simulation standard errors are  $0.2228$  and  $0.4346$ , respectively. These simulation standard errors are fairly small compared to the length of the prediction interval.  $\blacktriangleleft$

R Code For Two Text Examples . . . . .	432

## Preface

This manual contains solutions to all of the exercises in *Probability and Statistics*, 4th edition, by Morris DeGroot and myself. I have preserved most of the solutions to the exercises that existed in the 3rd edition. Certainly errors have been introduced, and I will post any errors brought to my attention on my web page <http://www.stat.cmu.edu/mark/> along with errors in the text itself. Feel free to send me comments.

For instructors who are familiar with earlier editions, I hope that you will find the 4th edition at least as useful. Some new material has been added, and little has been removed. Assuming that you will be spending the same amount of time using the text as before, something will have to be skipped. I have tried to arrange the material so that instructors can choose what to cover and what not to cover based on the type of course they want. This manual contains commentary on specific sections right before the solutions for those sections. This commentary is intended to explain special features of those sections and help instructors decide which parts they want to require of their students. Special attention is given to more challenging material and how the remainder of the text does or does not depend upon it.

To teach a mathematical statistics course for students with a strong calculus background, one could safely cover all of the material for which one could find time. The Bayesian sections include 4.8, 7.2, 7.3, 7.4, 8.6, 9.8, and 11.4. One can choose to skip some or all of this material if one desires, but that would be ignoring one of the unique features of the text. The more challenging material in Sections 7.7–7.9, and 9.2–9.4 is really only suitable for a mathematical statistics course. One should try to make time for some of the material in Sections 12.1–12.3 even if it meant cutting back on some of the nonparametrics and two-way ANOVA. To teach a more modern statistics course, one could skip Sections 7.7–7.9, 9.2–9.4, 10.8, and 11.7–11.8. This would leave time to discuss robust estimation (Section 10.7) and simulation (Chapter 12). Section 3.10 on Markov chains is not actually necessary even if one wishes to introduce Markov chain Monte Carlo (Section 12.5), although it is helpful for understanding what this topic is about.

## Using Statistical Software

The text was written without reference to any particular statistical or mathematical software. However, there are several places throughout the text where references are made to what general statistical software might be able to do. This is done for at least two reasons. One is that different instructors who wish to use statistical software while teaching will generally choose different programs. I didn't want the text to be tied to a particular program to the exclusion of others. A second reason is that there are still many instructors of mathematical probability and statistics courses who prefer not to use any software at all.

Given how pervasive computing is becoming in the use of statistics, the second reason above is becoming less compelling. Given the free and multiplatform availability and the versatility of the environment *R*, even the first reason is becoming less compelling. Throughout this manual, I have inserted pointers to which *R* functions will perform many of the calculations that would formerly have been done by hand when using this text. The software can be downloaded for Unix, Windows, or Mac OS from <http://www.r-project.org/>

That site also has manuals for installation and use. Help is also available directly from within the *R* environment.

Many tutorials for getting started with *R* are available online. At the official *R* site there is the detailed manual: <http://cran.r-project.org/doc/manuals/R-intro.html> that starts simple and has a good table of contents and lots of examples. However, reading it from start to finish is *not* an efficient way to get started. The sample sessions should be most helpful.

One major issue with using an environment like *R* is that it is essentially programming. That is, students who have never programmed seriously before are going to have a steep learning curve. Without going into the philosophy of whether students should learn statistics without programming, the field is moving in the direction of requiring programming skills. People who want only to understand what a statistical analysis

is about can still learn that without being able to program. But anyone who actually wants to do statistics as part of their job will be seriously handicapped without programming ability. At the end of this manual is a series of heavily commented *R* programs that illustrate many of the features of *R* in the context of a specific example from the text.

Mark J. Schervish

**INSTRUCTOR'S  
SOLUTIONS MANUAL**

# Chapter 1

## Introduction to Probability

### 1.2 Interpretations of Probability

#### Commentary

It is interesting to have the students determine some of their own subjective probabilities. For example, let  $X$  denote the temperature at noon tomorrow outside the building in which the class is being held. Have each student determine a number  $x_1$  such that the student considers the following two possible outcomes to be equally likely:  $X \leq x_1$  and  $X > x_1$ . Also, have each student determine numbers  $x_2$  and  $x_3$  (with  $x_2 < x_3$ ) such that the student considers the following three possible outcomes to be equally likely:  $X \leq x_2$ ,  $x_2 < X < x_3$ , and  $X \geq x_3$ . Determinations of more than three outcomes that are considered to be equally likely can also be made. The different values of  $x_1$  determined by different members of the class should be discussed, and also the possibility of getting the class to agree on a common value of  $x_1$ .

Similar determinations of equally likely outcomes can be made by the students in the class for quantities such as the following ones which were found in the 1973 World Almanac and Book of Facts: the number of freight cars that were in use by American railways in 1960 (1,690,396), the number of banks in the United States which closed temporarily or permanently in 1931 on account of financial difficulties (2,294), and the total number of telephones which were in service in South America in 1971 (6,137,000).

### 1.4 Set Theory

#### Solutions to Exercises

1. Assume that  $x \in B^c$ . We need to show that  $x \in A^c$ . We shall show this indirectly. Assume, to the contrary, that  $x \in A$ . Then  $x \in B$  because  $A \subset B$ . This contradicts  $x \in B^c$ . Hence  $x \in A$  is false and  $x \in A^c$ .
2. First, show that  $A \cap (B \cup C) \subset (A \cap B) \cup (A \cap C)$ . Let  $x \in A \cap (B \cup C)$ . Then  $x \in A$  and  $x \in B \cup C$ . That is,  $x \in A$  and either  $x \in B$  or  $x \in C$  (or both). So either  $(x \in A \text{ and } x \in B)$  or  $(x \in A \text{ and } x \in C)$  or both. That is, either  $x \in A \cap B$  or  $x \in A \cap C$ . This is what it means to say that  $x \in (A \cap B) \cup (A \cap C)$ . Thus  $A \cap (B \cup C) \subset (A \cap B) \cup (A \cap C)$ . Basically, running these steps backwards shows that  $(A \cap B) \cup (A \cap C) \subset A \cap (B \cup C)$ .
3. To prove the first result, let  $x \in (A \cup B)^c$ . This means that  $x$  is not in  $A \cup B$ . In other words,  $x$  is neither in  $A$  nor in  $B$ . Hence  $x \in A^c$  and  $x \in B^c$ . So  $x \in A^c \cap B^c$ . This proves that  $(A \cup B)^c \subset A^c \cap B^c$ . Next, suppose that  $x \in A^c \cap B^c$ . Then  $x \in A^c$  and  $x \in B^c$ . So  $x$  is neither in  $A$  nor in  $B$ , so it can't be in  $A \cup B$ . Hence  $x \in (A \cup B)^c$ . This shows that  $A^c \cap B^c \subset (A \cup B)^c$ . The second result follows from the first by applying the first result to  $A^c$  and  $B^c$  and then taking complements of both sides.

2 Chapter 1. Introduction to Probability

4. To see that  $A \cap B$  and  $A \cap B^c$  are disjoint, let  $x \in A \cap B$ . Then  $x \in B$ , hence  $x \notin B^c$  and so  $x \notin A \cap B^c$ . So no element of  $A \cap B$  is in  $A \cap B^c$ , hence the two events are disjoint. To prove that  $A = (A \cap B) \cup (A \cap B^c)$ , we shall show that each side is a subset of the other side. First, let  $x \in A$ . Either  $x \in B$  or  $x \in B^c$ . If  $x \in B$ , then  $x \in A \cap B$ . If  $x \in B^c$ , then  $x \in A \cap B^c$ . Either way,  $x \in (A \cap B) \cup (A \cap B^c)$ . So every element of  $A$  is an element of  $(A \cap B) \cup (A \cap B^c)$  and we conclude that  $A \subset (A \cap B) \cup (A \cap B^c)$ . Finally, let  $x \in (A \cap B) \cup (A \cap B^c)$ . Then either  $x \in A \cap B$ , in which case  $x \in A$ , or  $x \in A \cap B^c$ , in which case  $x \in A$ . Either way  $x \in A$ , so every element of  $(A \cap B) \cup (A \cap B^c)$  is also an element of  $A$  and  $(A \cap B) \cup (A \cap B^c) \subset A$ .
5. To prove the first result, let  $x \in (\cup_i A_i)^c$ . This means that  $x$  is not in  $\cup_i A_i$ . In other words, for every  $i \in I$ ,  $x$  is not in  $A_i$ . Hence for every  $i \in I$ ,  $x \in A_i^c$ . So  $x \in \cap_i A_i^c$ . This proves that  $(\cup_i A_i)^c \subset \cap_i A_i^c$ . Next, suppose that  $x \in \cap_i A_i^c$ . Then  $x \in A_i^c$  for every  $i \in I$ . So for every  $i \in I$ ,  $x$  is not in  $A_i$ . So  $x$  can't be in  $\cup_i A_i$ . Hence  $x \in (\cup_i A_i)^c$ . This shows that  $\cap_i A_i^c \subset (\cup_i A_i)^c$ . The second result follows from the first by applying the first result to  $A_i^c$  for  $i \in I$  and then taking complements of both sides.
6. (a) Blue card numbered 2 or 4.  
 (b) Blue card numbered 5, 6, 7, 8, 9, or 10.  
 (c) Any blue card or a red card numbered 1, 2, 3, 4, 6, 8, or 10.  
 (d) Blue card numbered 2, 4, 6, 8, or 10, or red card numbered 2 or 4.  
 (e) Red card numbered 5, 7, or 9.
7. (a) These are the points not in  $A$ , hence they must be either below 1 or above 5. That is  $A^c = \{x : x < 1 \text{ or } x > 5\}$ .  
 (b) These are the points in either  $A$  or  $B$  or both. So they must be between 1 and 5 or between 3 and 7. That is,  $A \cup B = \{x : 1 \leq x \leq 7\}$ .  
 (c) These are the points in  $B$  but not in  $C$ . That is  $BC^c = \{x : 3 < x \leq 7\}$ . (Note that  $B \subset C^c$ ).  
 (d) These are the points in none of the three sets, namely  $A^c B^c C^c = \{x : 0 < x < 1 \text{ or } x > 7\}$ .  
 (e) These are the points in the answer to part (b) and in  $C$ . There are no such values and  $(A \cup B)C = \emptyset$ .
8. Blood type A reacts only with anti-A, so type A blood corresponds to  $A \cap B^c$ . Type B blood reacts only with anti-B, so type B blood corresponds to  $A^c B$ . Type AB blood reacts with both, so  $A \cap B$  characterizes type AB blood. Finally, type O reacts with neither antigen, so type O blood corresponds to the event  $A^c B^c$ .
9. (a) For each  $n$ ,  $B_n = B_{n+1} \cup A_n$ , hence  $B_n \supset B_{n+1}$  for all  $n$ . For each  $n$ ,  $C_{n+1} \cap A_n = C_n$ , so  $C_n \subset C_{n+1}$ .  
 (b) Suppose that  $x \in \cap_{n=1}^{\infty} B_n$ . Then  $x \in B_n$  for all  $n$ . That is,  $x \in \cup_{i=n}^{\infty} A_i$  for all  $n$ . For  $n = 1$ , there exists  $i \geq n$  such that  $x \in A_i$ . Assume to the contrary that there are at most finitely many  $i$  such that  $x \in A_i$ . Let  $m$  be the largest such  $i$ . For  $n = m + 1$ , we know that there is  $i \geq n$  such that  $x \in A_i$ . This contradicts  $m$  being the largest  $i$  such that  $x \in A_i$ . Hence,  $x$  is in infinitely many  $A_i$ . For the other direction, assume that  $x$  is in infinitely many  $A_i$ . Then, for every  $n$ , there is a value of  $j > n$  such that  $x \in A_j$ , hence  $x \in \cup_{i=n}^{\infty} A_i = B_n$  for every  $n$  and  $x \in \cap_{n=1}^{\infty} B_n$ .  
 (c) Suppose that  $x \in \cup_{n=1}^{\infty} C_n$ . That is, there exists  $n$  such that  $x \in C_n = \cap_{i=n}^{\infty} A_i$ , so  $x \in A_i$  for all  $i \geq n$ . So, there at most finitely many  $i$  (a subset of  $1, \dots, n - 1$ ) such that  $x \notin A_i$ . Finally, suppose that  $x \in A_i$  for all but finitely many  $i$ . Let  $k$  be the last  $i$  such that  $x \notin A_i$ . Then  $x \in A_i$  for all  $i \geq k + 1$ , hence  $x \in \cap_{i=k+1}^{\infty} A_i = C_{k+1}$ . Hence  $x \in \cup_{n=1}^{\infty} C_n$ .

10. (a) All three dice show even numbers if and only if all three of  $A$ ,  $B$ , and  $C$  occur. So, the event is  $A \cap B \cap C$ .
- (b) None of the three dice show even numbers if and only if all three of  $A^c$ ,  $B^c$ , and  $C^c$  occur. So, the event is  $A^c \cap B^c \cap C^c$ .
- (c) At least one die shows an odd number if and only if at least one of  $A^c$ ,  $B^c$ , and  $C^c$  occur. So, the event is  $A^c \cup B^c \cup C^c$ .
- (d) At most two dice show odd numbers if and only if at least one die shows an even number, so the event is  $A \cup B \cup C$ . This can also be expressed as the union of the three events of the form  $A \cap B \cap C^c$  where exactly one die shows odd together with the three events of the form  $A \cap B^c \cap C^c$  where exactly two dice show odd together with the even  $A \cap B \cap C$  where no dice show odd.
- (e) We can enumerate all the sums that are no greater than 5:  $1 + 1 + 1$ ,  $2 + 1 + 1$ ,  $1 + 2 + 1$ ,  $1 + 1 + 2$ ,  $2 + 2 + 1$ ,  $2 + 1 + 2$ , and  $1 + 2 + 2$ . The first of these corresponds to the event  $A_1 \cap B_1 \cap C_1$ , the second to  $A_2 \cap B_1 \cap C_1$ , etc. The union of the seven such events is what is requested, namely  $(A_1 \cap B_1 \cap C_1) \cup (A_2 \cap B_1 \cap C_1) \cup (A_1 \cap B_2 \cap C_1) \cup (A_1 \cap B_1 \cap C_2) \cup (A_2 \cap B_2 \cap C_1) \cup (A_2 \cap B_1 \cap C_2) \cup (A_1 \cap B_2 \cap C_2)$ .
11. (a) All of the events mentioned can be determined by knowing the voltages of the two subcells. Hence the following set can serve as a sample space

$$S = \{(x, y) : 0 \leq x \leq 5 \text{ and } 0 \leq y \leq 5\},$$

where the first coordinate is the voltage of the first subcell and the second coordinate is the voltage of the second subcell. Any more complicated set from which these two voltages can be determined could serve as the sample space, so long as each outcome could at least hypothetically be learned.

- (b) The power cell is functional if and only if the sum of the voltages is at least 6. Hence,  $A = \{(x, y) \in S : x + y \geq 6\}$ . It is clear that  $B = \{(x, y) \in S : x = y\}$  and  $C = \{(x, y) \in S : x > y\}$ . The powercell is not functional if and only if the sum of the voltages is less than 6. It needs less than one volt to be functional if and only if the sum of the voltages is greater than 5. The intersection of these two is the event  $D = \{(x, y) \in S : 5 < x + y < 6\}$ . The restriction “ $\in S$ ” that appears in each of these descriptions guarantees that the set is a subset of  $S$ . One could leave off this restriction and add the two restrictions  $0 \leq x \leq 5$  and  $0 \leq y \leq 5$  to each set.
- (c) The description can be worded as “the power cell is not functional, and needs at least one more volt to be functional, and both subcells have the same voltage.” This is the intersection of  $A^c$ ,  $D^c$ , and  $B$ . That is,  $A^c \cap D^c \cap B$ . The part of  $D^c$  in which  $x + y \geq 6$  is not part of this set because of the intersection with  $A^c$ .
- (d) We need the intersection of  $A^c$  (not functional) with  $C^c$  (second subcell at least as big as first) and with  $B^c$  (subcells are not the same). In particular,  $C^c \cap B^c$  is the event that the second subcell is strictly higher than the first. So, the event is  $A^c \cap B^c \cap C^c$ .

## 1.5 The Definition of Probability

### Solutions to Exercises

1. Define the following events:

$$\begin{aligned} A &= \{\text{the selected ball is red}\}, \\ B &= \{\text{the selected ball is white}\}, \\ C &= \{\text{the selected ball is either blue, yellow, or green}\}. \end{aligned}$$

4 Chapter 1. Introduction to Probability

We are asked to find  $\Pr(C)$ . The three events  $A$ ,  $B$ , and  $C$  are disjoint and  $A \cup B \cup C = S$ . So  $1 = \Pr(A) + \Pr(B) + \Pr(C)$ . We are told that  $\Pr(A) = 1/5$  and  $\Pr(B) = 2/5$ . It follows that  $\Pr(C) = 2/5$ .

2. Let  $B$  be the event that a boy is selected, and let  $G$  be the event that a girl is selected. We are told that  $B \cup G = S$ , so  $G = B^c$ . Since  $\Pr(B) = 0.3$ , it follows that  $\Pr(G) = 0.7$ .
3. (a) If  $A$  and  $B$  are disjoint then  $B \subset A^c$  and  $BA^c = B$ , so  $\Pr(BA^c) = \Pr(B) = 1/2$ .  
(b) If  $A \subset B$ , then  $B = A \cup (BA^c)$  with  $A$  and  $BA^c$  disjoint. So  $\Pr(B) = \Pr(A) + \Pr(BA^c)$ . That is,  $1/2 = 1/3 + \Pr(BA^c)$ , so  $\Pr(BA^c) = 1/6$ .  
(c) According to Theorem 1.4.11,  $B = (BA) \cup (BA^c)$ . Also,  $BA$  and  $BA^c$  are disjoint so,  $\Pr(B) = \Pr(BA) + \Pr(BA^c)$ . That is,  $1/2 = 1/8 + \Pr(BA^c)$ , so  $\Pr(BA^c) = 3/8$ .
4. Let  $E_1$  be the event that student  $A$  fails and let  $E_2$  be the event that student  $B$  fails. We want  $\Pr(E_1 \cup E_2)$ . We are told that  $\Pr(E_1) = 0.5$ ,  $\Pr(E_2) = 0.2$ , and  $\Pr(E_1 E_2) = 0.1$ . According to Theorem 1.5.7,  $\Pr(E_1 \cup E_2) = 0.5 + 0.2 - 0.1 = 0.6$ .
5. Using the same notation as in Exercise 4, we now want  $\Pr(E_1^c \cap E_2^c)$ . According to Theorems 1.4.9 and 1.5.3, this equals  $1 - \Pr(E_1 \cup E_2) = 0.4$ .
6. Using the same notation as in Exercise 4, we now want  $\Pr([E_1 \cap E_2^c] \cup [E_1^c \cap E_2])$ . These two events are disjoint, so

$$\Pr([E_1 \cap E_2^c] \cup [E_1^c \cap E_2]) = \Pr(E_1 \cap E_2^c) + \Pr(E_1^c \cap E_2).$$

Use the reasoning from part (c) of Exercise 3 above to conclude that

$$\begin{aligned}\Pr(E_1 \cap E_2^c) &= \Pr(E_1) - \Pr(E_1 \cap E_2) = 0.4, \\ \Pr(E_1^c \cap E_2) &= \Pr(E_2) - \Pr(E_1 \cap E_2) = 0.1.\end{aligned}$$

It follows that the probability we want is 0.5.

7. Rearranging terms in Eq. (1.5.1) of the text, we get

$$\Pr(A \cap B) = \Pr(A) + \Pr(B) - \Pr(A \cup B) = 0.4 + 0.7 - \Pr(A \cup B) = 1.1 - \Pr(A \cup B).$$

So  $\Pr(A \cap B)$  is largest when  $\Pr(A \cup B)$  is smallest and vice-versa. The smallest possible value for  $\Pr(A \cup B)$  occurs when one of the events is a subset of the other. In the present exercise this could only happen if  $A \subset B$ , in which case  $\Pr(A \cup B) = \Pr(B) = 0.7$ , and  $\Pr(A \cap B) = 0.4$ . The largest possible value of  $\Pr(A \cup B)$  occurs when either  $A$  and  $B$  are disjoint or when  $A \cup B = S$ . The former is not possible since the probabilities are too large, but the latter is possible. In this case  $\Pr(A \cup B) = 1$  and  $\Pr(A \cap B) = 0.1$ .

8. Let  $A$  be the event that a randomly selected family subscribes to the morning paper, and let  $B$  be the event that a randomly selected family subscribes to the afternoon paper. We are told that  $\Pr(A) = 0.5$ ,  $\Pr(B) = 0.65$ , and  $\Pr(A \cup B) = 0.85$ . We are asked to find  $\Pr(A \cap B)$ . Using Theorem 1.5.7 in the text we obtain

$$\Pr(A \cap B) = \Pr(A) + \Pr(B) - \Pr(A \cup B) = 0.5 + 0.65 - 0.85 = 0.3.$$

9. The required probability is

$$\begin{aligned}\Pr(A \cap B^C) + \Pr(A^C B) &= [\Pr(A) - \Pr(A \cap B)] + [\Pr(B) - \Pr(A \cap B)] \\ &= \Pr(A) + \Pr(B) - 2\Pr(A \cap B).\end{aligned}$$

10. Theorem 1.4.11 says that  $A = (A \cap B) \cup (A \cap B^c)$ . Clearly the two events  $A \cap B$  and  $A \cap B^c$  are disjoint. It follows from Theorem 1.5.6 that  $\Pr(A) = \Pr(A \cap B) + \Pr(A \cap B^c)$ .

11. (a) The set of points for which  $(x - 1/2)^2 + (y - 1/2)^2 < 1/4$  is the interior of a circle that is contained in the unit square. (Its center is  $(1/2, 1/2)$  and its radius is  $1/2$ .) The area of this circle is  $\pi/4$ , so the area of the remaining region (what we want) is  $1 - \pi/4$ .  
(b) We need the area of the region between the two lines  $y = 1/2 - x$  and  $y = 3/2 - x$ . The remaining area is the union of two right triangles with base and height both equal to  $1/2$ . Each triangle has area  $1/8$ , so the region between the two lines has area  $1 - 2/8 = 3/4$ .  
(c) We can use calculus to do this. We want the area under the curve  $y = 1 - x^2$  between  $x = 0$  and  $x = 1$ . This equals

$$\int_0^1 (1 - x^2) dx = x - \frac{x^3}{3} \Big|_{x=0}^1 = \frac{2}{3}.$$

- (d) The area of a line is 0, so the probability of a line segment is 0.  
12. The events  $B_1, B_2, \dots$  are disjoint, because the event  $B_1$  contains the points in  $A_1$ , the event  $B_2$  contains the points in  $A_2$  but not in  $A_1$ , the event  $B_3$  contains the points in  $A_3$  but not in  $A_1$  or  $A_2$ , etc. By this same reasoning, it is seen that  $\bigcup_{i=1}^n A_i = \bigcup_{i=1}^n B_i$  and  $\bigcup_{i=1}^\infty A_i = \bigcup_{i=1}^\infty B_i$ . Therefore,

$$\Pr\left(\bigcup_{i=1}^n A_i\right) = \Pr\left(\bigcup_{i=1}^n B_i\right)$$

and

$$\Pr\left(\bigcup_{i=1}^\infty A_i\right) = \Pr\left(\bigcup_{i=1}^\infty B_i\right).$$

However, since the events  $B_1, B_2, \dots$  are disjoint,

$$\Pr\left(\bigcup_{i=1}^n B_i\right) = \sum_{i=1}^n \Pr(B_i)$$

and

$$\Pr\left(\bigcup_{i=1}^\infty B_i\right) = \sum_{i=1}^\infty \Pr(B_i).$$

13. We know from Exercise 12 that

$$\Pr\left(\bigcup_{i=1}^n A_i\right) = \sum_{i=1}^n \Pr(A_i).$$

Furthermore, from the definition of the events  $B_1, \dots, B_n$  it is seen that  $B_i \subset A_i$  for  $i = 1, \dots, n$ . Therefore, by Theorem 1.5.4,  $\Pr(B_i) \leq \Pr(A_i)$  for  $i = 1, \dots, n$ . It now follows that

$$\Pr\left(\bigcup_{i=1}^n A_i\right) \leq \sum_{i=1}^n \Pr(A_i).$$

(Of course, if the events  $A_1, \dots, A_n$  are disjoint, there is equality in this relation.)

For the second part, apply the first part with  $A_i$  replaced by  $A_i^c$  for  $i = 1, \dots, n$ . We get

$$\Pr\left(\bigcup_{i=1}^n A_i^c\right) \leq \sum_{i=1}^n \Pr(A_i^c). \quad (\text{S.1.1})$$

Exercise 5 in Sec. 1.4 says that the left side of (S.1.1) is  $\Pr([\bigcap A_i]^c)$ . Theorem 1.5.3 says that this last probability is  $1 - \Pr(\bigcap A_i)$ . Hence, we can rewrite (S.1.1) as

$$1 - \Pr\left(\bigcap_{i=1}^n A_i\right) \leq \sum_{i=1}^n \Pr(A_i^c).$$

Finally take one minus both sides of the above inequality (which reverses the inequality) and produces the desired result.

14. First, note that the probability of type AB blood is  $1 - (0.5 + 0.34 + 0.12) = 0.04$  by using Theorems 1.5.2 and 1.5.3.
  - (a) The probability of blood reacting to anti-A is the probability that the blood is either type A or type AB. Since these are disjoint events, the probability is the sum of the two probabilities, namely  $0.34 + 0.04 = 0.38$ . Similarly, the probability of reacting with anti-B is the probability of being either type B or type AB,  $0.12 + 0.04 = 0.16$ .
  - (b) The probability that both antigens react is the probability of type AB blood, namely 0.04.

## 1.6 Finite Sample Spaces

### Solutions to Exercises

1. The safe way to obtain the answer at this stage of our development is to count that 18 of the 36 outcomes in the sample space yield an odd sum. Another way to solve the problem is to note that regardless of what number appears on the first die, there are three numbers on the second die that will yield an odd sum and three numbers that will yield an even sum. Either way the probability is 1/2.
2. The event whose probability we want is the complement of the event in Exercise 1, so the probability is also 1/2.
3. The only differences greater than or equal to 3 that are available are 3, 4 and 5. These large difference only occur for the six outcomes in the upper right and the six outcomes in the lower left of the array in Example 1.6.5 of the text. So the probability we want is  $1 - 12/36 = 2/3$ .
4. Let  $x$  be the proportion of the school in grade 3 (the same as grades 2–6). Then  $2x$  is the proportion in grade 1 and  $1 = 2x + 5x = 7x$ . So  $x = 1/7$ , which is the probability that a randomly selected student will be in grade 3.

5. The probability of being in an odd-numbered grade is  $2x + x + x = 4x = 4/7$ .
6. Assume that all eight possible combinations of faces are equally likely. Only two of those combinations have all three faces the same, so the probability is  $1/4$ .
7. The possible genotypes of the offspring are  $aa$  and  $Aa$ , since one parent will definitely contribute an  $a$ , while the other can contribute either  $A$  or  $a$ . Since the parent who is  $Aa$  contributes each possible allele with probability  $1/2$  each, the probabilities of the two possible offspring are each  $1/2$  as well.
8. (a) The sample space contains 12 outcomes: (Head, 1), (Tail, 1), (Head, 2), (Tail, 2), etc.  
(b) Assume that all 12 outcomes are equally likely. Three of the outcomes have Head and an odd number, so the probability is  $1/4$ .

## 1.7 Counting Methods

### Commentary

If you wish to stress computer evaluation of probabilities, then there are programs for computing factorials and log-factorials. For example, in the statistical software *R*, there are functions `factorial` and `lfactorial` that compute these. If you cover Stirling's formula (Theorem 1.7.5), you can use these functions to illustrate the closeness of the approximation.

### Solutions to Exercises

1. Each pair of starting day and leap year/no leap year designation determines a calendar, and each calendar correspond to exactly one such pair. Since there are seven days and two designations, there are a total of  $7 \times 2 = 14$  different calendars.
2. There are 20 ways to choose the student from the first class, and no matter which is chosen, there are 18 ways to choose the student from the second class. No matter which two students are chosen from the first two classes, there are 25 ways to choose the student from the third class. The multiplication rule can be applied to conclude that the total number of ways to choose the three members is  $20 \times 18 \times 25 = 9000$ .
3. This is a simple matter of permutations of five distinct items, so there are  $5! = 120$  ways.
4. There are six different possible shirts, and no matter what shirt is picked, there are four different slacks. So there are 24 different combinations.
5. Let the sample space consist of all four-tuples of dice rolls. There are  $6^4 = 1296$  possible outcomes. The outcomes with all four rolls different consist of all of the permutations of six items taken four at a time. There are  $P_{6,4} = 360$  of these outcomes. So the probability we want is  $360/1296 = 5/18$ .
6. With six rolls, there are  $6^6 = 46656$  possible outcomes. The outcomes with all different rolls are the permutations of six distinct items. There are  $6! = 720$  outcomes in the event of interest, so the probability is  $720/46656 = 0.01543$ .
7. There are  $20^{12}$  possible outcomes in the sample space. If the 12 balls are to be thrown into different boxes, the first ball can be thrown into any one of the 20 boxes, the second ball can then be thrown into any one of the other 19 boxes, etc. Thus, there are  $20 \cdot 19 \cdot 18 \cdots 9$  possible outcomes in the event. So the probability is  $20!/[8!20^{12}]$ .

8. There are  $7^5$  possible outcomes in the sample space. If the five passengers are to get off at different floors, the first passenger can get off at any one of the seven floors, the second passenger can then get off at any one of the other six floors, etc. Thus, the probability is

$$\frac{7 \cdot 6 \cdot 5 \cdot 4 \cdot 3}{7^5} = \frac{360}{2401}.$$

9. There are  $6!$  possible arrangements in which the six runners can finish the race. If the three runners from team A finish in the first three positions, there are  $3!$  arrangements of these three runners among these three positions and there are also  $3!$  arrangements of the three runners from team B among the last three positions. Therefore, there are  $3! \times 3!$  arrangements in which the runners from team A finish in the first three positions and the runners from team B finish in the last three positions. Thus, the probability is  $(3!3!)/6! = 1/20$ .
10. We can imagine that the 100 balls are randomly ordered in a list, and then drawn in that order. Thus, the required probability in part (a), (b), or (c) of this exercise is simply the probability that the first, fiftieth, or last ball in the list is red. Each of these probabilities is the same  $\frac{r}{100}$ , because of the random order of the list.
11. In terms of factorials,  $P_{n,k} = n!/[k!(n-k)!]$ . Since we are assuming that  $n$  and  $n = k$  are large, we can use Stirling's formula to approximate both of them. The approximation to  $n!$  is  $(2\pi)^{1/2}n^{n+1/2}e^{-n}$ , and the approximation to  $(n-k)!$  is  $(2\pi)^{1/2}(n-k)^{n-k+1/2}e^{-n+k}$ . The approximation to the ratio is the ratio of the approximations because the ratio of each approximation to its corresponding factorial converges to 1. That is,

$$\frac{n!}{k!(n-k)!} \approx \frac{(2\pi)^{1/2}n^{n+1/2}e^{-n}}{k!(2\pi)^{1/2}(n-k)^{n-k+1/2}e^{-n+k}} = \frac{e^{-k}n^k}{k!} \left(1 - \frac{k}{n}\right)^{-n-k-1/2}.$$

Further simplification is available if one assumes that  $k$  is small compared to  $n$ , that is  $k/n \approx 0$ . In this case, the last factor is approximately  $e^k$ , and the whole approximation simplifies to  $n^k/k!$ . This makes sense because, if  $n/(n-k)$  is essentially 1, then the product of the  $k$  largest factors in  $n!$  is essentially  $n^k$ .

## 1.8 Combinatorial Methods

### Commentary

This section ends with an extended example called “The Tennis Tournament”. This is an application of combinatorics that uses a slightly subtle line of reasoning.

### Solutions to Exercises

1. We have to assign 10 houses to one pollster, and the other pollster will get to canvas the other 10 houses. Hence, the number of assignments is the number of combinations of 20 items taken 10 at a time,

$$\binom{20}{10} = 184,756.$$

2. The ratio of  $\binom{93}{30}$  to  $\binom{93}{31}$  is  $31/63 < 1$ , so  $\binom{93}{31}$  is larger.

3. Since  $93 = 63 + 30$ , the two numbers are the same.
4. Let the sample space consist of all subsets (not ordered tuples) of the 24 bulbs in the box. There are  $\binom{24}{4} = 10626$  such subsets. There is only one subset that has all four defectives, so the probability we want is  $1/10626$ .
5. The number is  $\frac{4251!}{(97!4154!)} = \binom{4251}{97}$ , an integer.
6. There are  $\binom{n}{2}$  possible pairs of seats that  $A$  and  $B$  can occupy. Of these pairs,  $n - 1$  pairs comprise two adjacent seats. Therefore, the probability is  $\frac{n - 1}{\binom{n}{2}} = \frac{2}{n}$ .
7. There are  $\binom{n}{k}$  possible sets of  $k$  seats to be occupied, and they are all equally likely. There are  $n - k + 1$  sets of  $k$  adjacent seats, so the probability we want is

$$\frac{n - k + 1}{\binom{n}{k}} = \frac{(n - k + 1)!k!}{n!}.$$

8. There are  $\binom{n}{k}$  possible sets of  $k$  seats to be occupied, and they are all equally likely. Because the circle has no start or end, there are  $n$  sets of  $k$  adjacent seats, so the probability we want is
$$\frac{n}{\binom{n}{k}} = \frac{(n - k)!k!}{(n - 1)!}.$$
9. This problem is slightly tricky. The total number of ways of choosing the  $n$  seats that will be occupied by the  $n$  people is  $\binom{2n}{n}$ . Offhand, it would seem that there are only two ways of choosing these seats so that no two adjacent seats are occupied, namely:

$X0X0\dots0$  and  $0X0X\dots0X$

Upon further consideration, however,  $n - 1$  more ways can be found, namely:

$X00X0X\dots0X$ ,  $X0X00X0X\dots0X$ , etc.

Therefore, the total number of ways of choosing the seats so that no two adjacent seats are occupied is  $n + 1$ . The probability is  $(n + 1)/\binom{2n}{n}$ .

10. We shall let the sample space consist of all subsets (unordered) of 10 out of the 24 light bulbs in the box. There are  $\binom{24}{10}$  such subsets. The number of subsets that contain the two defective bulbs is the number of subsets of size 8 out of the other 22 bulbs,  $\binom{22}{8}$ , so the probability we want is

$$\frac{\binom{22}{8}}{\binom{24}{10}} = \frac{10 \times 9}{24 \times 23} = 0.1630.$$

11. This exercise is similar to Exercise 10. Let the sample space consist of all subsets (unordered) of 12 out of the 100 people in the group. There are  $\binom{100}{12}$  such subsets. The number of subsets that contain  $A$  and  $B$  is the number of subsets of size 10 out of the other 98 people,  $\binom{98}{10}$ , so the probability we want is

$$\frac{\binom{98}{10}}{\binom{100}{12}} = \frac{12 \times 11}{100 \times 99} = 0.01333.$$

12. There are  $\binom{35}{10}$  ways of dividing the group into the two teams. As in Exercise 11, the number of ways of choosing the 10 players for the first team so as to include both  $A$  and  $B$  is  $\binom{33}{8}$ . The number of ways of choosing the 10 players for this team so as not to include either  $A$  or  $B$  ( $A$  and  $B$  will then be together on the other team) is  $\binom{33}{10}$ . The probability we want is then

$$\frac{\binom{33}{8} + \binom{33}{10}}{\binom{35}{10}} = \frac{10 \times 9 + 25 \times 24}{35 \times 34} = 0.5798.$$

13. This exercise is similar to Exercise 12. Here, we want four designated bulbs to be in the same group. The probability is

$$\frac{\binom{20}{6} + \binom{20}{10}}{\binom{24}{10}} = 0.1140.$$

14.

$$\begin{aligned}
 \binom{n}{k} + \binom{n}{k-1} &= \frac{n!}{k!(n-k)!} + \frac{n!}{(k-1)!(n-k+1)!} \\
 &= \frac{n!}{(k-1)!(n-k)!} \left( \frac{1}{k} + \frac{1}{n-k+1} \right) \\
 &= \frac{n!}{(k-1)!(n-k)!} \cdot \frac{n+1}{k(n-k+1)} \\
 &= \frac{(n+1)!}{k!(n-k+1)!} = \binom{n+1}{k}.
 \end{aligned}$$

15. (a) If we express  $2^n$  as  $(1+1)^n$  and expand  $(1+1)^n$  by the binomial theorem, we obtain the desired result.  
(b) If we express 0 as  $(1-1)^n$  and expand  $(1-1)^n$  by the binomial theorem, we obtain the desired result.
16. (a) It is easier to calculate first the probability that the committee will not contain either of the two senators from the designated state. This probability is  $\frac{\binom{98}{8}}{\binom{100}{8}}$ . Thus, the final answer is
- $$1 - \frac{\binom{98}{8}}{\binom{100}{8}} \approx 1 - .08546 = 0.1543.$$
- (b) There are  $\binom{100}{50}$  combinations that might be chosen. If the group is to contain one senator from each state, then there are two possible choices for each of the fifty states. Hence, the number of possible combinations containing one senator from each state is  $2^{50}$ .
17. Call the four players A, B, C, and D. The number of ways of choosing the positions in the deck that will be occupied by the four aces is  $\binom{52}{4}$ . Since player A will receive 13 cards, the number of ways of choosing the positions in the deck for the four aces so that all of them will be received by player A is  $\binom{13}{4}$ . Similarly, since player B will receive 13 other cards, the number of ways of choosing the positions for the four aces so that all of them will be received by player B is  $\binom{13}{4}$ . A similar result is true for each of the other players. Therefore, the total number of ways of choosing the positions in the deck for the four aces so that all of them will be received by the same player is  $4\binom{13}{4}$ . Thus, the final probability is  $4\binom{13}{4}/\binom{52}{4}$ .
18. There are  $\binom{100}{10}$  ways of choosing ten mathematics students. There are  $\binom{20}{2}$  ways of choosing two

students from a given class of 20 students. Therefore, there are  $\binom{20}{2}^5$  ways of choosing two students from each of the five classes. So, the final answer is  $\binom{20}{2}^5 / \binom{100}{10} \approx 0.0143$ .

19. From the description of what counts as a collection of customer choices, we see that each collection consists of a tuple  $(m_1, \dots, m_n)$ , where  $m_i$  is the number of customers who choose item  $i$  for  $i = 1, \dots, n$ . Each  $m_i$  must be between 0 and  $k$  and  $m_1 + \dots + m_n = k$ . Each such tuple is equivalent to a sequence of  $n+k-1$  0's and 1's as follows. The first  $m_1$  terms are 0 followed by a 1. The next  $m_2$  terms are 0 followed by a 1, and so on up to  $m_{n-1}$  0's followed by a 1 and finally  $m_n$  0's. Since  $m_1 + \dots + m_n = k$  and since we are putting exactly  $n-1$  1's into the sequence, each such sequence has exactly  $n+k-1$  terms. Also, it is clear that each such sequence corresponds to exactly one tuple of customer choices. The numbers of 0's between successive 1's give the numbers of customers who choose that item, and the 1's indicate where we switch from one item to the next. So, the number of combinations of choices is the number of such sequences:  $\binom{n+k-1}{k}$ .

20. We shall use induction. For  $n = 1$ , we must prove that

$$x + y = \binom{1}{0}x^0y^1 + \binom{1}{1}x^1y^0.$$

Since the right side of this equation is  $x + y$ , the theorem is true for  $n = 1$ . Now assume that the theorem is true for each  $n = 1, \dots, n_0$  for  $n_0 \geq 1$ . For  $n = n_0 + 1$ , the theorem says

$$(x + y)^{n_0+1} = \sum_{k=0}^{n_0+1} \binom{n_0+1}{k} x^k y^{n_0+1-k}. \quad (\text{S.1.2})$$

Since we have assumed that the theorem is true for  $n = n_0$ , we know that

$$(x + y)^{n_0} = \sum_{k=0}^{n_0} \binom{n_0}{k} x^k y^{n_0-k}. \quad (\text{S.1.3})$$

We shall multiply both sides of (S.1.3) by  $x + y$ . We then need to prove that  $x + y$  times the right side of (S.1.3) equals the right side of (S.1.2).

$$\begin{aligned} (x + y)(x + y)^{n_0} &= (x + y) \sum_{k=0}^{n_0} \binom{n_0}{k} x^k y^{n_0-k} \\ &= \sum_{k=0}^{n_0} \binom{n_0}{k} x^{k+1} y^{n_0-k} + \sum_{k=0}^{n_0} \binom{n_0}{k} x^k y^{n_0+1-k} \\ &= \sum_{k=1}^{n_0+1} \binom{n_0}{k-1} x^k y^{n_0+1-k} + \sum_{k=0}^{n_0} \binom{n_0}{k} x^k y^{n_0+1-k} \\ &= y^{n_0+1} + \sum_{k=1}^{n_0} \left[ \binom{n_0}{k-1} + \binom{n_0}{k} \right] x^k y^{n_0+1-k} + x^{n_0+1}. \end{aligned}$$

Now, apply the result in Exercise 14 to conclude that

$$\binom{n_0}{k-1} + \binom{n_0}{k} = \binom{n_0+1}{k}.$$

This makes the final summation above equal to the right side of (S.1.2).

21. We are asked for the number of unordered samples with replacement, as constructed in Exercise 19. Here,  $n = 365$ , so there are  $\binom{365+k}{k}$  different unordered sets of  $k$  birthdays chosen with replacement from  $1, \dots, 365$ .
22. The approximation to  $n!$  is  $(2\pi)^{1/2} n^{n+1/2} e^{-n}$ , and the approximation to  $(n/2)!$  is  $(2\pi)^{1/2} (n/2)^{n/2+1/2} e^{-n/2}$ . Then

$$\frac{n!}{(n/2)!^2} \approx \frac{(2\pi)^{1/2} n^{n+1/2} e^{-n}}{[(2\pi)^{1/2} (n/2)^{n/2+1/2} e^{-n/2}]^2} = (2\pi)^{-1/2} 2^{n+1} n^{-1/2}.$$

With  $n = 500$ , the approximation is  $e^{343.24}$ , too large to represent on a calculator with only two-digit exponents. The actual number is about 1/20 of 1% larger.

## 1.9 Multinomial Coefficients

### Commentary

Multinomial coefficients are useful as a counting method, and they are needed for the definition of the multinomial distribution in Sec. 5.9. They are not used much elsewhere in the text. Although this section does not have an asterisk, it could be skipped (together with Sec. 5.9) if one were not interested in the multinomial distribution or the types of counting arguments that rely on multinomial coefficients.

### Solutions to Exercises

1. We have three types of elements that need to be assigned to 21 houses so that exactly seven of each type are assigned. The number of ways to do this is the multinomial coefficient

$$\binom{21}{7, 7, 7} = 399,072,960.$$

2. We are asked for the number of arrangements of four distinct types of objects with 18 of one type, 12 of the next, 8 of the next and 12 of the last. This is the multinomial coefficient  $\binom{50}{18, 12, 8, 12}$ .

3. We need to divide the 300 members of the organization into three subsets: the 5 in one committee, the 8 in the second committee, and the 287 in neither committee. There are  $\binom{300}{5, 8, 287}$  ways to do this.

4. There are  $\binom{10}{3, 3, 2, 1, 1}$  arrangements of the 10 letters of four distinct types. All of them are equally likely, and only one spells statistics. So, the probability is  $1/\binom{10}{3, 3, 2, 1, 1} = 1/50400$ .

5. There are  $\binom{n}{n_1, n_2, n_3, n_4, n_5, n_6}$  many ways to arrange  $n_j$   $j$ 's (for  $j = 1, \dots, 6$ ) among the  $n$  rolls. The number of possible equally likely rolls is  $6^n$ . So, the probability we want is  $\frac{1}{6^n} \binom{n}{n_1, n_2, n_3, n_4, n_5, n_6}$ .

6. There are  $6^7$  possible outcomes for the seven dice. If each of the six numbers is to appear at least once among the seven dice, then one number must appear twice and each of the other five numbers must appear once. Suppose first that the number 1 appears twice and each of the other numbers appears once. The number of outcomes of this type in the sample space is equal to the number of different arrangements of the symbols 1, 1, 2, 3, 4, 5, 6, which is  $\frac{7!}{2!(1!)^5} = \frac{7!}{2}$ . There is an equal number of outcomes for each of the other five numbers which might appear twice among the seven dice. Therefore, the total number of outcomes in which each number appears at least once is  $\frac{6(7!)}{2}$ , and the probability of this event is

$$\frac{6(7!)}{(2)6^7} = \frac{7!}{2(6^6)}.$$

7. There are  $\binom{25}{10, 8, 7}$  ways of distributing the 25 cards to the three players. There are  $\binom{12}{6, 2, 4}$  ways of distributing the 12 red cards to the players so that each receives the designated number of red cards. There are then  $\binom{13}{4, 6, 3}$  ways of distributing the other 13 cards to the players, so that each receives the designated total number of cards. The product of these last two numbers of ways is, therefore, the number of ways of distributing the 25 cards to the players so that each receives the designated number of red cards and the designated total number of cards. So, the final probability is  $\binom{12}{6, 2, 4} \binom{13}{4, 6, 3} / \binom{25}{10, 8, 7}$ .
8. There are  $\binom{52}{13, 13, 13, 13}$  ways of distributing the cards to the four players. There are  $\binom{12}{3, 3, 3, 3}$  ways of distributing the 12 picture cards so that each player gets three. No matter which of these ways we choose, there are  $\binom{40}{10, 10, 10, 10}$  ways to distribute the remaining 40 nonpicture cards so that each player gets 10. So, the probability we need is

$$\frac{\binom{12}{3, 3, 3, 3} \binom{40}{10, 10, 10, 10}}{\binom{52}{13, 13, 13, 13}} = \frac{\frac{12!}{(3!)^4} \frac{40!}{(10!)^4}}{\frac{52!}{(13!)^4}} \approx 0.0324.$$

9. There are  $\binom{52}{13, 13, 13, 13}$  ways of distributing the cards to the four players. Call these four players A, B, C, and D. There is only one way of distributing the cards so that player A receives all red cards, player B receives all yellow cards, player C receives all blue cards, and player D receives all green cards. However, there are  $4!$  ways of assigning the four colors to the four players and therefore there are  $4!$  ways of distributing the cards so that each player receives 13 cards of the same color. So, the probability we need is

$$\frac{4!}{\binom{52}{13, 13, 13, 13}} = \frac{4!(13!)^4}{52!} \approx 4.474 \times 10^{-28}.$$

10. If we do not distinguish among boys with the same last name, then there are  $\binom{9}{2,3,4}$  possible arrangements of the nine boys. We are interested in the probability of a particular one of these arrangements. So, the probability we need is

$$\frac{1}{\binom{9}{2,3,4}} = \frac{2!3!4!}{9!} \approx 7.937 \times 10^{-4}.$$

11. We shall use induction. Since we have already proven the binomial theorem, we know that the conclusion to the multinomial theorem is true for every  $n$  if  $k = 2$ . We shall use induction again, but this time using  $k$  instead of  $n$ . For  $k = 2$ , we already know the result is true. Suppose that the result is true for all  $k \leq k_0$  and for all  $n$ . For  $k = k_0 + 1$  and arbitrary  $n$  we must show that

$$(x_1 + \cdots + x_{k_0+1})^n = \sum \binom{n}{n_1, \dots, n_{k_0+1}} x_1^{n_1} \cdots x_{k_0+1}^{n_{k_0+1}}, \quad (\text{S.1.4})$$

where the summation is over all  $n_1, \dots, n_{k_0+1}$  such that  $n_1 + \cdots + n_{k_0+1} = n$ . Let  $y_i = x_i$  for  $i = 1, \dots, k_0 - 1$  and let  $y_{k_0} = x_{k_0} + x_{k_0+1}$ . We then have

$$(x_1 + \cdots + x_{k_0+1})^n = (y_1 + \cdots + y_{k_0})^n.$$

Since we have assumed that the theorem is true for  $k = k_0$ , we know that

$$(y_1 + \cdots + y_{k_0})^n = \sum \binom{n}{m_1, \dots, m_{k_0}} y_1^{m_1} \cdots y_{k_0}^{m_{k_0}}, \quad (\text{S.1.5})$$

where the summation is over all  $m_1, \dots, m_{k_0}$  such that  $m_1 + \cdots + m_{k_0} = n$ . On the right side of (S.1.5), substitute  $x_{k_0} + x_{k_0+1}$  for  $y_{k_0}$  and apply the binomial theorem to obtain

$$\sum \binom{n}{m_1, \dots, m_{k_0}} y_1^{m_1} \cdots y_{k_0-1}^{m_{k_0-1}} \sum_{i=0}^{m_{k_0}} \binom{m_{k_0}}{i} x_{k_0}^i x_{k_0+1}^{m_{k_0}-i}. \quad (\text{S.1.6})$$

In (S.1.6), let  $n_i = m_i$  for  $i = 1, \dots, k_0 - 1$ , let  $n_{k_0} = i$ , and let  $n_{k_0+1} = m_{k_0} - i$ . Then, in the summation in (S.1.6),  $n_1 + \cdots + n_{k_0+1} = n$  if and only if  $m_1 + \cdots + m_{k_0} = n$ . Also, note that

$$\binom{n}{m_1, \dots, m_{k_0}} \binom{m_{k_0}}{i} = \binom{n}{n_1, \dots, n_{k_0+1}}.$$

So, (S.1.6) becomes

$$\sum \binom{n}{n_1, \dots, n_{k_0+1}} x_1^{n_1} \cdots x_{k_0+1}^{n_{k_0+1}},$$

where this last sum is over all  $n_1, \dots, n_{k_0+1}$  such that  $n_1 + \cdots + n_{k_0+1} = n$ .

12. For each element  $s'$  of  $S'$ , the elements of  $S$  that lead to boxful  $s'$  are all the different sequences of elements of  $s'$ . That is, think of each  $s'$  as an unordered set of 12 numbers chosen with replacement from 1 to 7. For example,  $\{1, 1, 2, 3, 3, 3, 5, 6, 7, 7, 7, 7\}$  is one such set. The following are some of the elements of  $S$  lead to the same set  $s'$ :  $(1, 1, 2, 3, 3, 3, 5, 6, 7, 7, 7, 7)$ ,  $(1, 2, 3, 5, 6, 7, 1, 3, 7, 3, 7, 7)$ ,  $(7, 1, 7, 2, 3, 5, 7, 1, 6, 3, 7, 3)$ . This problem is pretty much the same as that which leads to the definition of multinomial coefficients. We are looking for the number of orderings of 12 digits chosen from the numbers 1 to 7 that have two of 1, one of 2, three of 3, none of 4, one of 5, one of 6, and four of 7. This is just  $\binom{12}{1,1,3,0,1,1,4}$ . For a general  $s'$ , for  $i = 1, \dots, 7$ , let  $n_i(s')$  be the number of  $i$ 's in the box  $s'$ . Then  $n_1(s') + \dots + n_7(s') = 12$ , and the number of orderings of these numbers is

$$N(s') = \binom{12}{n_1(s'), n_2(s'), \dots, n_7(s')}.$$

The multinomial theorem tells us that

$$\sum_{\text{All } s'} N(s') = \sum \binom{12}{n_1, n_2, \dots, n_7} 1^{n_1} \cdots 1^{n_7} = 7^{12},$$

where the sum is over all possible combinations of nonnegative integers  $n_1, \dots, n_7$  that add to 12. This matches the number of outcomes in  $S$ .

## 1.10 The Probability of a Union of Events

### Commentary

This section ends with an example of the matching problem. This is an application of the formula for the probability of a union of an arbitrary number of events. It requires a long line of argument and contains an interesting limiting result. The example will be interesting to students with good mathematics backgrounds, but it might be too challenging for students who have struggled to master combinatorics. One can use statistical software, such as  $R$ , to help illustrate how close the approximation is. The formula (1.10.10) can be computed as

```
ints=1:n
sum(exp(-lfactorial(ints))*(-1)^(ints+1)),
```

where  $n$  has previously been assigned the value of  $n$  for which one wishes to compute  $p_n$ .

### Solutions to Exercises

- Let  $A_i$  be the event that person  $i$  receives exactly two aces for  $i = 1, 2, 3$ . We want  $\Pr(\cup_{i=1}^3 A_i)$ . We shall apply Theorem 1.10.1 directly. Let the sample space consist of all permutations of the 52 cards where the first five cards are dealt to person 1, the second five to person 2, and the third five to person 3. A permutation of 52 cards that leads to the occurrence of event  $A_i$  can be constructed as follows. First, choose which of person  $i$ 's five locations will receive the two aces. There are  $C_{5,2}$  ways to do this. Next, for each such choice, choose the two aces that will go in these locations, distinguishing the order in which they are placed. There are  $P_{4,2}$  ways to do this. Next, for each of the preceding choices, choose the locations for the other two aces from among the 47 locations that are not dealt to person  $i$ , distinguishing order. There are  $P_{47,2}$  ways to do this. Finally, for each of the preceding choices, choose a permutation of the remaining 48 cards among the remaining 48 locations. There are  $48!$  ways to do this. Since there are  $52!$  equally likely permutations in the sample space, we have

$$\Pr(A_i) = \frac{C_{5,2} P_{4,2} P_{47,2} 48!}{52!} = \frac{5! 4! 47! 48!}{2! 3! 2! 45! 52!} \approx 0.0399.$$

Careful examination of the expression for  $\Pr(A_i)$  reveals that it can also be expressed as

$$\Pr(A_i) = \frac{\binom{4}{2} \binom{48}{3}}{\binom{52}{5}}.$$

This expression corresponds to a different, but equally correct, way of describing the sample space in terms of equally likely outcomes. In particular, the sample space would consist of the different possible five-card sets that person  $i$  could receive without regard to order.

Next, compute  $\Pr(A_i A_j)$  for  $i \neq j$ . There are still  $C_{5,2}$  ways to choose the locations for person  $i$ 's aces amongst the five cards and for each such choice, there are  $P_{4,2}$  ways to choose the two aces in order. For each of the preceding choices, there are  $C_{5,2}$  ways to choose the locations for person  $j$ 's aces and 2 ways to order the remaining two aces amongst the two locations. For each combination of the preceding choices, there are  $48!$  ways to arrange the remaining 48 cards in the 48 unassigned locations. Then,  $\Pr(A_i A_j)$  is

$$\Pr(A_i A_j) = \frac{2C_{5,2}^2 P_{4,2} 48!}{52!} = \frac{2(5!)^2 4! 48!}{(2!)^3 (3!)^2 52!} \approx 3.694 \times 10^{-4}.$$

Once again, we can rewrite the expression for  $\Pr(A_i A_j)$  as

$$\Pr(A_i A_j) = \frac{\binom{4}{2} \binom{48}{3, 3, 42}}{\binom{52}{5, 5, 42}}.$$

This corresponds to treating the sample space as the set of all pairs of five-card subsets.

Next, notice that it is impossible for all three players to receive two aces, so  $\Pr(A_1 A_2 A_3) = 0$ . Applying Theorem 1.10.1, we obtain

$$\Pr\left(\bigcup_{i=1}^3 A_i\right) = 3 \times 0.0399 - 3 \times 3.694 \times 10^{-4} = 0.1186.$$

2. Let  $A$ ,  $B$ , and  $C$  stand for the events that a randomly selected family subscribes to the newspaper with the same name. Then  $\Pr(A \cup B \cup C)$  is the proportion of families that subscribe to at least one newspaper. According to Theorem 1.10.1, we can express this probability as

$$\Pr(A) + \Pr(B) + \Pr(C) - \Pr(A \cap B) - \Pr(AC) - \Pr(BC) + \Pr(A \cap BC).$$

The probabilities in this expression are the proportions of families that subscribe to the various combinations. These proportions are all stated in the exercise, so the formula yields

$$\Pr(A \cup B \cup C) = 0.6 + 0.4 + 0.3 - 0.2 - 0.1 - 0.2 + 0.05 = 0.85.$$

3. As seen from Fig. S.1.1, the required percentage is  $P_1 + P_2 + P_3$ . From the given values, we have, in percentages,

Figure S.1.1: Figure for Exercise 3 of Sec. 1.10.

$$\begin{aligned}
 P_7 &= 5, \\
 P_4 &= 20 - P_7 = 15, \\
 P_5 &= 20 - P_7 = 15, \\
 P_6 &= 10 - P_7 = 5, \\
 P_1 &= 60 - P_4 - P_6 - P_7 = 35, \\
 P_2 &= 40 - P_4 - P_5 - P_7 = 5, \\
 P_3 &= 30 - P_5 - P_6 - P_7 = 5.
 \end{aligned}$$

Therefore,  $P_1 + P_2 + P_3 = 45$ .

4. This is a case of the matching problem with  $n = 3$ . We are asked to find  $p_3$ . By Eq. (1.10.10) in the text, this equals

$$p_3 = 1 - \frac{1}{2} + \frac{1}{6} = \frac{2}{3}.$$

5. Determine first the probability that at least one guest will receive the proper hat. This probability is the value  $p_n$  specified in the matching problem, with  $n = 4$ , namely

$$p_4 = 1 - \frac{1}{2} + \frac{1}{6} - \frac{1}{24} = \frac{5}{8}.$$

So, the probability that no guest receives the proper hat is  $1 - 5/8 = 3/8$ .

6. Let  $A_1$  denote the event that no red balls are selected, let  $A_2$  denote the event that no white balls are selected, and let  $A_3$  denote the event that no blue balls are selected. The desired probability is  $\Pr(A_1 \cup A_2 \cup A_3)$  and we shall apply Theorem 1.10.1. The event  $A_1$  will occur if and only if the ten selected balls are either white or blue. Since there are 60 white and blue balls, out of a total of 90 balls, we have  $\Pr(A_1) = \binom{60}{10}/\binom{90}{10}$ . Similarly,  $\Pr(A_2)$  and  $\Pr(A_3)$  have the same value. The event  $A_1 A_2$  will occur if and only if all ten selected balls are blue. Therefore,  $\Pr(A_1 A_2) = \binom{30}{10}/\binom{90}{10}$ . Similarly,  $\Pr(A_2 A_3)$  and  $\Pr(A_1 A_3)$  have the same value. Finally, the event  $A_1 A_2 A_3$  will occur if and only if all three colors are missing, which is obviously impossible. Therefore,  $\Pr(A_1 A_2 A_3) = 0$ . When these values

are substituted into Eq. (1.10.1), we obtain the desired probability,

$$\Pr(A_1 \cup A_2 \cup A_3) = 3 \frac{\binom{60}{10}}{\binom{90}{10}} - 3 \frac{\binom{30}{10}}{\binom{90}{10}}.$$

7. Let  $A_1$  denote the event that no student from the freshman class is selected, and let  $A_2, A_3$ , and  $A_4$  denote the corresponding events for the sophomore, junior, and senior classes, respectively. The probability that at least one student will be selected from each of the four classes is equal to  $1 - \Pr(A_1 \cup A_2 \cup A_3 \cup A_4)$ . We shall evaluate  $\Pr(A_1 \cup A_2 \cup A_3 \cup A_4)$  by applying Theorem 1.10.2. The event  $A_1$  will occur if and only if the 15 selected students are sophomores, juniors, or seniors. Since there are 90 such students out of a total of 100 students, we have  $\Pr(A_1) = \binom{90}{15} / \binom{100}{15}$ . The values of  $\Pr(A_i)$  for  $i = 2, 3, 4$  can be obtained in a similar fashion. Next, the event  $A_1 A_2$  will occur if and only if the 15 selected students are juniors or seniors. Since there are a total of 70 juniors and seniors, we have  $\Pr(A_1 A_2) = \binom{70}{15} / \binom{100}{15}$ . The probability of each of the six events of the form  $A_i A_j$  for  $i < j$  can be obtained in this way. Next the event  $A_1 A_2 A_3$  will occur if and only if all 15 selected students are seniors. Therefore,  $\Pr(A_1 A_2 A_3) = \binom{40}{15} / \binom{100}{15}$ . The probabilities of the events  $A_1 A_2 A_4$  and  $A_1 A_3 A_4$  can also be obtained in this way. It should be noted, however, that  $\Pr(A_2 A_3 A_4) = 0$  since it is impossible that all 15 selected students will be freshmen. Finally, the event  $A_1 A_2 A_3 A_4$  is also obviously impossible, so  $\Pr(A_1 A_2 A_3 A_4) = 0$ . So, the probability we want is

$$1 - \left[ \frac{\binom{90}{15}}{\binom{100}{15}} + \frac{\binom{80}{15}}{\binom{100}{15}} + \frac{\binom{70}{15}}{\binom{100}{15}} + \frac{\binom{60}{15}}{\binom{100}{15}} - \frac{\binom{70}{15}}{\binom{100}{15}} - \frac{\binom{60}{15}}{\binom{100}{15}} - \frac{\binom{50}{15}}{\binom{100}{15}} - \frac{\binom{50}{15}}{\binom{100}{15}} - \frac{\binom{40}{15}}{\binom{100}{15}} - \frac{\binom{30}{15}}{\binom{100}{15}} + \frac{\binom{40}{15}}{\binom{100}{15}} + \frac{\binom{30}{15}}{\binom{100}{15}} + \frac{\binom{20}{15}}{\binom{100}{15}} \right].$$

8. It is impossible to place exactly  $n - 1$  letters in the correct envelopes, because if  $n - 1$  letters are placed correctly, then the  $n$ th letter must also be placed correctly.
9. Let  $p_n = 1 - q_n$ . As discussed in the text,  $p_{10} < p_{300} < 0.63212 < p_{53} < p_{21}$ . Since  $p_n$  is smallest for  $n = 10$ , then  $q_n$  is largest for  $n = 10$ .
10. There is exactly one outcome in which only letter 1 is placed in the correct envelope, namely the outcome in which letter 1 is correctly placed, letter 2 is placed in envelope 3, and letter 3 is placed in envelope 2. Similarly there is exactly one outcome in which only letter 2 is placed correctly, and one in which only letter 3 is placed correctly. Hence, of the  $3! = 6$  possible outcomes, 3 outcomes yield the result that exactly one letter is placed correctly. So, the probability is  $3/6 = 1/2$ .
11. Consider choosing 5 envelopes at random into which the 5 red letters will be placed. If there are exactly  $r$  red envelopes among the five selected envelopes ( $r = 0, 1, \dots, 5$ ), then exactly  $x = 2r$  envelopes will

contain a card with a matching color. Hence, the only possible values of  $x$  are 0, 2, 4..., 10. Thus, for  $x = 0, 2, \dots, 10$  and  $r = x/2$ , the desired probability is the probability that there are exactly  $r$  red

envelopes among the five selected envelopes, which is  $\frac{\binom{5}{r} \binom{5}{5-r}}{\binom{10}{5}}$ .

12. It was shown in the solution of Exercise 12 of Sec. 1.5. that

$$\Pr\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} \Pr(B_i) = \lim_{n \rightarrow \infty} \sum_{i=1}^n \Pr(B_i) = \lim_{n \rightarrow \infty} \Pr\left(\bigcup_{i=1}^n B_i\right) = \lim_{n \rightarrow \infty} \Pr\left(\bigcup_{i=1}^n A_i\right).$$

However, since  $A_1 \subset A_2 \subset \dots \subset A_n$ , it follows that  $\bigcup_{i=1}^n A_i = A_n$ . Hence,

$$\Pr\left(\bigcup_{i=1}^{\infty} A_i\right) = \lim_{n \rightarrow \infty} \Pr(A_n).$$

13. We know that

$$\bigcap_{i=1}^{\infty} A_i = \left(\bigcup_{i=1}^{\infty} A_i^c\right)^c.$$

Hence,

$$\Pr\left(\bigcap_{i=1}^{\infty} A_i\right) = 1 - \Pr\left(\bigcup_{i=1}^{\infty} A_i^c\right).$$

However, since  $A_1 \supset A_2 \supset \dots$ , then  $A_1^c \subset A_2^c \subset \dots$ . Therefore, by Exercise 12,

$$\Pr\left(\bigcup_{i=1}^{\infty} A_i^c\right) = \lim_{n \rightarrow \infty} \Pr(A_n^c) = \lim_{n \rightarrow \infty} [1 - \Pr(A_n)] = 1 - \lim_{n \rightarrow \infty} \Pr(A_n).$$

It now follows that

$$\Pr\left(\bigcap_{i=1}^{\infty} A_i\right) = \lim_{n \rightarrow \infty} \Pr(A_n).$$

## 1.12 Supplementary Exercises

### Solutions to Exercises

1. No, since both  $A$  and  $B$  might occur.
2.  $\Pr(A^c \cap B^c \cap D^c) = \Pr[(A \cup B \cup D)^c] = 0.3$ .

$$3. \frac{\binom{250}{18} \cdot \binom{100}{12}}{\binom{350}{30}}.$$

4. There are  $\binom{20}{10}$  ways of choosing 10 cards from the deck. For  $j = 1, \dots, 5$ , there  $\binom{4}{2}$  ways of choosing two cards with the number  $j$ . Hence, the answer is

$$\frac{\binom{4}{2} \cdots \binom{4}{2}}{\binom{20}{10}} = \frac{6^5}{\binom{20}{10}} \approx 0.0421.$$

5. The region where total utility demand is at least 215 is shaded in Fig. S.1.2. The area of the shaded

Figure S.1.2: Region where total utility demand is at least 215 in Exercise 5 of Sec. 1.12.

region is

$$\frac{1}{2} \times 135 \times 135 = 9112.5$$

The probability is then  $9112.5/29204 = 0.3120$ .

6. (a) There are  $\binom{r+w}{r}$  possible positions that the red balls could occupy in the ordering as they are drawn. Therefore, the probability that they will be in the first  $r$  positions is  $1/\binom{r+w}{r}$ .
- (b) There are  $\binom{r+1}{r}$  ways that the red balls can occupy the first  $r+1$  positions in the ordering. Therefore, the probability is  $\binom{r+1}{r}/\binom{r+w}{r} = (r+1)/\binom{r+w}{r}$ .
7. The presence of the blue balls is irrelevant in this problem, since whenever a blue ball is drawn it is ignored. Hence, the answer is the same as in part (a) of Exercise 6.
8. There are  $\binom{10}{7}$  ways of choosing the seven envelopes into which the red cards will be placed. There

are  $\binom{7}{j} \binom{3}{7-j}$  ways of choosing exactly  $j$  red envelopes and  $7 - j$  green envelopes. Therefore, the probability that exactly  $j$  red envelopes will contain red cards is

$$\binom{7}{j} \binom{3}{7-j} / \binom{10}{7} \quad \text{for } j = 4, 5, 6, 7.$$

But if  $j$  red envelopes contain red cards, then  $j - 4$  green envelopes must also contain green cards. Hence, this is also the probability of exactly  $k = j + (j - 4) = 2j - 4$  matches.

9. There are  $\binom{10}{5}$  ways of choosing the five envelopes into which the red cards will be placed. There are  $\binom{7}{j} \binom{3}{5-j}$  ways of choosing exactly  $j$  red envelopes and  $5 - j$  green envelopes. Therefore the probability that exactly  $j$  red envelopes will contain red cards is

$$\binom{7}{j} \binom{3}{5-j} / \binom{10}{5} \quad \text{for } j = 2, 3, 4, 5.$$

But if  $j$  red envelopes contain red cards, then  $j - 2$  green envelopes must also contain green cards. Hence, this is also the probability of exactly  $k = j + (j - 2) = 2j - 2$  matches.

10. If there is a point  $x$  that belongs to neither  $A$  nor  $B$ , then  $x$  belongs to both  $A^c$  and  $B^c$ . Hence,  $A^c$  and  $B^c$  are not disjoint. Therefore,  $A^c$  and  $B^c$  will be disjoint if and only if  $A \cup B = S$ .
11. We can use Fig. S.1.1 by relabeling the events  $A$ ,  $B$ , and  $C$  in the figure as  $A_1$ ,  $A_2$ , and  $A_3$  respectively. It is now easy to see that the probability that exactly one of the three events occurs is  $p_1 + p_2 + p_3$ . Also,

$$\begin{aligned} \Pr(A_1) &= p_1 + p_4 + p_6 + p_7, \\ \Pr(A_1 \cap A_2) &= p_4 + p_7, \text{ etc.} \end{aligned}$$

By breaking down each probability in the given expression in this way, we obtain the desired result.

12. The proof can be done in a manner similar to that of Theorem 1.10.2. Here is an alternative argument. Consider first a point that belongs to exactly one of the events  $A_1, \dots, A_n$ . Then this point will be counted in exactly one of the  $\Pr(A_i)$  terms in the given expression, and in none of the intersections. Hence, it will be counted exactly once in the given expression, as required. Now consider a point that belongs to exactly  $r$  of the events  $A_1, \dots, A_n$  ( $r \geq 2$ ). Then it will be counted in exactly  $r$  of the  $\Pr(A_i)$  terms, exactly  $\binom{r}{2}$  of the  $\Pr(A_i A_j)$  terms, exactly  $\binom{r}{3}$  of the  $\Pr(A_i A_j A_k)$  terms, etc. Hence, in the given expression it will be counted the following number of times:

$$\begin{aligned} r &- 2\binom{r}{2} + 3\binom{r}{3} - \dots \pm r\binom{r}{r} \\ &= r \left[ \binom{r-1}{0} - \binom{r-1}{1} + \binom{r-1}{2} - \dots \pm \binom{r-1}{r-1} \right] = 0, \end{aligned}$$

by Exercise b of Sec. 1.8. Hence, a point will be counted in the given expression if and only if it belongs to exactly one of the events  $A_1, \dots, A_n$ , and then it will be counted exactly once.

13. (a) In order for the winning combination to have no consecutive numbers, between every pair of numbers in the winning combination there must be at least one number not in the winning combination. That is, there must be at least  $k - 1$  numbers not in the winning combination to be in between the pairs of numbers in the winning combination. Since there are  $k$  numbers in the winning combination, there must be at least  $k + k - 1 = 2k - 1$  numbers available in order for it to be possible to have no consecutive numbers in the winning combination. So,  $n$  must be at least  $2k - 1$  to allow consecutive numbers.
- (b) Let  $i_1, \dots, i_k$  and  $j_1, \dots, j_k$  be as described in the problem. For one direction, suppose that  $i_1, \dots, i_k$  contains at least one pair of consecutive integers, say  $i_{a+1} = i_a + 1$ . Then

$$j_{a+1} = i_{a+1} - a = i_a + 1 - a = i_a - (a - 1) = j_a.$$

So,  $j_1, \dots, j_k$  contains repeats. For the other direction, suppose that  $j_1, \dots, j_k$  contains repeats, say  $j_{a+1} = j_a$ . Then

$$i_{a+1} = j_{a+1} + a = j_a + a = i_a + 1.$$

So  $i_1, \dots, i_k$  contains a pair of consecutive numbers.

- (c) Since  $i_1 < i_2 < \dots < i_k$ , we know that  $i_a + 1 \leq i_{a+1}$ , so that  $j_a = i_a - a + 1 \leq i_{a+1} - a = j_{a+1}$  for each  $a = 1, \dots, k - 1$ . Since  $i_k \leq n$ ,  $j_k = i_k - k + 1 \leq n - k + 1$ . The set of all  $(j_1, \dots, j_k)$  with  $1 \leq j_1 < \dots < j_k \leq n - k + 1$  is just the number of combinations of  $n - k + 1$  items taken  $k$  at a time, that is  $\binom{n - k + 1}{k}$ .
- (d) By part (b), there are no pairs of consecutive integers in the winning combination  $(i_1, \dots, i_k)$  if and only if  $(j_1, \dots, j_k)$  has no repeats. The total number of winning combinations is  $\binom{n}{k}$ . In part (c), we computed the number of winning combinations with no repeats among  $(j_1, \dots, j_k)$  to be  $\binom{n - k + 1}{k}$ . So, the probability of no consecutive integers is

$$\frac{\binom{n - k + 1}{k}}{\binom{n}{k}} = \frac{(n - k)!(n - k + 1)!}{n!(n - 2k + 1)!}.$$

- (e) The probability of at least one pair of consecutive integers is one minus the answer to part (d).

# Chapter 2

## Conditional Probability

### 2.1 The Definition of Conditional Probability

#### Commentary

It is useful to stress the point raised in the note on page 59. That is, conditional probabilities behave just like probabilities. This will come up again in Sec. 3.6 where conditional distributions are introduced.

This section ends with an extended example called “The Game of Craps”. This example helps to reinforce a subtle line of reasoning about conditional probability that was introduced in Example 2.1.5. In particular, it uses the idea that conditional probabilities given an event  $B$  can be calculated as if we knew ahead of time that  $B$  had to occur.

#### Solutions to Exercises

1. If  $A \subset B$ , then  $A \cap B = A$  and  $\Pr(A \cap B) = \Pr(A)$ . So  $\Pr(A|B) = \Pr(A)/\Pr(B)$ .
2. Since  $A \cap B = \emptyset$ , it follows that  $\Pr(A \cap B) = 0$ . Therefore,  $\Pr(A | B) = 0$ .
3. Since  $A \cap S = A$  and  $\Pr(S) = 1$ , it follows that  $\Pr(A | S) = \Pr(A)$ .
4. Let  $A_i$  stand for the event that the shopper purchases brand  $A$  on his  $i$ th purchase, for  $i = 1, 2, \dots$ . Similarly, let  $B_i$  be the event that he purchases brand  $B$  on the  $i$ th purchase. Then

$$\begin{aligned}\Pr(A_1) &= \frac{1}{2}, \\ \Pr(A_2 | A_1) &= \frac{1}{3}, \\ \Pr(B_3 | A_1 \cap A_2) &= \frac{2}{3}, \\ \Pr(B_4 | A_1 \cap A_2 \cap B_3) &= \frac{1}{3}.\end{aligned}$$

The desired probability is the product of these four probabilities, namely  $1/27$ .

5. Let  $R_i$  be the event that a red ball is drawn on the  $i$ th draw, and let  $B_i$  be the event that a blue ball is drawn on the  $i$ th draw for  $i = 1, \dots, 4$ . Then

$$\Pr(R_1) = \frac{r}{r+b},$$

$$\begin{aligned}\Pr(R_2 | R_1) &= \frac{r+k}{r+b+k}, \\ \Pr(R_3 | R_1 \cap R_2) &= \frac{r+2k}{r+b+2k}, \\ \Pr(B_4 | R_1 \cap R_2 \cap R_3) &= \frac{b}{r+b+3k}.\end{aligned}$$

The desired probability is the product of these four probabilities, namely

$$\frac{r(r+k)(r+2k)b}{(r+b)(r+b+k)(r+b+2k)(r+b+3k)}.$$

6. This problem illustrates the importance of relying on the rules of conditional probability rather than on intuition to obtain the answer. Intuitively, but incorrectly, it might seem that since the observed side is green, and since the other side might be either red or green, the probability that it will be green is  $1/2$ . The correct analysis is as follows: Let  $A$  be the event that the selected card is green on both sides, and let  $B$  be the event that the observed side is green. Since each of the three cards is equally likely to be selected,  $\Pr(A) = \Pr(A \cap B) = 1/3$ . Also,  $\Pr(B) = 1/2$ . The desired probability is  $\Pr(A | B) = \left(\frac{1}{3}\right) / \left(\frac{1}{2}\right) = \frac{2}{3}$ .
7. We know that  $\Pr(A) = 0.6$  and  $\Pr(A \cap B) = 0.2$ . Therefore,  $\Pr(B | A) = \frac{0.2}{0.6} = \frac{1}{3}$ .
8. In Exercise 2 in Sec. 1.10 it was found that  $\Pr(A \cup B \cup C) = 0.85$ . Since  $\Pr(A) = 0.6$ , it follows that  $\Pr(A | A \cup B \cup C) = \frac{0.60}{0.85} = \frac{12}{17}$ .
9. (a) If card  $A$  has been selected, each of the other four cards is equally likely to be the other selected card. Since three of these four cards are red, the required probability is  $3/4$ .  
(b) We know, without being told, that at least one red card must be selected, so this information does not affect the probabilities of any events. We have

$$\Pr(\text{both cards red}) = \Pr(R_1) \Pr(R_2 | R_1) = \frac{4}{5} \cdot \frac{3}{4} = \frac{3}{5}.$$

10. As in the text, let  $\pi_0$  stand for the probability that the sum on the first roll is either 7 or 11, and let  $\pi_i$  be the probability that the sum on the first roll is  $i$  for  $i = 2, \dots, 12$ . In this version of the game of craps, we have

$$\begin{aligned}\pi_0 &= \frac{2}{9}, \\ \pi_4 &= \pi_{10} = \frac{3}{36} \cdot \frac{\frac{3}{36}}{\frac{3}{36} + \frac{6}{36} + \frac{2}{36}} = \frac{1}{44}, \\ \pi_5 &= \pi_9 = \frac{4}{36} \cdot \frac{\frac{4}{36}}{\frac{4}{36} + \frac{6}{36} + \frac{2}{36}} = \frac{1}{27}, \\ \pi_6 &= \pi_8 = \frac{5}{36} \cdot \frac{\frac{5}{36}}{\frac{5}{36} + \frac{6}{36} + \frac{2}{36}} = \frac{25}{468}.\end{aligned}$$

The probability of winning, which is the sum of these probabilities, is 0.448.

11. This is the conditional version of Theorem 1.5.3. From the definition of conditional probability, we have

$$\begin{aligned}\Pr(A^c|B) &= \frac{\Pr(A^c \cap B)}{\Pr(B)}, \\ 1 - \Pr(A|B) &= 1 - \frac{\Pr(A \cap B)}{\Pr(B)}, \\ &= \frac{\Pr(B) - \Pr(A \cap B)}{\Pr(B)}.\end{aligned}\tag{S.2.1}$$

According to Theorem 1.5.6 (switching the names  $A$  and  $B$ ),  $\Pr(B) - \Pr(A \cap B) = \Pr(A^c \cap B)$ . Combining this with (S.2.1) yields  $1 - \Pr(A|B) = \Pr(A^c|B)$ .

12. This is the conditional version of Theorem 1.5.7. Let  $A_1 = A \cap D$  and  $A_2 = B \cap D$ . Then  $A_1 \cup A_2 = (A \cup B) \cap D$  and  $A_1 \cap A_2 = A \cap B \cap D$ . Now apply Theorem 1.5.7 to determine  $\Pr(A_1 \cup A_2)$ .

$$\begin{aligned}\Pr([A \cup B] \cap D) &= \Pr(A_1 \cup A_2) = \Pr(A_1) + \Pr(A_2) - \Pr(A_1 \cap A_2) = \Pr(A \cap D) \\ &\quad + \Pr(B \cap D) - \Pr(A \cap B \cap D).\end{aligned}$$

Now, divide the extreme left and right ends of this string of equalities by  $\Pr(D)$  to obtain

$$\begin{aligned}\Pr(A \cup B|D) &= \frac{\Pr([A \cup B] \cap D)}{\Pr(D)} = \frac{\Pr(A \cap D) + \Pr(B \cap D) - \Pr(A \cap B \cap D)}{\Pr(D)} \\ &= \Pr(A|D) + \Pr(B|D) - \Pr(A \cap B|D).\end{aligned}$$

13. Let  $A_1$  denote the event that the selected coin has a head on each side, let  $A_2$  denote the event that it has a tail on each side, let  $A_3$  denote the event that it is fair, and let  $B$  denote the event that a head is obtained. Then

$$\begin{aligned}\Pr(A_1) &= \frac{3}{9}, \quad \Pr(A_2) = \frac{4}{9}, \quad \Pr(A_3) = \frac{2}{9}, \\ \Pr(B | A_1) &= 1, \quad \Pr(B | A_2) = 0, \quad \Pr(B | A_3) = \frac{1}{2}.\end{aligned}$$

Hence,

$$\Pr(B) = \sum_{i=1}^3 \Pr(A_i) \Pr(B | A_i) = \frac{4}{9}.$$

14. We partition the space of possibilities into three events  $B_1, B_2, B_3$  as follows. Let  $B_1$  be the event that the machine is in good working order. Let  $B_2$  be the event that the machine is wearing down. Let  $B_3$  be the event that it needs maintenance. We are told that  $\Pr(B_1) = 0.8$  and  $\Pr(B_2) = \Pr(B_3) = 0.1$ . Let  $A$  be the event that a part is defective. We are asked to find  $\Pr(A)$ . We are told that  $\Pr(A|B_1) = 0.02$ ,  $\Pr(A|B_2) = 0.1$ , and  $\Pr(A|B_3) = 0.3$ . The law of total probability allows us to compute  $\Pr(A)$  as follows

$$\Pr(A) = \sum_{j=1}^3 \Pr(B_j) \Pr(A|B_j) = 0.8 \times 0.02 + 0.1 \times 0.1 + 0.1 \times 0.3 = 0.056.$$

15. The analysis is similar to that given in the previous exercise, and the probability is 0.47.
16. In the usual notation, we have

$$\begin{aligned}\Pr(B_2) &= \Pr(A_1 \cap B_2) + \Pr(B_1 \cap B_2) = \Pr(A_1) \Pr(B_2 | A_1) + \Pr(B_1) \Pr(B_2 | B_1) \\ &= \frac{1}{4} \cdot \frac{2}{3} + \frac{3}{4} \cdot \frac{1}{3} = \frac{5}{12}.\end{aligned}$$

17. Clearly, we must assume that  $\Pr(B_j \cap C) > 0$  for all  $j$ , otherwise (2.1.5) is undefined. By applying the definition of conditional probability to each term, the right side of (2.1.5) can be rewritten as

$$\sum_{i=1}^k \frac{\Pr(B_i \cap C)}{\Pr(C)} \frac{\Pr(A \cap B_i \cap C)}{\Pr(B_i \cap C)} = \frac{1}{\Pr(C)} \sum_{i=1}^k \Pr(A \cap B_i \cap C).$$

According to the law of total probability, the last sum above is  $\Pr(A \cap C)$ , hence the ratio is  $\Pr(A|C)$ .

## 2.2 Independent Events

### Commentary

Near the end of this section, we introduce conditionally independent events. This is a prelude to conditionally independent and conditionally i.i.d. random variables that are introduced in Sec. 3.7. Conditional independence has become more popular in statistical modeling with the introduction of latent-variable models and expert systems. Although these models are not introduced in this text, students who will encounter them in the future would do well to study conditional independence early and often.

Conditional independence is also useful for illustrating how learning data can change the distribution of an unknown value. The first examples of this come in Sec. 2.3 after Bayes' theorem. The assumption that a sample of random variables is conditionally i.i.d. given an unknown parameter is the analog in Bayesian inference to the assumption that the random sample is i.i.d. marginally. Instructors who are not going to cover Bayesian topics might wish to bypass this material, even though it can also be useful in its own right. If you decide to not discuss conditional independence, then there is some material later in the book that you might wish to bypass as well:

- Exercise 23 in this section.
- The discussion of conditionally independent events on pages 81–84 in Sec. 2.3.
- Exercises 12, 14 and 15 in Sec. 2.3.
- The discussion of conditionally independent random variables that starts on page 163.
- Exercises 13 and 14 in Sec. 3.7.
- Virtually all of the Bayesian material.

This section ends with an extended example called “The Collector’s Problem”. This example combines methods from Chapters 1 and 2 to solve an easily stated but challenging problem.

## Solutions to Exercises

1. If  $\Pr(B) < 1$ , then  $\Pr(B^c) = 1 - \Pr(B) > 0$ . We then compute

$$\begin{aligned}\Pr(A^c|B^c) &= \frac{\Pr(A^c \cap B^c)}{\Pr(B^c)} \\ &= \frac{1 - \Pr(A \cup B)}{1 - \Pr(B)} \\ &= \frac{1 - \Pr(A) - \Pr(B) + \Pr(A \cap B)}{1 - \Pr(B)} \\ &= \frac{1 - \Pr(A) - \Pr(B) + \Pr(A)\Pr(B)}{1 - \Pr(B)} \\ &= \frac{[1 - \Pr(A)][1 - \Pr(B)]}{1 - \Pr(B)} \\ &= 1 - \Pr(A) = \Pr(A^c).\end{aligned}$$

2.

$$\begin{aligned}\Pr(A^c B^c) &= \Pr[(A \cup B)^c] = 1 - \Pr(A \cup B) \\ &= 1 - [\Pr(A) + \Pr(B) - \Pr(A \cap B)] \\ &= 1 - \Pr(A) - \Pr(B) + \Pr(A)\Pr(B) \\ &= [1 - \Pr(A)][1 - \Pr(B)] \\ &= \Pr(A^c)\Pr(B^c).\end{aligned}$$

3. Since the event  $A \cap B$  is a subset of the event  $A$ , and  $\Pr(A) = 0$ , it follows that  $\Pr(A \cap B) = 0$ . Hence,  $\Pr(A \cap B) = 0 = \Pr(A)\Pr(B)$ .
4. The probability that the sum will be seven on any given roll of the dice is  $1/6$ . The probability that this event will occur on three successive rolls is therefore  $(1/6)^3$ .
5. The probability that both systems will malfunction is  $(0.001)^2 = 10^{-6}$ . The probability that at least one of the systems will function is therefore  $1 - 10^{-6}$ .
6. The probability that the man will win the first lottery is  $100/10000 = 0.01$ , and the probability that he will win the second lottery is  $100/5000 = 0.02$ . The probability that he will win at least one lottery is, therefore,

$$0.01 + 0.02 - (0.01)(0.02) = 0.0298.$$

7. Let  $E_1$  be the event that  $A$  is in class, and let  $E_2$  be the event that  $B$  is in class. Let  $C$  be the event that at least one of the students is in class. That is,  $C = E_1 \cup E_2$ .
- (a) We want  $\Pr(C)$ . We shall use Theorem 1.5.7 to compute the probability. Since  $E_1$  and  $E_2$  are independent, we have  $\Pr(E_1 \cap E_2) = \Pr(E_1)\Pr(E_2)$ . Hence

$$\Pr(C) = \Pr(E_1) + \Pr(E_2) - \Pr(E_1 \cap E_2) = 0.8 + 0.6 - 0.8 \times 0.6 = 0.92.$$

- (b) We want  $\Pr(E_1|C)$ . We computed  $\Pr(C) = 0.92$  in part (a). Since  $E_1 \subset C$ ,  $\Pr(E_1 \cap C) = \Pr(E_1) = 0.8$ . So,  $\Pr(E_1|C) = 0.8/0.92 = 0.8696$ .

8. The probability that all three numbers will be equal to a specified value is  $1/6^3$ . Therefore, the probability that all three numbers will be equal to any one of the six possible values is  $6/6^3 = 1/36$ .
9. The probability that exactly  $n$  tosses will be required on a given performance is  $1/2^n$ . Therefore, the probability that exactly  $n$  tosses will be required on all three performances is  $(1/2^n)^3 = 1/8^n$ . The probability that the same number of tosses will be required on all three performances is  $\sum_{n=1}^{\infty} \frac{1}{8^n} = \frac{1}{7}$ .
10. The probability  $p_j$  that exactly  $j$  children will have blue eyes is

$$p_j = \binom{5}{j} \left(\frac{1}{4}\right)^j \left(\frac{3}{4}\right)^{5-j} \quad \text{for } j = 0, 1, \dots, 5.$$

The desired probability is

$$\frac{p_3 + p_4 + p_5}{p_1 + p_2 + p_3 + p_4 + p_5}.$$

11. (a) We must determine the probability that at least two of the four oldest children will have blue eyes.  
The probability  $p_j$  that exactly  $j$  of these four children will have blue eyes is

$$p_j = \binom{4}{j} \left(\frac{1}{4}\right)^j \left(\frac{3}{4}\right)^{4-j}.$$

The desired probability is therefore  $p_2 + p_3 + p_4$ .

- (b) The two different types of information provided in Exercise 10 and part (a) are similar to the two different types of information provided in part (a) and part (b) of Exercise 9 of Sec. 2.1.
12. (a)  $\Pr(A^c \cap B^c \cap C^c) = \Pr(A^c)\Pr(B^c)\Pr(C^c) = \frac{3}{4} \cdot \frac{2}{3} \cdot \frac{1}{2} = \frac{1}{4}$ .
- (b) The desired probability is

$$\begin{aligned} \Pr(A \cap B^c \cap C^c) &+ \Pr(A^c \cap B \cap C^c) + \Pr(A^c \cap B^c \cap C) = \frac{1}{4} \cdot \frac{2}{3} \cdot \frac{1}{2} \\ &+ \frac{3}{4} \cdot \frac{1}{3} \cdot \frac{1}{2} + \frac{3}{4} \cdot \frac{2}{3} \cdot \frac{1}{2} = \frac{11}{24}. \end{aligned}$$

13. The probability of obtaining a particular sequence of ten particles in which one particle penetrates the shield and nine particles do not is  $(0.01)(0.99)^9$ . Since there are 10 such sequences in the sample space, the desired probability is  $10(0.01)(0.99)^9$ .
14. The probability that none of the ten particles will penetrate the shield is  $(0.99)^{10}$ . Therefore, the probability that at least one particle will penetrate the shield is  $1 - (0.99)^{10}$ .
15. If  $n$  particles are emitted, the probability that at least one particle will penetrate the shield is  $1 - (0.99)^n$ . In order for this value to be at least 0.8 we must have

$$\begin{aligned} 1 - (0.99)^n &\geq 0.8 \\ (0.99)^n &\leq 0.2 \\ n \log(0.99) &\leq \log(0.2). \end{aligned}$$

Since  $\log(0.99)$  is negative, this final relation is equivalent to the relation

$$n \geq \frac{\log(0.2)}{\log(0.99)} \approx 160.1.$$

So 161 or more particles are needed.

16. To determine the probability that team  $A$  will win the World Series, we shall calculate the probabilities that  $A$  will win in exactly four, five, six, and seven games, and then sum these probabilities. The probability that  $A$  will win four straight games is  $(1/3)^4$ . The probability that  $A$  will win in five games is equal to the probability that the fourth victory of team  $A$  will occur in the fifth game. As explained in Example 2.2.8, this probability is  $\binom{4}{3} \left(\frac{1}{3}\right)^4 \left(\frac{2}{3}\right)$ . Similarly, the probabilities that  $A$  will win in six games and in seven games are  $\binom{5}{3} \left(\frac{1}{3}\right)^4 \left(\frac{2}{3}\right)^2$  and  $\binom{6}{3} \left(\frac{1}{3}\right)^4 \left(\frac{2}{3}\right)^3$ , respectively. By summing these probabilities, we obtain the result  $\sum_{i=3}^6 \binom{i}{3} \left(\frac{1}{3}\right)^4 \left(\frac{2}{3}\right)^{i-3}$ , which equals  $379/2187$ .

A second way to solve this problem is to pretend that all seven games are going to be played, regardless of whether one team has won four games before the seventh game. From this point of view, of the seven games that are played, the team that wins the World Series might win four, five, six, or seven games. Therefore, the probability that team  $A$  will win the series can be determined by calculating the probabilities that team  $A$  will win exactly four, five, six, and seven games, and then summing these probabilities. In this way, we obtain the result

$$\sum_{i=4}^7 \binom{7}{i} \left(\frac{1}{3}\right)^i \left(\frac{2}{3}\right)^{7-i}.$$

It can be shown that this answer is equal to the answer that we obtained first.

17. In order for the target to be hit for the first time on the third throw of boy  $A$ , all five of the following independent events must occur: (1)  $A$  misses on his first throw, (2)  $B$  misses on his first throw, (3)  $A$  misses on his second throw, (4)  $B$  misses on his second throw, (5)  $A$  hits on his third throw. The probability of all five events occurring is  $\frac{2}{3} \cdot \frac{3}{4} \cdot \frac{2}{3} \cdot \frac{3}{4} \cdot \frac{1}{3} = \frac{1}{12}$ .
18. Let  $E$  denote the event that boy  $A$  hits the target before boy  $B$ . There are two methods of solving this problem. The first method is to note that the event  $E$  can occur in two different ways: (i) If  $A$  hits the target on the first throw. This event occurs with probability  $\frac{1}{3}$ . (ii) If both  $A$  and  $B$  miss the target on their first throws, and then subsequently  $A$  hits the target before  $B$ . The probability that  $A$  and  $B$  will both miss on their first throws is  $\frac{2}{3} \cdot \frac{3}{4} = \frac{1}{2}$ . When they do miss, the conditions of the game become exactly the same as they were at the beginning of the game. In effect, it is as if the boys were starting a new game all over again, and so the probability that  $A$  will subsequently hit the target before  $B$  is again  $\Pr(E)$ . Therefore, by considering these two ways in which the event  $E$  can occur, we obtain the relation

$$\Pr(E) = \frac{1}{3} + \frac{1}{2} \Pr(E).$$

The solution is  $\Pr(E) = \frac{2}{3}$ .

The second method of solving the problem is to calculate the probabilities that the target will be hit for the first time on boy  $A$ 's first throw, on his second throw, on his third throw, etc., and then to sum these probabilities. For the target to be hit for the first time on his  $j$ th throw, both  $A$  and  $B$  must miss on each of their first  $j - 1$  throws, and then  $A$  must hit on his next throw. The probability of this event is

$$\left(\frac{2}{3}\right)^{j-1} \left(\frac{3}{4}\right)^{j-1} \left(\frac{1}{3}\right) = \left(\frac{1}{2}\right)^{j-1} \left(\frac{1}{3}\right).$$

Hence,

$$\Pr(E) = \frac{1}{3} \sum_{j=1}^{\infty} \left(\frac{1}{2}\right)^{j-1} = \frac{1}{3}(2) = \frac{2}{3}.$$

19. Let  $A_1$  denote the event that no red balls are selected, let  $A_2$  denote the event that no white balls are selected, and let  $A_3$  denote the event that no blue balls are selected. We must determine the value of  $\Pr(A_1 \cup A_2 \cup A_3)$ . We shall apply Theorem 1.10.1. The event  $A_1$  will occur if and only if all ten selected balls are white or blue. Since there is probability 0.8 that any given selected ball will be white or blue, we have  $\Pr(A_1) = (0.8)^{10}$ . Similarly,  $\Pr(A_2) = (0.7)^{10}$  and  $\Pr(A_3) = (0.5)^{10}$ . The event  $A_1 \cap A_2$  will occur if and only if all ten selected balls are blue. Therefore  $\Pr(A_1 \cap A_2) = (0.5)^{10}$ . Similarly,  $\Pr(A_2 \cap A_3) = (0.2)^{10}$  and  $\Pr(A_1 \cap A_3) = (0.3)^{10}$ . Finally, the event  $A_1 \cap A_2 \cap A_3$  cannot possibly occur, so  $\Pr(A_1 \cap A_2 \cap A_3) = 0$ . So, the desired probability is

$$(0.8)^{10} + (0.7)^{10} + (0.5)^{10} - (0.5)^{10} - (0.2)^{10} - (0.3)^{10} \approx 0.1356.$$

20. To prove that  $B_1, \dots, B_k$  are independent events, we must prove that for every subset of  $r$  of these events ( $r = 1, \dots, k$ ), we have

$$\Pr(B_{i_1} \cap \dots \cap B_{i_r}) = \Pr(B_{i_1}) \cdots \Pr(B_{i_r}).$$

We shall simplify the notation by writing simply  $B_1, \dots, B_r$  instead of  $B_{i_1}, \dots, B_{i_r}$ . Hence, we must show that

$$\Pr(B_1 \cap \dots \cap B_r) = \Pr(B_1) \cdots \Pr(B_r). \quad (\text{S.2.2})$$

Suppose that the relation (S.2.2) is satisfied whenever  $B_j = A_j^c$  for  $m$  or fewer values of  $j$  and  $B_j = A_j$  for the other  $k - m$  or more values of  $j$ . We shall show that (S.2.2) is also satisfied whenever  $B_j = A_j^c$  for  $m + 1$  values of  $j$ . Without loss of generality, we shall assume that  $j = r$  is one of these  $m + 1$  values, so that  $B_r = A_r^c$ . It is always true that

$$\Pr(B_1 \cap \dots \cap B_r) = \Pr(B_1 \cap \dots \cap B_{r-1}) - \Pr(B_1 \cap \dots \cap B_{r-1} \cap B_r^c).$$

Since among the events  $B_1, \dots, B_{r-1}$  there are  $m$  or fewer values of  $j$  such that  $B_j = A_j^c$ , it follows from the induction hypothesis that

$$\Pr(B_1 \cap \dots \cap B_{r-1}) = \Pr(B_1) \cdots \Pr(B_{r-1}).$$

Furthermore, since  $B_r^c = A_r$ , the same induction hypothesis implies that

$$\Pr(B_1 \cap \dots \cap B_{r-1} B_r^c) = \Pr(B_1) \cdots \Pr(B_{r-1}) \Pr(B_r^c).$$

It now follows that

$$\Pr(B_1 \cap \dots \cap B_r) = \Pr(B_1) \cdots \Pr(B_{r-1})[1 - \Pr(B_r^c)] = \Pr(B_1) \cdots \Pr(B_r).$$

Thus, we have shown that if the events  $B_1, \dots, B_k$  are independent whenever there are  $m$  or fewer values of  $j$  such that  $B_j = A_j^c$ , then the events  $B_1, \dots, B_k$  are also independent whenever there are  $m+1$  values of  $j$  such that  $B_j = A_j^c$ . Since  $B_1, \dots, B_k$  are obviously independent whenever there are zero values of  $j$  such that  $B_j = A_j^c$  (i.e., whenever  $B_j = A_j$  for  $j = 1, \dots, k$ ), the induction argument is complete. Therefore, the events  $B_1, \dots, B_k$  are independent regardless of whether  $B_j = A_j$  or  $B_j = A_j^c$  for each value of  $j$ .

21. For the “only if” direction, we need to prove that if  $A_1, \dots, A_k$  are independent then

$$\Pr(A_{i_1} \cap \dots \cap A_{i_m} | A_{j_1} \cap \dots \cap A_{j_\ell}) = \Pr(A_{i_1} \cap \dots \cap A_{i_m}),$$

for all disjoint subsets  $\{i_1, \dots, i_m\}$  and  $\{j_1, \dots, j_\ell\}$  of  $\{1, \dots, k\}$ . If  $A_1, \dots, A_k$  are independent, then

$$\Pr(A_{i_1} \cap \dots \cap A_{i_m} \cap A_{j_1} \cap \dots \cap A_{j_\ell}) = \Pr(A_{i_1} \cap \dots \cap A_{i_m}) \Pr(A_{j_1} \cap \dots \cap A_{j_\ell}),$$

hence it follows that

$$\Pr(A_{i_1} \cap \dots \cap A_{i_m} | A_{j_1} \cap \dots \cap A_{j_\ell}) = \frac{\Pr(A_{i_1} \cap \dots \cap A_{i_m} \cap A_{j_1} \cap \dots \cap A_{j_\ell})}{\Pr(A_{j_1} \cap \dots \cap A_{j_\ell})} = \Pr(A_{i_1} \cap \dots \cap A_{i_m}).$$

For the “if” direction, assume that  $\Pr(A_{i_1} \cap \dots \cap A_{i_m} | A_{j_1} \cap \dots \cap A_{j_\ell}) = \Pr(A_{i_1} \cap \dots \cap A_{i_m})$  for all disjoint subsets  $\{i_1, \dots, i_m\}$  and  $\{j_1, \dots, j_\ell\}$  of  $\{1, \dots, k\}$ . We must prove that  $A_1, \dots, A_k$  are independent. That is, we must prove that for every subset  $\{s_1, \dots, s_n\}$  of  $\{1, \dots, k\}$ ,  $\Pr(A_{s_1} \cap \dots \cap A_{s_n}) = \Pr(A_{s_1}) \cdots \Pr(A_{s_n})$ . We shall do this by induction on  $n$ . For  $n = 1$ , we have that  $\Pr(A_{s_1}) = \Pr(A_{s_1})$  for each subset  $\{s_1\}$  of  $\{1, \dots, k\}$ . Now, assume that for all  $n \leq n_0$  and for all subsets  $\{s_1, \dots, s_n\}$  of  $\{1, \dots, k\}$  it is true that  $\Pr(A_{s_1} \cap \dots \cap A_{s_n}) = \Pr(A_{s_1}) \cdots \Pr(A_{s_n})$ . We need to prove that for every subset  $\{t_1, \dots, t_{n_0+1}\}$  of  $\{1, \dots, k\}$

$$\Pr(A_{t_1} \cap \dots \cap A_{t_{n_0+1}}) = \Pr(A_{t_1}) \cdots \Pr(A_{t_{n_0+1}}). \quad (\text{S.2.3})$$

It is clear that

$$\Pr(A_{t_1} \cap \dots \cap A_{t_{n_0+1}}) = \Pr(A_{t_1} \cap \dots \cap A_{t_{n_0}} | A_{t_{n_0+1}}) \Pr(A_{t_{n_0+1}}). \quad (\text{S.2.4})$$

We have assumed that  $\Pr(A_{t_1} \cap \dots \cap A_{t_{n_0}} | A_{t_{n_0+1}}) = \Pr(A_{t_1} \cap \dots \cap A_{t_{n_0}})$  for all disjoint subsets  $\{t_1, \dots, t_{n_0}\}$  and  $\{t_{n_0+1}\}$  of  $\{1, \dots, k\}$ . Since the right side of this last equation is the probability of the intersection of only  $n_0$  events, then we know that

$$\Pr(A_{t_1} \cap \dots \cap A_{t_{n_0}}) = \Pr(A_{t_1}) \cdots \Pr(A_{t_{n_0}}).$$

Combining this with Eq. (S.2.4) implies that (S.2.3) holds.

22. For the “only if” direction, we assume that  $A_1$  and  $A_2$  are conditionally independent given  $B$  and we must prove that  $\Pr(A_2 | A_1 \cap B) = \Pr(A_2 | B)$ . Since  $A_1$  and  $A_2$  are conditionally independent given  $B$ ,  $\Pr(A_1 \cap A_2 | B) = \Pr(A_1 | B) \Pr(A_2 | B)$ . This implies that

$$\Pr(A_2 | B) = \frac{\Pr(A_1 \cap A_2 | B)}{\Pr(A_1 | B)}.$$

Also,

$$\Pr(A_2|A_1 \cap B) = \frac{\Pr(A_1 \cap A_2 \cap B)}{\Pr(A_1 \cap B)} = \frac{\Pr(A_1 \cap A_2 \cap B)/\Pr(B)}{\Pr(A_1 \cap B)/\Pr(B)} = \frac{\Pr(A_1 \cap A_2|B)}{\Pr(A_1|B)}.$$

Hence,  $\Pr(A_2|A_1 \cap B) = \Pr(A_2|B)$ .

For the “if” direction, we assume that  $\Pr(A_2|A_1 \cap B) = \Pr(A_2|B)$ , and we must prove that  $A_1$  and  $A_2$  are conditionally independent given  $B$ . That is, we must prove that  $\Pr(A_1 \cap A_2|B) = \Pr(A_1|B) \Pr(A_2|B)$ . We know that

$$\Pr(A_1 \cap A_2|B) \Pr(B) = \Pr(A_2|A_1 \cap B) \Pr(A_1 \cap B),$$

since both sides are equal to  $\Pr(A_1 \cap A_2 \cap B)$ . Divide both sides of this equation by  $\Pr(B)$  and use the assumption  $\Pr(A_2|A_1 \cap B) = \Pr(A_2|B)$  together with  $\Pr(A_1 \cap B)/\Pr(B) = \Pr(A_1|B)$  to obtain

$$\Pr(A_1 \cap A_2|B) = \Pr(A_2|B) \Pr(A_1|B).$$

23. (a) Conditional on  $B$  the events  $A_1, \dots, A_{11}$  are independent with probability 0.8 each. The conditional probability that a particular collection of eight programs out of the 11 will compile is  $0.8^8 0.2^3 = 0.001342$ . There are  $\binom{11}{8} = 165$  different such collections of eight programs out of the 11, so the probability of exactly eight programs will compile is  $165 \times 0.001342 = 0.2215$ .
- (b) Conditional on  $B^c$  the events  $A_1, \dots, A_{11}$  are independent with probability 0.4 each. The conditional probability that a particular collection of eight programs out of the 11 will compile is  $0.4^8 0.6^3 = 0.0001416$ . There are  $\binom{11}{8} = 165$  different such collections of eight programs out of the 11, so the probability of exactly eight programs will compile is  $165 \times 0.0001416 = 0.02335$ .
24. Let  $n > 1$ , and assume that  $A_1, \dots, A_n$  are mutually exclusive. For the “if” direction, assume that at most one of the events has strictly positive probability. Then, the intersection of every collection of size 2 or more has probability 0. Also, the product of every collection of 2 or more probabilities is 0, so the events satisfy Definition 2.2.2 and are mutually independent. For the “only if” direction, assume that the events are mutually independent. The intersection of every collection of size 2 or more is empty and must have probability 0. Hence the product of the probabilities of every collection of size 2 or more must be 0. This means that at least one factor from every product of at least 2 probabilities must itself be 0. Hence there can be no more than one of the probabilities greater than 0, otherwise the product of the two nonzero probabilities would be nonzero.

## 2.3 Bayes’ Theorem

### Commentary

This section ends with two extended discussions on how Bayes’ theorem is applied. The first involves a sequence of simple updates to the probability of a specific event. It illustrates how conditional independence allows one to use posterior probabilities after observing some events as prior probabilities before observing later events. This idea is subtle, but very useful in Bayesian inference. The second discussion builds upon this idea and illustrates the type of reasoning that can be used in real inference problems. Examples 2.3.7 and 2.3.8 are particularly useful in this regard. They show how data can bring very different prior probabilities into

closer posterior agreement. Exercise 12 illustrates the effect of the size of a sample on the degree to which the data can reduce differences in subjective probabilities.

Statistical software like *R* can be used to facilitate calculations like those that occur in the above-mentioned examples. For example, suppose that the 11 prior probabilities are assigned to the vector `prior` and that the data consist of `s` successes and `f` failures. Then the posterior probabilities can be computed by

```
ints=1:11
post=prior*((ints-1)/10)^s*(1-(ints-1)/10)^f
post=post/sum(post)
```

## Solutions to Exercises

- It must be true that  $\sum_{i=1}^k \Pr(B_i) = 1$  and  $\sum_{i=1}^k \Pr(B_i | A) = 1$ . However, if  $\Pr(B_1 | A) < \Pr(B_1)$  and  $\Pr(B_i | A) \leq \Pr(B_i)$  for  $i = 2, \dots, k$ , we would have  $\sum_{i=1}^k \Pr(B_i | A) < \sum_{i=1}^k \Pr(B_i)$ , a contradiction. Therefore, it must be true that  $\Pr(B_i | A) > \Pr(B_i)$  for at least one value of  $i$  ( $i = 2, \dots, k$ ).
- It was shown in the text that  $\Pr(A_2 | B) = 0.26 < \Pr(A_2) = 0.3$ . Similarly,

$$\Pr(A_1 | B) = \frac{(0.2)(0.01)}{(0.2)(0.01) + (0.3)(0.02) + (0.5)(0.03)} = 0.09.$$

Since  $\Pr(A_1) = 0.2$ , we have  $\Pr(A_1 | B) < \Pr(A_1)$ . Furthermore,

$$\Pr(A_3 | B) = \frac{(0.5)(0.03)}{(0.2)(0.01) + (0.3)(0.02) + (0.5)(0.03)} = 0.65.$$

Since  $\Pr(A_3) = 0.5$ , we have  $\Pr(A_3 | B) > \Pr(A_3)$ .

- Let  $C$  denote the event that the selected item is nondefective. Then

$$\Pr(A_2 | C) = \frac{(0.3)(0.98)}{(0.2)(0.99) + (0.3)(0.98) + (0.5)(0.97)} = 0.301.$$

*Commentary:* It should be noted that if the selected item is observed to be defective, the probability that the item was produced by machine  $M_2$  is decreased from the prior value of 0.3 to the posterior value of 0.26. However, if the selected item is observed to be nondefective, this probability changes very little, from a prior value of 0.3 to a posterior value of 0.301. In this example, therefore, obtaining a defective is more informative than obtaining a nondefective, but it is much more probable that a nondefective will be obtained.

- The desired probability  $\Pr(\text{Cancer} | \text{Positive})$  can be calculated as follows:

$$\begin{aligned} & \frac{\Pr(\text{Cancer}) \Pr(\text{Positive} | \text{Cancer})}{\Pr(\text{Cancer}) \Pr(\text{Positive} | \text{Cancer}) + \Pr(\text{No Cancer}) \Pr(\text{Positive} | \text{No Cancer})} \\ &= \frac{(0.00001)(0.95)}{(0.00001)(0.95) + (0.99999)(0.05)} = 0.00019. \end{aligned}$$

*Commentary:* It should be noted that even though this test provides a correct diagnosis 95 percent of the time, the probability that a person has this type of cancer, given that he has a positive reaction to

the test, is *not* 0.95. In fact, as this exercise shows, even though a person has a positive reaction, the probability that she has this type of cancer is still only 0.00019. In other words, the probability that the person has this type of cancer is 19 times larger than it was before he took this test ( $\frac{0.00019}{0.000001} = 19$ ), but it is still very small because the disease is so rare in the population.

5. The desired probability  $\Pr(\text{Lib.}|\text{NoVote})$  can be calculated as follows:

$$\begin{aligned} & \frac{\Pr(\text{Lib.}) \Pr(\text{NoVote}|\text{Lib.})}{\Pr(\text{Cons.}) \Pr(\text{NoVote}|\text{Cons.}) + \Pr(\text{Lib.}) \Pr(\text{NoVote}|\text{Lib.}) + \Pr(\text{Ind.}) \Pr(\text{NoVote}|\text{Ind.})} \\ &= \frac{(0.5)(0.18)}{(0.3)(0.35) + (0.5)(0.18) + (0.2)(0.50)} = \frac{18}{59}. \end{aligned}$$

6. (a) Let  $A_1$  denote the event that the machine is adjusted properly, let  $A_2$  denote the event that it is adjusted improperly, and let  $B$  be the event that four of the five inspected items are of high quality. Then

$$\begin{aligned} \Pr(A_1 | B) &= \frac{\Pr(A_1) \Pr(B | A_1)}{\Pr(A_1) \Pr(B | A_1) + \Pr(A_2) \Pr(B | A_2)} \\ &= \frac{(0.9) \binom{5}{4} (0.5)^5}{(0.9) \binom{5}{4} (0.5)^5 + (0.1) \binom{5}{4} (0.25)^4 (0.75)} = \frac{96}{97}. \end{aligned}$$

- (b) The prior probabilities before this additional item is observed are the values found in part (a):  $\Pr(A_1) = 96/97$  and  $\Pr(A_2) = 1/97$ . Let  $C$  denote the event that the additional item is of medium quality. Then

$$\Pr(A_1 | C) = \frac{\frac{96}{97} \cdot \frac{1}{2}}{\frac{96}{97} \cdot \frac{1}{2} + \frac{1}{97} \cdot \frac{3}{4}} = \frac{64}{65}.$$

7. (a) Let  $\pi_i$  denote the posterior probability that coin  $i$  was selected. The prior probability of each coin is  $1/5$ . Therefore

$$\pi_i = \frac{\frac{1}{5} p_i}{\sum_{j=1}^5 \frac{1}{5} p_j} \quad \text{for } i = 1, \dots, 5.$$

The five values are  $\pi_1 = 0$ ,  $\pi_2 = 0.1$ ,  $\pi_3 = 0.2$ ,  $\pi_4 = 0.3$ , and  $\pi_5 = 0.4$ .

- (b) The probability of obtaining another head is equal to

$$\sum_{i=1}^5 \Pr(\text{Coin } i) \Pr(\text{Head} | \text{Coin } i) = \sum_{i=1}^5 \pi_i p_i = \frac{3}{4}.$$

- (c) The posterior probability  $\pi_i$  of coin  $i$  would now be

$$\pi_i = \frac{\frac{1}{5}(1 - p_i)}{\sum_{j=1}^5 \frac{1}{5}(1 - p_j)} \quad \text{for } i = 1, \dots, 5.$$

Thus,  $\pi_1 = 0.4$ ,  $\pi_2 = 0.3$ ,  $\pi_3 = 0.2$ ,  $\pi_4 = 0.1$ , and  $\pi_5 = 0$ . The probability of obtaining a head on the next toss is therefore  $\sum_{i=1}^5 \pi_i p_i = \frac{1}{4}$ .

8. (a) If coin  $i$  is selected, the probability that the first head will be obtained on the fourth toss is  $(1 - p_i)^3 p_i$ . Therefore, the posterior probability that coin  $i$  was selected is

$$\pi_i = \frac{\frac{1}{5}(1 - p_i)^3 p_i}{\sum_{j=1}^5 \frac{1}{5}(1 - p_j)^3 p_j} \quad \text{for } i = 1, \dots, 5.$$

The five values are  $\pi_1 = 0$ ,  $\pi_2 = 0.5870$ ,  $\pi_3 = 0.3478$ ,  $\pi_4 = 0.0652$ , and  $\pi_5 = 0$ .

- (b) If coin  $i$  is used, the probability that exactly three additional tosses will be required to obtain another head is  $(1 - p_i)^2 p_i$ . Therefore, the desired probability is

$$\sum_{i=1}^5 \pi_i (1 - p_i)^2 p_i = 0.1291.$$

9. We shall continue to use the notation from the solution to Exercise 14 in Sec. 2.1. Let  $C$  be the event that exactly one out of seven observed parts is defective. We are asked to find  $\Pr(B_j|C)$  for  $j = 1, 2, 3$ . We need  $\Pr(C|B_j)$  for each  $j$ . Let  $A_i$  be the event that the  $i$ th part is defective. For all  $i$ ,  $\Pr(A_i|B_1) = 0.02$ ,  $\Pr(A_i|B_2) = 0.1$ , and  $\Pr(A_i|B_3) = 0.3$ . Since the seven parts are conditionally independent given each state of the machine, the probability of each possible sequence of seven parts with one defective is  $\Pr(A_i|B_j)[1 - \Pr(A_i|B_j)]^6$ . There are seven distinct such sequences, so

$$\begin{aligned}\Pr(C|B_1) &= 7 \times 0.02 \times 0.98^6 = 0.1240, \\ \Pr(C|B_2) &= 7 \times 0.1 \times 0.9^6 = 0.3720, \\ \Pr(C|B_3) &= 7 \times 0.3 \times 0.7^6 = 0.2471.\end{aligned}$$

The expression in the denominator of Bayes' theorem is

$$\Pr(C) = 0.8 \times 0.1240 + 0.1 \times 0.3720 + 0.1 \times 0.2471 = 0.1611.$$

Bayes' theorem now says

$$\begin{aligned}\Pr(B_1|C) &= \frac{0.8 \times 0.1240}{0.1611} = 0.6157, \\ \Pr(B_2|C) &= \frac{0.1 \times 0.3720}{0.1611} = 0.2309, \\ \Pr(B_3|C) &= \frac{0.1 \times 0.2471}{0.1611} = 0.1534.\end{aligned}$$

10. Bayes' theorem says that the posterior probability of each  $B_i$  is  $\Pr(B_i|E) = \Pr(B_i)\Pr(E|B_i)/\Pr(E)$ . So  $\Pr(B_i|E) < \Pr(B_i)$  if and only if  $\Pr(E|B_i) < \Pr(E)$ . Since  $\Pr(E) = 3/4$ , we need to find those  $i$  for which  $\Pr(E|B_i) < 3/4$ . These are  $i = 5, 6$ .
11. This time, we want  $\Pr(B_4|E^c)$ . We know that  $\Pr(E^c) = 1 - \Pr(E) = 1/4$  and  $\Pr(E^c|B_4) = 1 - \Pr(E|B_4) = 1/4$ . This means that  $E^c$  and  $B_4$  are independent so that  $\Pr(B_4|E^c) = \Pr(B_4) = 1/4$ .

12. We are doing the same calculations as in Examples 2.3.7 and 2.3.8 except that we only have five patients and three successes. So, in particular

$$\Pr(B_j | A) = \frac{\Pr(B_j) \binom{5}{3} ([j-1]/10)^3 (1 - [j-1]/10)^2}{\sum_{i=1}^{11} \Pr(B_i) \binom{5}{3} ([i-1]/10)^3 (1 - [i-1]/10)^2}. \quad (\text{S.2.5})$$

In one case,  $\Pr(B_i) = 1/11$  for all  $i$ , and in the other case, the prior probabilities are given in the table in Example 2.3.8 of the text. The numbers that show up in both calculations are

$i$	$\left(\frac{i-1}{10}\right)^3 \left(1 - \frac{i-1}{10}\right)^2$	$i$	$\left(\frac{i-1}{10}\right)^3 \left(1 - \frac{i-1}{10}\right)^2$
1	0	7	0.0346
2	0.0008	8	0.0309
3	0.0051	9	0.0205
4	0.0132	10	0.0073
5	0.0230	11	0
6	0.0313		

We can use these with the two sets of prior probabilities to compute the posterior probabilities according to Eq. (S.2.5).

$i$	Example 2.3.7	Example 2.3.8	$i$	Example 2.3.7	Example 2.3.8
1	0	0	7	0.2074	0.1641
2	0.0049	0.0300	8	0.1852	0.0879
3	0.0307	0.0972	9	0.1229	0.0389
4	0.07939	0.1633	10	0.0437	0.0138
5	0.1383	0.1969	11	0	0
6	0.1875	0.2077			

These numbers are not nearly so close as those in the examples in the text because we do not have as much information in the small sample of five patients.

13. (a) Let  $B_1$  be the event that the coin is fair, and let  $B_2$  be the event that the coin has two heads. Let  $H_i$  be the event that we obtain a head on the  $i$ th toss for  $i = 1, 2, 3, 4$ . We shall apply Bayes' theorem conditional on  $H_1 H_2$ .

$$\begin{aligned} & \Pr(B_1 | H_1 \cap H_2 \cap H_3) \\ &= \frac{\Pr(B_1 | H_1 \cap H_2) \Pr(H_3 | B_1 \cap H_1 \cap H_2)}{\Pr(B_1 | H_1 \cap H_2) \Pr(H_3 | B_1 \cap H_1 \cap H_2) + \Pr(B_2 | H_1 \cap H_2) \Pr(H_3 | B_2 \cap H_1 \cap H_2)} \\ &= \frac{(1/5) \times (1/2)}{(1/5) \times (1/2) + (4/5) \times 1} = \frac{1}{9}. \end{aligned}$$

- (b) If the coin ever shows a tail, it can't have two heads. Hence the posterior probability of  $B_1$  becomes 1 after we observe a tail.
14. In Exercise 23 of Sec. 2.2,  $B$  is the event that the programming task was easy. In that exercise, we computed  $\Pr(A|B) = 0.2215$  and  $\Pr(A|B^c) = 0.02335$ . We are also told that  $\Pr(B) = 0.4$ . Bayes'

theorem tells us that

$$\begin{aligned}\Pr(B|A) &= \frac{\Pr(B)\Pr(A|B)}{\Pr(B)\Pr(A|B) + \Pr(B^c)\Pr(A|B^c)} = \frac{0.4 \times 0.2215}{0.4 \times 0.2215 + (1 - 0.4)0.02335} \\ &= 0.8635.\end{aligned}$$

15. The law of total probability tells us how to compute  $\Pr(E_1)$ .

$$\Pr(E_1) = \sum_{i=1}^{11} \Pr(B_i) \frac{i-1}{10}.$$

Using the numbers in Example 2.3.8 for  $\Pr(B_i)$  we obtain 0.274. This is smaller than the value 0.5 computed in Example 2.3.7 because the prior probabilities in Example 2.3.8 are much higher for the  $B_i$  with low values of  $i$ , particularly  $i = 2, 3, 4$ , and they are much smaller for those  $B_i$  with large values of  $i$ . Since  $\Pr(E_1)$  is a weighted average of the values  $(i-1)/10$  with the weights being  $\Pr(B_i)$  for  $i = 1, \dots, 11$ , the more weight we give to small values of  $(i-1)/10$ , the smaller the weighted average will be.

16. (a) From the description of the problem  $\Pr(D_i|B) = 0.01$  for all  $i$ . If we can show that  $\Pr(D_i|B^c) = 0.01$  for all  $i$ , then  $\Pr(D_i) = 0.01$  for all  $i$ . We will prove this by induction. We have assumed that  $D_1$  is independent of  $B$  and hence it is independent of  $B^c$ . This makes  $\Pr(D_1|B^c) = 0.01$ . Now, assume that  $\Pr(D_i|B^c) = 0.01$  for all  $i \leq j$ . Write

$$\Pr(D_{j+1}|B^c) = \Pr(D_{j+1}|D_j \cap B^c) \Pr(D_j|B^c) + \Pr(D_{j+1}|D_j^c \cap B^c) \Pr(D_j^c|B^c).$$

The induction hypothesis says that  $\Pr(D_j|B^c) = 0.01$  and  $\Pr(D_j^c|B^c) = 0.99$ . In the problem description, we have  $\Pr(D_{j+1}|D_j \cap B^c) = 2/5$  and  $\Pr(D_{j+1}|D_j^c \cap B^c) = 1/165$ . Plugging these into (16a) gives

$$\Pr(D_{j+1}|B^c) = \frac{2}{5} \times 0.01 + \frac{1}{165} \times 0.99 = 0.01.$$

This completes the proof.

- (b) It is straightforward to compute

$$\Pr(E|B) = 0.99 \times 0.99 \times 0.01 \times 0.01 \times 0.99 \times 0.99 = 0.00009606.$$

By the conditional independence assumption stated in the problem description, we have

$$\Pr(E|B^c) = \Pr(D_1^c|B^c) \Pr(D_2^c|D_1^c \cap B^c) \Pr(D_3|D_2^c \cap B^c) \Pr(D_4|D_3 \cap B^c) \Pr(D_5^c|D_4 \cap B^c) \Pr(D_6^c|D_5^c \cap B^c).$$

The six factors on the right side of this equation are respectively 0.99, 164/165, 1/165, 2/5, 3/5, and 164/165. The product is 0.001423. It follows that

$$\begin{aligned}\Pr(B|E) &= \frac{\Pr(E|B)\Pr(B)}{\Pr(E|B)\Pr(B) + \Pr(E|B^c)\Pr(B^c)} \\ &= \frac{0.00009606 \times (2/3)}{0.00009606 \times (2/3) + 0.001423 \times (1/3)} = 0.1190.\end{aligned}$$

## 2.4 The Gambler's Ruin Problem

### Commentary

This section is independent of the rest of the book. Instructors can discuss this section at any time that they find convenient or they can omit it entirely.

If Sec. 3.10 on Markov chains has been discussed before this section is discussed, it is helpful to point out that the game considered here forms a Markov chain with stationary transition probabilities. The state of the chain at any time is the fortune of gambler  $A$  at that time. Therefore, the possible states of the chain are the  $k + 1$  integers  $0, 1, \dots, k$ . If the chain is in state  $i$  ( $i = 1, \dots, k - 1$ ) at any time  $n$ , then at time  $n + 1$  it will move to state  $i + 1$  with probability  $p$  and it will move to state  $i - 1$  with probability  $1 - p$ . It is assumed that if the chain is either in the state  $0$  or the state  $k$  at any time, then it will remain in that same state at every future time. (These are absorbing states.) Therefore, the  $(k + 1) \times (k + 1)$  transition matrix  $\mathbf{P}$  of the chain is as follows:

$$\mathbf{P} = \begin{bmatrix} 1 & 0 & 0 & 0 & \cdots & 0 & 0 & 0 \\ 1-p & 0 & p & 0 & \cdots & 0 & 0 & 0 \\ 0 & 1-p & 0 & p & \cdots & 0 & 0 & 0 \\ 0 & 0 & 1-p & 0 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & 1-p & 0 & p \\ 0 & 0 & 0 & 0 & \cdots & 0 & 0 & 1 \end{bmatrix}.$$

### Solutions to Exercises

- Clearly  $a_i$  in Eq. (2.4.9) is an increasing function of  $i$ . Hence, if  $a_{98} < 1/2$ , then  $a_i < 1/2$  for all  $i \leq 98$ . For  $i = 98$ , Eq. (2.4.9) yields almost exactly  $4/9$ , which is less than  $1/2$ .
- The probability of winning a fair game is just the ratio of the initial fortune to the total funds available. This ratio is the same in all three cases.
- If the initial fortune of gambler  $A$  is  $i$  dollars, then for conditions (a), (b), and (c), the initial fortune of gambler  $B$  is  $i/2$  dollars. Hence,  $k = 3i/2$ . If we let  $r = (1-p)/p > 1$ , then it follows from Eq. (2.4.8) that the probability that  $A$  will win under conditions (a), (b), or (c) is

$$\frac{r^i - 1}{r^{3i/2} - 1} = \frac{1 - (1/r_i)}{r^{i/2} - (1/r_i)}.$$

If  $i$  and  $j$  are positive integers with  $i < j$ , it now follows that

$$\frac{1 - (1/r_j)}{r^{j/2} - (1/r_j)} < \frac{1 - (1/r_j)}{r^{i/2} - (1/r_j)} < \frac{1 - (1/r_i)}{r^{i/2} - (1/r_i)}.$$

Thus the larger the initial fortune of gambler  $A$  is, the smaller is his probability of winning. Therefore, he has the largest probability of winning under condition (a).

- If we consider this problem from the point of view of gambler  $B$ , then each play of the game is unfavorable to her. Hence, by a procedure similar to that described in the solution to Exercise 3, it follows that she has the smallest probability of winning when her initial fortune is largest. Therefore, gambler  $A$  has the largest probability of winning when her initial fortune is largest, which corresponds to condition (c).

5. In this exercise,  $p = 1/2$  and  $k = i + 2$ . Therefore  $a_i = i/(i + 2)$ . In order to make  $a_i \geq 0.99$ , we must have  $i \geq 198$ .
6. In this exercise  $p = 2/3$ , and  $k = i + 2$ . Therefore, by Eq. (2.4.9),

$$a_i = \frac{\left(\frac{1}{2}\right)^i - 1}{\left(\frac{1}{2}\right)^{i+2} - 1}.$$

It follows that  $a_i \geq 0.99$  if and only if

$$2^i \geq 75.25.$$

Therefore, we must have  $i \geq 7$ .

7. In this exercise  $p = 1/3$  and  $k = i + 2$ . Therefore, by Eq. (2.4.9)

$$a_i = \frac{2^i - 1}{2^{i+2} - 1} = \frac{1 - (1/2^i)}{4 - (1/2^i)}.$$

But for every number  $x$  ( $0 < x < 1$ ), we have  $\frac{1-x}{4-x} < \frac{1}{4}$ . Hence,  $a_i < 1/4$  for every positive integer  $i$ .

8. This problem can be expressed as a gambler's ruin problem. Suppose that the initial fortunes of both gambler  $A$  and gambler  $B$  are 3 dollars, that gambler  $A$  will win one dollar from gambler  $B$  whenever a head is obtained on the coin, and gambler  $B$  will win one dollar from gambler  $A$  whenever a tail is obtained on the coin. Then the condition that  $X_n = Y_n + 3$  means that  $A$  has won all of  $B$ 's fortune, and the condition that  $Y_n = X_n + 3$  means that  $A$  is ruined. Therefore, if  $p = 1/2$ , the required probability is given by Eq. (2.4.6) with  $i = 3$  and  $k = 6$ , and the answer is  $1/2$ . If  $p \neq 1/2$ , the required probability is given by Eq. (2.4.9) with  $i = 3$  and  $k = 6$ . In either case, the answer can be expressed in the form

$$\frac{1}{\left(\frac{1-p}{p}\right)^3 + 1}.$$

9. This problem can be expressed as a gambler's ruin problem. We consider the initial fortune of gambler  $A$  to be five dollars and the initial fortune of gambler  $B$  to be ten dollars. Gambler  $A$  wins one dollar from gambler  $B$  each time that box  $B$  is selected, and gambler  $B$  wins one dollar from gambler  $A$  each time that box  $A$  is selected. Since  $i = 5$ ,  $k = 15$ , and  $p = 1/2$ , it follows from Eq. (2.4.6) that the probability that gambler  $A$  will win (and box  $B$  will become empty) is  $1/3$ . Therefore, the probability that box  $A$  will become empty first is  $2/3$ .

## 2.5 Supplementary Exercises

### Solutions to Exercises

1. Let  $\Pr(D) = p > 0$ . Then

$$\begin{aligned} \Pr(A) &= p \Pr(A | D) + (1-p) \Pr(A | D^c) \\ &\geq p \Pr(B | D) + (1-p) \Pr(B | D^c) = \Pr(B). \end{aligned}$$

2. (a) Sample space:

$HT$	$TH$
$HHT$	$TTH$
$HHHT$	$TTTH$
...	...

$$(b) \Pr(HHT \text{ or } TTH) = \left(\frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2}\right) + \left(\frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2}\right) = \frac{1}{4}.$$

3. Since  $\Pr(A | B) = \frac{\Pr(A \cap B)}{\Pr(B)}$  and  $\Pr(B | A) = \frac{\Pr(A \cap B)}{\Pr(A)}$ , we have  $\frac{\Pr(A \cap B)}{(1/5)} + \frac{\Pr(A \cap B)}{(1/3)} = \frac{2}{3}$ . Hence  $\Pr(A \cap B) = 1/12$ , and  $\Pr(A^c \cup B^c) = 1 - \Pr(A \cap B) = 11/12$ .

4.  $\Pr(A \cup B^c | B) = \Pr(A | B) + \Pr(B^c | B) - \Pr(A \cap B^c | B) = \Pr(A) + 0 - 0 = \Pr(A)$ .

5. The probability of obtaining the number 6 exactly three times in ten rolls is  $a = \binom{10}{3} \left(\frac{1}{6}\right)^3 \left(\frac{5}{6}\right)^7$ . Hence, the probability of obtaining the number 6 on the first three rolls and on none of the subsequent rolls is  $b = \left(\frac{1}{6}\right)^3 \left(\frac{5}{6}\right)^7$ . Hence, the required probability is  $\frac{b}{a} = 1/\binom{10}{3}$ .

6.  $\Pr(A \cap B) = \frac{\Pr(A \cap B \cap D)}{\Pr(D | A \cap B)} = \frac{0.04}{0.25} = 0.16$ . But also, by independence,

$$\Pr(A \cap B) = \Pr(A) \Pr(B) = 4[\Pr(A)]^2.$$

Hence,  $4[\Pr(A)]^2 = 0.16$ , so  $\Pr(A) = 0.2$ . It now follows that

$$\Pr(A \cup B) = \Pr(A) + \Pr(B) - \Pr(A \cap B) = (0.2) + 4(0.2) - (0.16) = 0.84.$$

7. The three events are always independent under the stated conditions. The proof is a straightforward generalization of the proof of Exercise 2 in Sec. 2.2.
8. No, since  $\Pr(A \cap B) = 0$  but  $\Pr(A) \Pr(B) > 0$ . This also follows from Theorem 2.2.3.
9. Let  $\Pr(A) = p$ . Then  $\Pr(A \cap B) = \Pr(A \cap B \cap C) = 0$ ,  $\Pr(A \cap C) = 4p^2$ ,  $\Pr(B \cap C) = 8p^2$ . Therefore, by Theorem 1.10.1,  $5p = p + 2p + 4p - [0 + 4p^2 + 8p^2] + 0$ , and  $p = 1/6$ .
10.  $\Pr(\text{Sum} = 7) = 2\Pr[(1, 6)] + 2\Pr[(2, 5)] + 2\Pr[(3, 4)] = 2(0.1)(0.1) + 2(0.1)(0.1) + 2(0.3)(0.3) = 0.22$ .
11.  $1 - \Pr(\text{losing 50 times}) = 1 - \left(\frac{49}{50}\right)^{50}$ .
12. The event will occur when  $(X_1, X_2, X_3)$  has the following values:

$$\begin{array}{ccccccc} (6, 5, 1) & (6, 4, 1) & (6, 3, 1) & (5, 4, 1) & (5, 3, 1) & (4, 3, 1) \\ (6, 5, 2) & (6, 4, 2) & (6, 3, 2) & (5, 4, 2) & (5, 3, 2) & (4, 3, 2) \\ (6, 5, 3) & (6, 4, 3) & (6, 2, 1) & (5, 4, 3) & (5, 2, 1) & (4, 2, 1) \\ (6, 5, 4) & & & & & (3, 2, 1). \end{array}$$

Each of these 20 points has probability  $1/6^3$ , so the answer is  $20/216 = 5/54$ .

13. Let  $A$ ,  $B$ , and  $C$  stand for the events that each of the students is in class on a particular day.

- (a) We want  $\Pr(A \cup B \cup C)$ . We can use Theorem 1.10.1. Independence makes it easy to compute the probabilities of the various intersections.

$$\Pr(A \cup B \cup C) = 0.3 + 0.5 + 0.8 - [0.3 \times 0.5 + 0.3 \times 0.8 + 0.5 \times 0.8] + 0.3 \times 0.5 \times 0.8 = 0.93.$$

- (b) Once again, use independence to calculate probabilities of intersections.

$$\begin{aligned} & \Pr(A \cap B^c \cap C^c) + \Pr(A^c \cap B \cap C^c) + \Pr(A^c \cap B^c \cap C) \\ &= (0.3)(0.5)(0.2) + (0.7)(0.5)(0.2) + (0.7)(0.5)(0.8) = 0.38. \end{aligned}$$

14. Seven games will be required if and only if team  $A$  wins exactly three of the first six games. This probability is  $\binom{6}{3}p^3(1-p)^3$ , following the model calculation in Example 2.2.5.

15.  $\Pr(\text{Each box contains one red ball}) = \frac{3!}{3^3} = \frac{2}{9} = \Pr(\text{Each box contains one white ball}).$

$$\text{So } \Pr(\text{Each box contains both colors}) = \left(\frac{2}{9}\right)^2.$$

16. Let  $A_i$  be the event that box  $i$  has at least three balls. Then

$$\Pr(A_i) = \sum_{j=3}^5 \Pr(\text{Box } i \text{ has exactly } j \text{ balls}) = \frac{\binom{5}{3}(n-1)^2}{n^5} + \frac{\binom{5}{4}(n-1)}{n^5} + \frac{1}{n^5} = p, \text{ say.}$$

Since there are only five balls, it is impossible for two boxes to have at least three balls at the same time. Therefore, the events  $A_i$  are disjoint, and the probability that at least one of the events  $A_i$  occurs is  $np$ . Hence, the probability that no box contains more than two balls is  $1 - np$ .

17.  $\Pr(U + V = j)$  is as follows, for  $j = 0, 1, \dots, 18$ :

$j$	Prob.	$j$	Prob.
0	0.01	10	0.09
1	0.02	11	0.08
2	0.03	12	0.07
3	0.04	13	0.06
4	0.05	14	0.05
5	0.06	15	0.04
6	0.07	16	0.03
7	0.08	17	0.02
8	0.09	18	0.01
9	0.10		

Thus

$$\begin{aligned} \Pr(U + V = W + X) &= \sum_{j=0}^{18} \Pr(U + V = j) \Pr(W + X = j) \\ &= (0.01)^2 + (0.02)^2 + \cdots + (0.01)^2 = 0.067. \end{aligned}$$

18. Let  $A_i$  denote the event that member  $i$  does not serve on any of the three committees ( $i = 1, \dots, 8$ ). Then

$$\begin{aligned}\Pr(A_i) &= \frac{\binom{7}{3}}{\binom{8}{3}} \cdot \frac{\binom{7}{4}}{\binom{8}{4}} \cdot \frac{\binom{7}{5}}{\binom{8}{5}} = \frac{5}{8} \cdot \frac{4}{8} \cdot \frac{3}{8} = a \\ \Pr(A_i \cap A_j) &= \frac{\binom{6}{3}}{\binom{8}{3}} \cdot \frac{\binom{6}{4}}{\binom{8}{4}} \cdot \frac{\binom{6}{5}}{\binom{8}{5}} = \left(\frac{5}{8} \cdot \frac{4}{7}\right) \left(\frac{4}{8} \cdot \frac{3}{7}\right) \left(\frac{3}{8} \cdot \frac{2}{7}\right) = b \text{ for } i < j, \\ \Pr(A_i \cap A_j \cap A_k) &= \frac{\binom{5}{3}}{\binom{8}{3}} \cdot \frac{\binom{5}{4}}{\binom{8}{4}} \cdot \frac{\binom{5}{5}}{\binom{8}{5}} = \left(\frac{5}{8} \cdot \frac{4}{7} \cdot \frac{3}{6}\right) \left(\frac{4}{8} \cdot \frac{3}{7} \cdot \frac{2}{6}\right) \left(\frac{3}{8} \cdot \frac{2}{7} \cdot \frac{1}{6}\right) \\ &= c \text{ for } i < j < k, \\ \Pr(A_i \cap A_j \cap A_k \cap A_\ell) &= 0, \quad i < j < k < \ell.\end{aligned}$$

Hence, by Theorem 1.10.2,

$$\Pr\left(\bigcup_{i=1}^8 A_i\right) = 8a - \binom{8}{2}b + \binom{8}{3}c + 0$$

Therefore, the required probability is  $1 - .7207 = .2793$ .

19. Let  $E_i$  be the event that  $A$  and  $B$  are both selected for committee  $i$  ( $i = 1, 2, 3$ ) and let  $\Pr(E_i) = p_i$ . Then

$$p_1 = \frac{\binom{6}{1}}{\binom{8}{3}} \approx 0.1071, \quad p_2 = \frac{\binom{6}{2}}{\binom{8}{4}} \approx 0.2143, \quad p_3 = \frac{\binom{6}{3}}{\binom{8}{5}} \approx 0.3571.$$

Since  $E_1, E_2$ , and  $E_3$  are independent, it follows from Theorem 1.10.1 that the required probability is

$$\begin{aligned}\Pr(E_1 \cup E_2 \cup E_3) &= p_1 + p_2 + p_3 - p_1 p_2 - p_2 p_3 - p_1 p_3 + p_1 p_2 p_3 \\ &\approx 0.5490.\end{aligned}$$

20. Let  $E$  denote the event that  $B$  wins.  $B$  will win if  $A$  misses on her first turn and  $B$  wins on her first turn, which has probability  $\left(\frac{5}{6}\right)\left(\frac{1}{6}\right)$ , or if both players miss on their first turn and  $B$  then goes on to subsequently win, which has probability  $\left(\frac{5}{6}\right)\left(\frac{5}{6}\right) \Pr(E)$ . (See Exercise 17, Sec. 2.2.) Hence,  $\Pr(E) = \left(\frac{5}{6}\right)\left(\frac{1}{6}\right) + \left(\frac{5}{6}\right)\left(\frac{5}{6}\right) \Pr(E)$ , and  $\Pr(E) = \frac{5}{11}$ . This problem could also be solved by summing the infinite series  $\left(\frac{5}{6}\right)\left(\frac{1}{6}\right) + \left(\frac{5}{6}\right)^3\left(\frac{1}{6}\right) + \left(\frac{5}{6}\right)^5\left(\frac{1}{6}\right) + \dots$

21.  $A$  will win if he wins on his first toss (probability  $1/2$ ) or if all three players miss on their first tosses (probability  $1/8$ ) and then  $A$  subsequently wins. Hence,

$$\Pr(A \text{ wins}) = \frac{1}{2} + \frac{1}{8} \Pr(A \text{ wins}),$$

and  $\Pr(A \text{ wins}) = 4/7$ .

Similarly,  $B$  will win if  $A$  misses on his first toss and  $B$  wins on his first toss, or if all three players miss on their first tosses and then  $B$  subsequently wins. Hence,

$$\Pr(B \text{ wins}) = \frac{1}{4} + \frac{1}{8} \Pr(B \text{ wins}),$$

and  $\Pr(B \text{ wins}) = 2/7$ . Thus,  $\Pr(C \text{ wins}) = 1 - 4/7 - 2/7 = 1/7$ .

22. Let  $A_j$  denote the outcome of the  $j$ th roll. Then

$$\begin{aligned} \Pr(X = x) &= \Pr(A_2 \neq A_1, A_3 \neq A_2, \dots, A_{x-1} \neq A_{x-2}, A_x = A_{x-1}). \\ &= \Pr(A_2 \neq A_1) \Pr(A_3 \neq A_2 \mid A_2 \neq A_1) \cdots \Pr(A_x = A_{x-1} \mid A_{x-1} \neq A_{x-2}, \text{etc.}) \\ &= \underbrace{\left(\frac{5}{6}\right) \cdots \left(\frac{5}{6}\right)}_{x-2 \text{ factors}} \left(\frac{1}{6}\right) = \left(\frac{5}{6}\right)^{x-2} \left(\frac{1}{6}\right). \end{aligned}$$

23. Let  $A$  be the event that the person you meet is a statistician, and let  $B$  be the event that he is shy. Then

$$\Pr(A \mid B) = \frac{(0.8)(0.1)}{(0.8)(0.1) + (0.15)(0.9)} = 0.372.$$

$$24. \Pr(A \mid \text{lemon}) = \frac{(0.05)(0.2)}{(0.05)(0.2) + (0.02)(0.5) + (0.1)(0.3)} = \frac{1}{5}.$$

$$25. \text{(a)} \quad \Pr(\text{Defective} \mid \text{Removed}) = \frac{(0.9)(0.3)}{(0.9)(0.3) + (0.2)(0.7)} = \frac{27}{41} = 0.659.$$

$$\text{(b)} \quad \Pr(\text{Defective} \mid \text{Not Removed}) = \frac{(0.1)(0.3)}{(0.1)(0.3) + (0.8)(0.7)} = \frac{3}{59} = 0.051.$$

26. Let  $X$  and  $Y$  denote the number of tosses required on the first experiment and second experiment, respectively. Then  $X = n$  if and only if the first  $n - 1$  tosses of the first experiment are tails and the  $n$ th toss is a head, which has probability  $1/2^n$ . Furthermore,  $Y > n$  if and only if the first  $n$  tosses of the second experiment are all tails, which also has probability  $1/2^n$ .

Hence

$$\begin{aligned} \Pr(Y > X) &= \sum_{n=1}^{\infty} \Pr(Y > n \mid X = n) \Pr(X = n) \\ &= \sum_{n=1}^{\infty} \frac{1}{2^n} \cdot \frac{1}{2^n} = \sum_{n=1}^{\infty} \frac{1}{4^n} = \frac{1}{3}. \end{aligned}$$

27. Let  $A$  denote the event that the family has at least one boy, and  $B$  the event that it has at least one girl. Then

$$\begin{aligned}\Pr(B) &= 1 - (1/2)^n, \\ \Pr(A \cap B) &= 1 - \Pr(\text{All girls}) - \Pr(\text{All boys}) = 1 - (1/2)^n - (1/2)^n.\end{aligned}$$

Hence,

$$\Pr(A | B) = \frac{\Pr(A \cap B)}{\Pr(B)} = \frac{1 - (1/2)^{n-1}}{1 - (1/2)^n}$$

28. (a) Let  $X$  denote the number of heads, Then

$$\begin{aligned}\Pr(X = n-1 | X \geq n-2) &= \frac{\Pr(X = n-1)}{\Pr(X \geq n-2)} \\ &= \frac{\binom{n}{n-1} (1/2)^n}{\left[ \binom{n}{n-2} + \binom{n}{n-1} + \binom{n}{n} \right] (1/2)^n} = \frac{n}{\frac{n(n-1)}{2} + n + 1} = \frac{2n}{n^2 + n + 2}.\end{aligned}$$

- (b) The required probability is the probability of obtaining exactly one head on the last two tosses, namely  $1/2$ .
29. (a) Let  $X$  denote the number of aces selected.  
Then

$$\begin{aligned}\Pr(X = i) &= \frac{\binom{4}{i} \binom{48}{13-i}}{\binom{52}{13}}, \quad i = 0, 1, 2, 3, 4. \\ \Pr(X \geq 2 | X \geq 1) &= \frac{1 - \Pr(X = 0) - \Pr(X = 1)}{1 - \Pr(X = 0)} \\ &\approx \frac{1 - 0.3038 - 0.4388}{1 - 0.3038} = 0.3697.\end{aligned}$$

- (b) Let  $A$  denote the event that the ace of hearts and no other aces are obtained, and let  $H$  denote the event that the ace of hearts is obtained.

Then

$$\Pr(A) = \frac{\binom{48}{12}}{\binom{52}{13}} \approx 0.1097, \quad \Pr(H) = \frac{13}{52} = 0.25.$$

The required probability is

$$\frac{\Pr(H) - \Pr(A)}{\Pr(H)} \approx \frac{0.25 - 0.1097}{0.25} = 0.5612.$$

30. The probability that a particular letter, say letter  $A$ , will be placed in the correct envelope is  $1/n$ . The probability that none of the other  $n - 1$  letters will then be placed in the correct envelope is  $q_{n-1} = 1 - p_{n-1}$ . Therefore, the probability that only letter  $A$ , and no other letter, will be placed in the correct envelope is  $q_{n-1}/n$ . It follows that the probability that exactly one of the  $n$  letters will be placed in the correct envelope, without specifying which letter will be correctly placed is  $nq_{n-1}/n = q_{n-1}$ .
31. The probability that two specified letters will be placed in the correct envelopes is  $1[n(n - 1)]$ . The probability that none of the other  $n - 2$  letters will then be placed in the correct envelopes is  $q_{n-2}$ . Therefore, the probability that only the two specified letters, and no other letters, will be placed in the correct envelopes is  $\frac{1}{n(n - 1)}q_{n-2}$ . It follows that the probability that exactly two of the  $n$  letters will be placed in the correct envelopes, without specifying which pair will be correctly placed, is  $\binom{n}{2} \frac{1}{n(n - 1)}q_{n-2} = \frac{1}{2}q_{n-2}$ .

32. The probability that exactly one student will be in class is

$$\Pr(A) \Pr(B^c) + \Pr(A^c) \Pr(B) = (0.8)(0.4) + (0.2)(0.6) = 0.44.$$

The probability that exactly one student will be in class and that student will be  $A$  is

$$\Pr(A) \Pr(B^c) = 0.32.$$

Hence, the required probability is  $\frac{32}{44} = \frac{8}{11}$ .

33. By Exercise 3 of Sec. 1.10, the probability that a family subscribes to exactly one of the three newspapers is 0.45. As can be seen from the solution to that exercise, the probability that a family subscribes only to newspaper A is 0.35. Hence, the required probability is  $35/45 = 7/9$ .
34. A more reasonable analysis by prisoner  $A$  might proceed as follows: The pair to be executed is equally likely to be  $(A, B)$ ,  $(A, C)$ , or  $(B, C)$ . If it is  $(A, B)$  or  $(A, C)$ , the jailer will surely respond  $B$  or  $C$ , respectively. If it is  $(B, C)$ , the jailer is equally likely to respond  $B$  or  $C$ . Hence, if the jailer responds  $B$ , the conditional probability that the pair to be executed is  $(A, B)$  is

$$\begin{aligned}\Pr[(A, B) \mid \text{response}] &= \frac{1 \cdot \Pr(A, B)}{1 \cdot \Pr(A, B) + 0 \cdot \Pr(A, C) + \frac{1}{2} \Pr(B, C)} \\ &= \frac{1 \cdot \frac{1}{3}}{1 \cdot \frac{1}{3} + 0 \cdot \frac{1}{3} + \frac{1}{2} \cdot \frac{1}{3}} = \frac{2}{3}.\end{aligned}$$

Thus, the probability that  $A$  will be executed is the same  $2/3$  as it was before he questioned the jailer. This answer will change if the probability that the jailer will respond  $B$ , given  $(B, C)$ , is assumed to be some value other than  $1/2$ .

35. The second situation, with stakes of two dollars, is equivalent to the situation in which  $A$  and  $B$  have initial fortunes of 25 dollars and bet one dollar on each play. In the notation of Sec. 2.4, we have  $i = 50$  and  $k = 100$  in the first situation and  $i = 25$  and  $k = 50$  in the second situation. Hence, if  $p = 1/2$ , it follows from Eq. (2.4.6) that gambler  $A$  has the same probability  $1/2$  of ruining gambler  $B$  in either

situation. If  $p \neq 1/2$ , then it follows from Eq. (2.4.9) that the probabilities  $\alpha_1$  and  $\alpha_2$  of winning in the two situations equal the values

$$\begin{aligned}\alpha_1 &= \frac{([1-p]/p)^{50} - 1}{([1-p]/p)^{100} - 1} = \frac{1}{([1-p]/p)^{50} + 1}, \\ \alpha_2 &= \frac{([1-p]/p)^{25} - 1}{([1-p]/p)^{50} - 1} = \frac{1}{([1-p]/p)^{25} + 1}.\end{aligned}$$

Hence, if  $p < 1/2$ , then  $([1-p]/p) > 1$  and  $\alpha_2 > \alpha_1$ . If  $p > 1/2$ , then  $([1-p]/p) < 1$  and  $\alpha_1 > \alpha_2$ .

36. (a) Since each candidate is equally likely to appear at each point in the sequence, the one who happens to be the best out of the first  $i$  has probability  $r/i$  of appearing in the first  $r$  interviews when  $i > r$ .
- (b) If  $i \leq r$ , then  $A$  and  $B_i$  are disjoint and  $\Pr(A \cap B_i) = 0$  because we cannot hire any of the first  $r$  candidates. So  $\Pr(A|B_i) = \Pr(A \cap B_i)/\Pr(B_i) = 0$ . Next, let  $i > r$  and assume that  $B_i$  occurs. Let  $C_i$  denote the event that we keep interviewing until we see candidate  $i$ . If  $C_i$  also occurs, then we shall rank candidate  $i$  higher than any of the ones previously seen and the algorithm tells us to stop and hire candidate  $i$ . In this case  $A$  occurs. This means that  $B_i \cap C_i \subset A$ . However, if  $C_i$  fails, then we shall hire someone before we get to interview candidate  $i$  and  $A$  will not occur. This means that  $B_i \cap C_i^c \cap A = \emptyset$ . Since  $B_i \cap A = (B_i \cap C_i \cap A) \cup (B_i \cap C_i^c \cap A)$ , we have  $B_i \cap A = B_i \cap C_i$  and  $\Pr(B_i \cap A) = \Pr(B_i \cap C_i)$ . So  $\Pr(A|B_i) = \Pr(C_i|B_i)$ . Conditional on  $B_i$ ,  $C_i$  occurs if and only if the best of the first  $i-1$  candidates appears in the first  $r$  positions. The conditional probability of  $C_i$  given  $B_i$  is then  $r/(i-1)$ .
- (c) If we use the value  $r > 0$  to determine our algorithm, then we can compute

$$p_r = \Pr(A) = \sum_{i=1}^n \Pr(B_i) \Pr(A|B_i) = \sum_{i=r+1}^n \frac{1}{n} \frac{r}{i-1} = \frac{r}{n} \sum_{i=r+1}^n \frac{1}{i-1}.$$

For  $r = 0$ , if we take  $r/r = 1$ , then only the first term in the sum produces a nonzero result and  $p_0 = 1/n$ . This is indeed the probability that the first candidate will be the best one seen so far when the first interview occurs.

- (d) Using the formula for  $p_r$  with  $r > 0$ , we have

$$q_r = p_r - p_{r-1} = \frac{1}{n} \left[ \sum_{i=r+1}^n \frac{1}{i-1} - 1 \right],$$

which clearly decreases as  $r$  increases because the terms in the sum are the same for all  $r$ , but there are fewer terms when  $r$  is larger. Since all the terms are positive,  $q_r$  is strictly decreasing.

- (e) Since  $p_r = q_r + p_{r-1}$  for  $r \geq 1$ , we have that  $p_r = p_0 + q_1 + \dots + q_r$ . If there exists  $r$  such that  $q_r \leq 0$ , then  $q_j < 0$  for all  $j > r$  and  $p_j \leq p_{r-1}$  for all  $j \geq r$ . On the other hand, for each  $r$  such that  $q_r > 0$ ,  $p_r > p_{r-1}$ . Hence, we should choose  $r$  to be the last value such that  $q_r > 0$ .
- (f) For  $n = 10$ , the first few values of  $q_r$  are

$r$	1	2	3	4
$q_r$	0.1829	0.0829	0.0390	-0.0004

So, we should use  $r = 3$ . We can then compute  $p_3 = 0.3987$ .

# Chapter 3

## Random Variables and Distributions

### 3.1 Random Variables and Discrete Distributions

#### Solutions to Exercises

1. Each of the 11 integers from 10 to 20 has the same probability of being the value of  $X$ . Six of the 11 integers are even, so the probability that  $X$  is even is  $6/11$ .
2. The sum of the values of  $f(x)$  must be equal to 1. Since  $\sum_{x=1}^5 f(x) = 15c$ , we must have  $c = 1/15$ .
3. By looking over the 36 possible outcomes enumerated in Example 1.6.5, we find that  $X = 0$  for 6 outcomes,  $X = 1$  for 10 outcomes,  $X = 2$  for 8 outcomes,  $X = 3$  for 6 outcomes,  $X = 4$  for 4 outcomes, and  $X = 5$  for 2 outcomes. Hence, the p.f.  $f(x)$  is as follows:

$x$	0	1	2	3	4	5
$f(x)$	3/18	5/18	4/18	3/18	2/18	1/18

4. For  $x = 0, 1, \dots, 10$ , the probability of obtaining exactly  $x$  heads is  $\binom{10}{x} \left(\frac{1}{2}\right)^{10}$ .
5. For  $x = 2, 3, 4, 5$ , the probability of obtaining exactly  $x$  red balls is  $\binom{7}{x} \binom{3}{5-x} / \binom{10}{5}$ .
6. The desired probability is the sum of the entries for  $k = 0, 1, 2, 3, 4$ , and 5 in that part of the table of binomial probabilities given in the back of the book corresponding to  $n = 15$  and  $p = 0.5$ . The sum is 0.1509.
7. Suppose that a machine produces a defective item with probability 0.7 and produces a nondefective item with probability 0.3. If  $X$  denotes the number of defective items that are obtained when 8 items are inspected, then the random variable  $X$  will have the binomial distribution with parameters  $n = 8$  and  $p = 0.7$ . By the same reasoning, however, if  $Y$  denotes the number of nondefective items that are obtained, then  $Y$  will have the binomial distribution with parameters  $n = 8$  and  $p = 0.3$ . Furthermore,  $Y = 8 - X$ . Therefore,  $X \geq 5$  if and only if  $Y \leq 3$  and it follows that  $\Pr(X \geq 5) = \Pr(Y \leq 3)$ . Probabilities for the binomial distribution with  $n = 8$  and  $p = 0.3$  are given in the table in the back of the book. The value of  $\Pr(Y \leq 3)$  will be the sum of the entries for  $k = 0, 1, 2$ , and 3.

8. The number of red balls obtained will have the binomial distribution with parameters  $n = 20$  and  $p = 0.1$ . The required probability can be found from the table of binomial probabilities in the back of the book. Add up the numbers in the  $n = 20$  and  $p = 0.1$  section from  $k = 4$  to  $k = 20$ . Or add up the numbers from  $k = 0$  to  $k = 3$  and subtract the sum from 1. The answer is 0.1330.
9. We need  $\sum_{x=0}^{\infty} f(x) = 1$ , which means that  $c = 1 / \sum_{x=0}^{\infty} 2^{-x}$ . The last sum is known from Calculus to equal  $1/(1 - 1/2) = 2$ , so  $c = 1/2$ .
10. (a) The p.f. of  $X$  is  $f(x) = c(x+1)(8-x)$  for  $x = 0, \dots, 7$  where  $c$  is chosen so that  $\sum_{x=0}^7 f(x) = 1$ . So,  $c$  is one over  $\sum_{x=0}^7 (x+1)(8-x)$ , which sum equals 120, so  $c = 1/120$ . That is  $f(x) = (x+1)(8-x)/120$  for  $x = 0, \dots, 7$ .
- (b)  $\Pr(X \geq 5) = [(5+1)(8-5) + (6+1)(8-6) + (7+1)(8-7)]/120 = 1/3$ .
11. In order for the specified function to be a p.f., it must be the case that  $\sum_{x=1}^{\infty} \frac{c}{x} = 1$  or equivalently  $\sum_{x=1}^{\infty} \frac{1}{x} = \frac{1}{c}$ . But  $\sum_{x=1}^{\infty} \frac{1}{x} = \infty$ , so there cannot be such a constant  $c$ .

## 3.2 Continuous Distributions

### Commentary

This section ends with a brief discussion of probability distributions that are neither discrete nor continuous. Although such distributions have great theoretical interest and occasionally arise in practice, students can go a long way without actually concerning themselves about these distributions.

### Solutions to Exercises

1. We compute  $\Pr(X \leq 8/27)$  by integrating the p.d.f. from 0 to  $8/27$ .

$$\Pr\left(X \leq \frac{8}{27}\right) = \int_0^{8/27} \frac{2}{3}x^{-1/3} dx = x^{2/3} \Big|_0^{8/27} = \frac{4}{9}.$$

2. The p.d.f. has the appearance of Fig. S.3.1.

Figure S.3.1: Figure for Exercise 2 of Sec. 3.2.

$$(a) \Pr\left(X < \frac{1}{2}\right) = \int_0^{1/2} 4(1 - x^3) dx / 3 = 0.6458.$$

$$(b) \Pr\left(\frac{1}{4} < X < \frac{3}{4}\right) = \int_{1/4}^{3/4} 4(1-x^3)dx/3 = 0.5625.$$

$$(c) \Pr\left(X > \frac{1}{3}\right) = \int_{1/3}^1 4(1-x^3)dx/3 = 0.5597.$$

3. The p.d.f. has the appearance of Fig. S.3.2.

Figure S.3.2: Figure for Exercise 3 of Sec. 3.2.

$$(a) \Pr(X < 0) = \frac{1}{36} \int_{-3}^0 (9-x^2)dx = 0.5.$$

$$(b) \Pr(-1 < X < 1) = \frac{1}{36} \int_{-1}^1 (9-x^2)dx = 0.4815.$$

$$(c) \Pr(X > 2) = \frac{1}{36} \int_2^3 (9-x^2)dx = 0.07407.$$

The answer in part (a) could also be obtained directly from the fact that the p.d.f. is symmetric about the point  $x = 0$ . Therefore, the probability to the left of  $x = 0$  and the probability to the right of  $x = 0$  must each be equal to  $1/2$ .

4. (a) We must have

$$\int_{-\infty}^{\infty} f(x) dx = \int_1^2 cx^2 dx = \frac{7}{3}c = 1.$$

Therefore,  $c = 3/7$ . This p.d.f. has the appearance of Fig. S.3.3.

Figure S.3.3: Figure for Exercise 4a of Sec. 3.2.

$$(b) \int_{3/2}^2 f(x) dx = 37/56.$$

$$5. (a) \int_0^t \frac{1}{8}x dx = 1/4, \text{ or } t^2/16 = 1/4. \text{ Hence, } t = 2.$$

$$(b) \int_t^4 (x/8) dx = 1/2, \text{ or } 1 - t^2/16 = 1/2. \text{ Hence, } t = \sqrt{8}.$$

6. The value of  $X$  must be between 0 and 4. We will have

$$Y = \begin{cases} 0 & \text{if } 0 \leq X < 1/2, \\ 1 & \text{if } 1/2 < X < 3/2, \\ 2 & \text{if } 3/2 < X < 5/2, \\ 3 & \text{if } 5/2 < X < 7/2, \\ 4 & \text{if } 7/2 < X \leq 4. \end{cases}$$

We need not worry about how to define  $Y$  if  $X \in \{1/2, 3/2, 5/2, 7/2\}$ , because the probability that  $X$  will be equal to one of these four values is 0. It now follows that

$$\begin{aligned} \Pr(Y = 0) &= \int_0^{1/2} f(x) dx = \frac{1}{64}, \\ \Pr(Y = 1) &= \int_{1/2}^{3/2} f(x) dx = \frac{1}{8}, \\ \Pr(Y = 2) &= \int_{3/2}^{5/2} f(x) dx = \frac{1}{4}, \\ \Pr(Y = 3) &= \int_{5/2}^{7/2} f(x) dx = \frac{3}{8}, \\ \Pr(Y = 4) &= \int_{7/2}^4 f(x) dx = \frac{15}{64}. \end{aligned}$$

7. Since the uniform distribution extends over an interval of length 10 units, the value of the p.d.f. must be  $1/10$  throughout the interval. Hence,

$$\int_0^7 f(x) dx = \frac{7}{10}.$$

8. (a) We must have

$$\int_{-\infty}^{\infty} f(x) dx = \int_0^{\infty} c \exp(-2x) dx = \frac{1}{2}c = 1.$$

Therefore,  $c = 2$ . This p.d.f. has the appearance of Fig. S.3.4.

Figure S.3.4: Figure for Exercise 8a of Sec. 3.2.

$$(b) \int_1^2 f(x) dx = \exp(-2) - \exp(-4).$$

9. Since  $\int_0^{\infty} 1/(1+x) dx = \infty$ , there is no constant  $c$  such that  $\int_0^{\infty} f(x) dx = 1$ .

10. (a) We must have

$$\int_{-\infty}^{\infty} f(x) dx = \int_0^1 \frac{c}{(1-x)^{1/2}} dx = 2c = 1.$$

Therefore  $c = 1/2$ . This p.d.f. has the appearance of Fig. S.3.5.

Figure S.3.5: Figure for Exercise 10a of Sec. 3.2.

It should be noted that although the values of  $f(x)$  become arbitrarily large in the neighborhood of  $x = 1$ , the total area under the curve is equal to 1. It is seen, therefore, that the values of a p.d.f. can be greater than 1 and, in fact, can be arbitrarily large.

$$(b) \int_0^{1/2} f(x) dx = 1 - (1/2)^{1/2}.$$

11. Since  $\int_0^1 (1/x) dx = \infty$ , there is no constant  $c$  such that  $\int_0^1 f(x) dx = 1$ .

12. We shall find the c.d.f. of  $Y$  and evaluate it at 50. The c.d.f. of a random variable  $Y$  is  $F(y) = \Pr(Y \leq y)$ . In Fig. 3.1, on page 94 of the text, the event  $\{Y \leq y\}$  has area  $(y-1) \times (200-4) = 196(y-1)$  if  $1 \leq y \leq 150$ . We need to divide this by the area of the entire rectangle, 29,204. The c.d.f. of  $Y$  is then

$$F(y) = \begin{cases} 0 & \text{for } y < 1, \\ \frac{196(y-1)}{29204} & \text{for } 1 \leq y \leq 150, \\ 1 & \text{for } y > 150. \end{cases} .$$

So, in particular,  $\Pr(Y \leq 50) = 0.3289$ .

13. We find  $\Pr(X < 20) = \int_0^{20} cx dx = 200c$ . Setting this equal to 0.9 yields  $c = 0.0045$ .

### 3.3 The Cumulative Distribution Function

#### Commentary

This section includes a discussion of quantile functions. These arise repeatedly in the construction of hypothesis tests and confidence intervals later in the book.

**Solutions to Exercises**

1. The c.d.f.  $F(x)$  of  $X$  is 0 for  $x < 0$ . It jumps to  $0.3 = \Pr(X = 0)$  at  $x = 0$ , and it jumps to 1 and stays there at  $x = 1$ . The c.d.f. is sketched in Fig. S.3.6.

Figure S.3.6: C.d.f. of  $X$  in Exercise 1 of Sec. 3.3.

2. The c.d.f. must have the appearance of Fig. S.3.7.

Figure S.3.7: C.d.f. for Exercise 2 of Sec. 3.3.

3. Here  $\Pr(X = n) = 1/2^n$  for  $n = 1, 2, \dots$ . Therefore, the c.d.f. must have the appearance of Fig. S.3.8.

Figure S.3.8: C.d.f. for Exercise 3 of Sec. 3.3.

4. The numbers can be read off of the figure or found by subtracting two numbers off of the figure.

- (a) The jump at  $x = -1$  is  $F(-1) - F(-1^-) = 0.1$ .
- (b) The c.d.f. to the left of  $x = 0$  is  $F(0^-) = 0.1$ .
- (c) The c.d.f. at  $x = 0$  is  $F(0) = 0.2$ .

- (d) There is no jump at  $x = 1$ , so  $\Pr(X = 1) = 0$ .
- (e)  $F(3) - F(0) = 0.6$ .
- (f)  $F(3^-) - F(0) = 0.4$ .
- (g)  $F(3) - F(0^-) = 0.7$ .
- (h)  $F(2) - F(1) = 0$ .
- (i)  $F(2) - F(1^-) = 0$ .
- (j)  $1 - F(5) = 0$ .
- (k)  $1 - F(5^-) = 0$ .
- (l)  $F(4) - F(3^-) = 0.2$ .

5.  $f(x) = \frac{dF(x)}{dx} = \begin{cases} 0 & \text{for } x < 0, \\ \frac{2}{9}x & \text{for } 0 < x < 3, \\ 0 & \text{for } x > 3. \end{cases}$

The value of  $f(x)$  at  $x = 0$  and  $x = 3$  is irrelevant. This p.d.f. has the appearance of Fig. S.3.9.

Figure S.3.9: Figure for Exercise 5 of Sec. 3.3.

6.  $f(x) = \frac{dF(x)}{dx} = \begin{cases} \exp(x-3) & \text{for } x < 3, \\ 0 & \text{for } x > 3. \end{cases}$

The value of  $f(x)$  at  $x = 3$  is irrelevant. This p.d.f. has the appearance of Fig. S.3.10.

Figure S.3.10: Figure for Exercise 6 of Sec. 3.3.

It should be noted that although this p.d.f. is positive over the unbounded interval where  $x < 3$ , the total area under the curve is finite and is equal to 1.

7. The c.d.f. equals 0 for  $x < -2$  and it equals 1 for  $x > 8$ . For  $-2 \leq x \leq 8$ , the c.d.f. equals

$$F(x) = \int_{-2}^x \frac{dy}{10} = \frac{x+2}{10}.$$

The c.d.f. has the appearance of Fig. S.3.11.

Figure S.3.11: Figure for Exercise 7 of Sec. 3.3.

8.  $\Pr(Z \leq z)$  is the probability that  $Z$  lies within a circle of radius  $z$  centered at the origin. This probability is

$$\frac{\text{Area of circle of radius } z}{\text{Area of circle of radius } 1} = z^2, \quad \text{for } 0 \leq z \leq 1.$$

The c.d.f. is plotted in Fig. S.3.12.

Figure S.3.12: C.d.f. for Exercise 8 of Sec. 3.3.

9.  $\Pr(Y = 0) = \Pr(X \leq 1) = 1/5$  and  $\Pr(Y = 5) = \Pr(X \geq 3) = 2/5$ . Also,  $Y$  is distributed uniformly between  $Y = 1$  and  $Y = 3$ , with a total probability of  $2/5$ . Therefore, over this interval  $F(y)$  will be linear with a total increase of  $2/5$ . The c.d.f. is plotted in Fig. S.3.13.

10. To find the quantile function  $F^{-1}(p)$  when we know the c.d.f., we can set  $F(x) = p$  and solve for  $x$ .

$$\frac{x}{1+x} = p; \quad x = p + px; \quad x(1-p) = p; \quad x = \frac{p}{1-p}.$$

The quantile function is  $F^{-1}(p) = p/(1-p)$ .

11. As in Exercise 10, we set  $F(x) = p$  and solve for  $x$ .

$$\frac{1}{9}x^2 = p; \quad x^2 = 9p; \quad x = 3p^{1/2}.$$

The quantile function of  $X$  is  $F^{-1}(p) = 3p^{1/2}$ .

Figure S.3.13: C.d.f. for Exercise 9 of Sec. 3.3.

12. Once again, we set  $F(x) = p$  and solve for  $x$ .

$$\exp(x - 3) = p; \quad x - 3 = \log(p); \quad x = 3 + \log(p).$$

The quantile function of  $X$  is  $F^{-1}(p) = 3 + \log(p)$ .

13. VaR at probability level 0.95 is the negative of the 0.05 quantile. Using the result from Example 3.3.8, the 0.05 quantile of the uniform distribution on the interval  $[-12, 24]$  is  $0.05 \times 24 - 0.95 \times 12 = -10.2$ . So, VaR at probability level 0.95 is 10.2
14. Using the table of binomial probabilities in the back of the book, we can compute the c.d.f.  $F$  of the binomial distribution with parameters 10 and 0.2. We then find the first values of  $x$  such that  $F(x) \geq 0.25$ ,  $F(x) \geq 0.5$ , and  $F(x) \geq 0.75$ . The first few distinct values of the c.d.f. are

$x$	0	1	2	3
$F(x)$	0.0174	0.3758	0.6778	0.8791

So, the quartiles are 1 and 3, while the median is 2.

15. Since  $f(x) = 0$  for  $x \leq 0$  and for  $x \geq 1$ , the c.d.f.  $F(x)$  will be flat (0) for  $x \leq 0$  and flat (1) for  $x \geq 1$ . Between 0 and 1, we compute  $F(x)$  by integrating the p.d.f. For  $0 < x < 1$ ,

$$F(x) = \int_0^x 2y dy = x^2.$$

The requested plot is identical to Fig. S.3.12 for Exercise 8 in this section.

16. For each  $0 < p < 1$ , we solve for  $x$  in the equation  $F(x) = p$ , with  $F$  specified in (3.3.2):

$$\begin{aligned} p &= 1 - \frac{1}{1+x}, \\ \frac{1}{1-p} &= 1+x, \\ \frac{1}{1-p} - 1 &= x. \end{aligned}$$

The quantile function is  $F^{-1}(p) = 1/(1-p) - 1$  for  $0 < p < 1$ .

17. (a) Let  $0 < p_1 < p_2 < 1$ . Define  $A_i = \{x : F(x) \geq p_i\}$  for  $i = 1, 2$ . Since  $p_1 < p_2$  and  $F$  is nondecreasing, it follows that  $A_2 \subset A_1$ . Hence, the smallest number in  $A_1$  (which equals  $F^{-1}(p_1)$  by definition) is no greater than the smallest number in  $A_2$  (which equals  $F^{-1}(p_2)$  by definition). That is,  $F^{-1}(p_1) \leq F^{-1}(p_2)$ , and the quantile function is nondecreasing.
- (b) Let  $x_0 = \lim_{\substack{p \rightarrow 0 \\ p > 0}} F^{-1}(p)$ . We are asked to prove that  $x_0$  is the greatest lower bound of the set  $C = \{c : F(c) > 0\}$ . First, we show that no  $x > x_0$  is a lower bound on  $C$ . Let  $x > x_0$  and  $x_1 = (x + x_0)/2$ . Then  $x_0 < x_1 < x$ . Because  $F^{-1}(p)$  is nondecreasing, it follows that there exists  $p > 0$  such that  $F^{-1}(p) < x_1$ , which in turn implies that  $p \leq F(x_1)$ , and  $F(x_1) > 0$ . Hence  $x_1 \in C$ , and  $x$  is not a lower bound on  $C$ . Next, we prove that  $x_0$  is a lower bound on  $C$ . Let  $x \in C$ . We need only prove that  $x_0 \leq x$ . Because  $F^{-1}(p)$  is nondecreasing, we must have  $\lim_{\substack{p \rightarrow 0 \\ p > 0}} F^{-1}(p) \leq F^{-1}(q)$  for all  $q > 0$ . Hence,  $x_0 \leq F^{-1}(p)$  for all  $q > 0$ . Because  $x \in C$ , we have  $F(x) > 0$ . Let  $q = F(x)$  so that  $q > 0$ . Then  $x_0 \leq F^{-1}(q) \leq x$ . The proof that  $x_1$  is the least upper bound on the set of all  $d$  such that  $F(d) < 1$  is very similar.
- (c) Let  $0 < p < 1$ . Because  $F^{-1}$  is nondecreasing,  $F^{-1}(p^-)$  is the least upper bound on the set  $C = \{F^{-1}(q) : q < p\}$ . We need to show that  $F^{-1}(p)$  is also that least upper bound. Clearly,  $F^{-1}(p)$  is an upper bound, because  $F^{-1}$  is nondecreasing and  $p > q$  for all  $q < p$ . To see that  $F^{-1}(p)$  is the least upper bound, let  $y$  be an upper bound. We need to show  $F^{-1}(p) \leq y$ . By definition,  $F^{-1}(p)$  is the greatest lower bound on the set  $D = \{x : F(x) \geq p\}$ . Because  $y$  is an upper bound on  $C$ , it follows that  $F^{-1}(q) \leq y$  for all  $q < p$ . Hence,  $F(y) \geq q$  for all  $q < p$ . Because  $F$  is nondecreasing, we have  $F(y) \geq p$ , hence  $y \in D$ , and  $F^{-1}(p) \leq y$ .
18. We know that  $\Pr(X = c) = F(c) - F(c^-)$ . We will prove that  $p_1 = F^*(c)$  and  $p_0 = F(c^-)$ . For each  $p \in (0, 1)$  define
- $$C_p = \{x : F(x) \geq p\}.$$
- Condition (i) says that, for every  $p \in (p_0, p_1)$ ,  $c$  is the greatest lower bound on the set  $C_p$ . Hence  $F(c) \geq p$  for all  $p < p_1$  and  $F(c) \geq p_1$ . If  $F(c) > p_1$ , then for  $p = (p_1 + F(c))/2$ ,  $F^{-1}(p) \leq c$ , and condition (iii) rules this out. So  $F(c) = p_1$ . The rest of the proof is broken into two cases. First, if  $p_0 = 0$ , then for every  $\epsilon > 0$ ,  $c$  is the greatest lower bound on the set  $C_\epsilon$ . This means that  $F(x) < \epsilon$  for all  $x < c$ . Since this is true for all  $\epsilon > 0$ ,  $F(x) = 0$  for all  $x < c$ , and  $F(c^-) = 0 = p_0$ . For the second case, assume  $p_0 > 0$ . Condition (ii) says  $F^{-1}(p_0) < c$ . Since  $F^{-1}(p_0)$  is the greatest lower bound on the set  $C_{p_0}$ , we have  $F(x) < p_0$  for all  $x < c$ . Hence,  $p_0 \geq F(c^-)$ . Also, for all  $p < p_0$ ,  $p \leq F(c^-)$ , hence  $p_0 \leq F(c^-)$ . Together, the last two inequalities imply  $p_0 = F(c^-)$ .
19. First, we show that  $F^{-1}(F(x)) \leq x$ . By definition  $F^{-1}(F(x))$  is the smallest  $y$  such that  $F(y) \geq F(x)$ . Clearly  $F(x) \geq F(x)$ , hence  $F^{-1}(F(x)) \leq x$ . Next, we show that, if  $p > F(x)$ , then  $F^{-1}(p) > x$ . Let  $p > F(x)$ . By Exercise 17, we know that  $F^{-1}(p) \geq x$ . By definition,  $F^{-1}(p)$  is the greatest lower bound on the set  $C_p = \{y : F(y) \geq p\}$ . All  $y \in C_p$  satisfy  $F(y) > (p + F(x))/2$ . Since  $F$  is continuous from the right,  $F(F^{-1}(p)) \geq (p + F(x))/2$ . But  $F(x) < (p + F(x))/2$ , so  $x \neq F^{-1}(p)$ , hence  $F^{-1}(p) > x$ .
20. Figure S.3.14 has the plotted c.d.f., which equals  $0.0045x^2/2$  for  $0 < x < 20$ . On the plot, we see that  $F(10) = 0.225$ .

## 3.4 Bivariate Distributions

### Commentary

The bivariate distribution function is mentioned at the end of this section. The only part of this discussion that is used later in the text is the fact that the joint p.d.f. is the second mixed partial derivative of the

Figure S.3.14: C.d.f. for Exercise 20 of Sec. 3.3.

bivariate p.d.f. (in the discussion of functions of two or more random variables is Sec. 3.9.) If an instructor prefers not to discuss how to calculate probabilities of rectangles and is not going to cover functions of two or more random variables, there will be no loss of continuity.

### Solutions to Exercises

1. (a) Let the constant value of the p.d.f. on the rectangle be  $c$ . The area of the rectangle is 2. So, the integral of the p.d.f. is  $2c = 1$ , hence  $c = 1/2$ .
- (b)  $\Pr(X \geq Y)$  is the integral of the p.d.f. over that part of the rectangle where  $x \geq y$ . This region is shaded in Fig. S.3.15. The region is a trapezoid with area  $1 \times (1 + 2)/2 = 1.5$ . The integral of the

Figure S.3.15: Region where  $x \geq y$  in Exercise 1b of Sec. 3.4.

- constant  $1/2$  over this region is then  $0.75 = \Pr(X \geq Y)$ .
2. The answers are found by summing the following entries in the table:

- (a) The entries in the third row of the table: 0.27.

- (b) The last three columns of the table: 0.53.  
 (c) The nine entries in the upper left corner of the table: 0.69  
 (d)  $(0, 0), (1, 1), (2, 2)$ , and  $(3, 3)$ : 0.3.  
 (e)  $(1, 0), (2, 0), (3, 0), (2, 1), (3, 1), (3, 2)$ : 0.25.
3. (a) If we sum  $f(x, y)$  over the 25 possible pairs of values  $(x, y)$ , we obtain  $40c$ . Since this sum must be equal to 1, it follows that  $c = 1/40$ .  
 (b)  $f(0, -2) = (1/40) \cdot 2 = 1/20$ .  
 (c)  $\Pr(X = 1) = \sum_{y=-2}^2 f(1, y) = 7/40$ .  
 (d) The answer is found by summing  $f(x, y)$  over the following pairs:  $(-2, -2), (-2, -1), (-1, -2), (-1, -1), (-1, 0), (0, -1), (0, 0), (0, 1), (1, 0), (1, 1), (1, 2), (2, 1)$ , and  $(2, 2)$ . The sum is 0.7.
4. (a)  $\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x, y) dx dy = \int_0^1 \int_0^2 cy^2 dx dy = 2c/3$ . Since the value of this integral must be 1, it follows that  $c = 3/2$ .  
 (b) The region over which to integrate is shaded in Fig. S.3.16.

Figure S.3.16: Region of integration for Exercise 4b of Sec. 3.4.

$$\begin{aligned}\Pr(X + Y > 2) &= \int \int_{\text{shaded region}} f(x, y) dx dy \\ &= \int_1^2 \int_{2-x}^1 \frac{3}{2}y^2 dy dx = \frac{3}{8}.\end{aligned}$$

- (c) The region over which to integrate is shaded in Fig. S.3.17.

Figure S.3.17: Region of integration for Exercise 4c of Sec. 3.4.

$$\Pr\left(Y < \frac{1}{2}\right) = \int_0^2 \int_0^{1/2} \frac{3}{2}y^2 dy dx = \frac{1}{8}.$$

Figure S.3.18: Region of integration for Exercise 4d of Sec. 3.4.

- (d) The region over which to integrate is shaded in Fig. S.3.18.

$$\Pr(X \leq 1) = \int_0^1 \int_0^1 \frac{3}{2}y^2 dy dx = \frac{1}{2}.$$

- (e) The probability that  $(X, Y)$  will lie on the line  $x = 3y$  is 0 for every continuous joint distribution.
5. (a) By sketching the curve  $y = 1 - x^2$ , we find that  $y \leq 1 - x^2$  for all points on or below this curve. Also,  $y \geq 0$  for all points on or above the x-axis. Therefore,  $0 \leq y \leq 1 - x^2$  only for points in the shaded region in Fig. S.3.19.

Figure S.3.19: Figure for Exercise 5a of Sec. 3.4.

Hence,

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x, y) dx dy = \int_{-1}^1 \int_0^{1-x^2} c(x^2 + y) dy dx = \frac{4}{5}c.$$

Therefore,  $c = 5/4$ .

- (b) Integration is done over the shaded region in Fig. S.3.20.

$$\Pr\left(0 \leq X \leq \frac{1}{2}\right) = \int_{\text{shaded region}} \int f(x, y) dx dy = \int_0^{\frac{1}{2}} \int_0^{1-x^2} \frac{5}{4}(x^2 + y) dy dx = \frac{79}{256}.$$

Figure S.3.20: Region of integration for Exercise 5b of Sec. 3.4.

Figure S.3.21: Region of integration for Exercise 5c of Sec. 3.4.

- (c) The region over which to integrate is shaded in Fig. S.3.21.

$$\begin{aligned} \Pr(Y \leq X + 1) &= \int_{\substack{\text{shaded} \\ \text{region}}} \int f(x, y) dx dy = 1 - \int_{\substack{\text{unshaded} \\ \text{region}}} \int f(x, y) dx dy \\ &= 1 - \int_{-1}^0 \int_{x+1}^{1-x^2} \frac{5}{4}(x^2 + y) dy dx = \frac{13}{16}. \end{aligned}$$

- (d) The probability that  $(X, Y)$  will lie on the curve  $y = x^2$  is 0 for every continuous joint distribution.  
6. (a) The region  $S$  is the shaded region in Fig. S.3.22. Since the area of  $S$  is 2, and the joint p.d.f. is to

Figure S.3.22: Figure for Exercise 6a of Sec. 3.4.

be constant over  $S$ , then the value of the constant must be  $1/2$ .

- (b) The probability that  $(X, Y)$  will belong to any subset  $S_0$  is proportional to the area of that subset. Therefore,
- $$\Pr[(X, Y) \in S_0] = \int_{S_0} \int \frac{1}{2} dx dy = \frac{1}{2}(\text{area of } S_0) = \frac{\alpha}{2}.$$
7. (a)  $\Pr(X \leq 1/4)$  will be equal to the sum of the probabilities of the corners  $(0, 0)$  and  $(0, 1)$  and the probability that the point is an interior point of the square and lies in the shaded region in Fig. S.3.23. The probability that the point will be an interior point of the square rather than one

Figure S.3.23: Figure for Exercise 7a of Sec. 3.4.

of the four corners is  $1 - (0.1 + 0.2 + 0.4 + 0.1) = 0.2$ . The probability that it will lie in the shaded region, given that it is an interior point is  $1/4$ . Therefore,

$$\Pr\left(X \leq \frac{1}{4}\right) = 0.1 + 0.4 + (0.2)\left(\frac{1}{4}\right) = 0.55.$$

- (b) The region over which to integrate is shaded in Fig. S.3.24.

Figure S.3.24: Figure for Exercise 7b of Sec. 3.4.

$$\Pr(X + Y \leq 1) = 0.1 + 0.2 + 0.4 + (0.2)\left(\frac{1}{2}\right) = 0.8.$$

8. (a) Since the joint c.d.f. is continuous and is twice-differentiable in the given rectangle, the joint distribution of  $X$  and  $Y$  is continuous. Therefore,

$$\begin{aligned} \Pr(1 \leq X \leq 2 \text{ and } 1 \leq Y \leq 2) &= \Pr(1 < X \leq 2 \text{ and } 1 < Y \leq 2) = \\ F(2, 2) - F(1, 2) - F(2, 1) + F(1, 1) &= \frac{24}{156} - \frac{6}{156} - \frac{10}{156} + \frac{2}{156} = \frac{5}{78} \end{aligned}$$

- (b)

$$\begin{aligned} \Pr(2 \leq X \leq 4 \text{ and } 2 \leq Y \leq 4) &= \Pr(2 \leq X \leq 3 \text{ and } 2 \leq Y \leq 4) \\ &= F(3, 4) - F(2, 4) - F(3, 2) + F(2, 2) \\ &= 1 - \frac{64}{156} - \frac{66}{156} + \frac{24}{156} = \frac{25}{78}. \end{aligned}$$

- (c) Since  $y$  must lie in the interval  $0 \leq y \leq 4$ ,  $F_2(y) = 0$  for  $y < 0$  and  $F_2(y) = 1$  for  $y > 4$ . For  $0 \leq y \leq 4$ ,

$$F_2(y) = \lim_{x \rightarrow \infty} F(x, y) = \lim_{x \rightarrow 3} \frac{1}{156} xy(x^2 + y) = \frac{1}{52} y(9 + y).$$

- (d) We have  $f(x, y) = 0$  unless  $0 \leq x \leq 3$  and  $0 \leq y \leq 4$ . In this rectangle we have

$$f(x, y) = \frac{\partial^2 F(x, y)}{\partial x \partial y} = \frac{1}{156}(3x^2 + 2y).$$

- (e) The region over which to integrate is shaded in Fig. S.3.25.

$$\Pr(Y \leq X) = \iint_{\substack{\text{shaded} \\ \text{region}}} f(x, y) dx dy = \int_0^3 \int_0^x \frac{1}{156}(3x^2 + 2y) dy dx = \frac{93}{208}.$$

9. The joint p.d.f. of water demand  $X$  and electricity demand  $Y$  is in (3.4.2), and is repeated here:

$$f(x, y) = \begin{cases} 1/29204 & \text{if } 4 \leq x \leq 200 \text{ and } 1 \leq y \leq 150, \\ 0 & \text{otherwise.} \end{cases}$$

Figure S.3.25: Figure for Exercise 8e of Sec. 3.4.

We need to integrate this function over the set where  $x > y$ . That region can be written as  $\{(x, y) : 4 < x < 200, 1 < y < \min\{x, 150\}\}$ . The reason for the complicated upper limit on  $y$  is that we require both  $y < x$  and  $y < 150$ .

$$\begin{aligned} \int_4^{200} \int_1^{\min\{x, 150\}} \frac{1}{29204} dy dx &= \int_4^{200} \frac{\min\{x-1, 149\}}{29204} dx \\ &= \int_4^{150} \frac{x-1}{29204} dx + \int_{150}^{200} \frac{149}{29204} dx \\ &= \left. \frac{(x-1)^2}{2 \times 29204} \right|_{x=4}^{150} + \frac{50 \times 149}{29204} \\ &= \frac{149^2 - 3^2}{58408} + \frac{7450}{29204} = 0.63505. \end{aligned}$$

10. (a) The sum of  $f(x, y)$  over all  $x$  for each fixed  $y$  is

$$\exp(-3y) \sum_{x=0}^{\infty} \frac{(2y)^2}{x!} = \exp(-3y) \exp(2y) = \exp(-y),$$

where the first equality follows from the power series expansion of  $\exp(2y)$ . The integral of the resulting sum is easily calculated to be 1.

- (b) We can compute  $\Pr(X = 0)$  by integrating  $f(0, y)$  over all  $y$ :

$$\Pr(X = 0) = \int_0^{\infty} \frac{(2y)^0}{0!} \exp(-3y) dy = \frac{1}{3}.$$

11. Let  $f(x, y)$  stand for the joint p.f. in Table 3.3 in the text for  $x = 0, 1$  and  $y = 1, 2, 3, 4$ .

- (a) We are asked for the probability for the set  $\{Y \in \{2, 3\}\} \cap \{X = 1\}$ , which is  $f(1, 2) + f(1, 3) = 0.166 + 0.107 = 0.273$ .  
(b) This time, we want  $\Pr(X = 0) = f(0, 1) + f(0, 2) + f(0, 3) + f(0, 4) = 0.513$ .

## 3.5 Marginal Distributions

### Commentary

Students can get confused when solving problems like Exercises 7 and 8 in this section. They notice that the functional form of  $f(x, y)$  factors into  $g_1(x)g_2(y)$  for those  $(x, y)$  pairs such that  $f(x, y) > 0$ , but they don't understand that the factorization needs to hold even for those  $(x, y)$  pairs such that  $f(x, y) = 0$ . When the

two marginal p.d.f.'s are both strictly positive on intervals, then the set of  $(x, y)$  pairs where  $f_1(x)f_2(y) > 0$  must be a rectangle (with sides parallel to the coordinate axes), even if the rectangle is infinite in one or more directions. Hence, it is a *necessary* condition for independence that the set of  $(x, y)$  pairs such that  $f(x, y) > 0$  be a rectangle with sides parallel to the coordinate axes. Of course, it is also necessary that  $f(x, y) = g_1(x)g_2(y)$  for those  $(x, y)$  such that  $f(x, y) > 0$ . The two necessary conditions together are sufficient to insure independence, but neither is sufficient alone. See the solution to Exercise 8 below for an illustration of how to illustrate that point.

### Solutions to Exercises

- The joint p.d.f. is constant over a rectangle with sides parallel to the coordinate axes. So, for each  $x$ , the integral over  $y$  will equal the constant times the length of the interval of  $y$  values, namely  $d - c$ . Similarly, for each  $y$ , the integral over  $x$  will equal the constant times the length of the interval of  $x$  values, namely  $b - a$ . Of course the constant  $k$  must equal one over the area of the rectangle. So  $k = 1/[(b - a)(d - c)]$ . So the marginal p.d.f.'s of  $X$  and  $Y$  are

$$f_1(x) = \begin{cases} \frac{1}{b-a} & \text{for } a \leq x \leq b, \\ 0 & \text{otherwise,} \end{cases}$$

$$f_2(y) = \begin{cases} \frac{1}{d-c} & \text{for } c \leq y \leq d, \\ 0 & \text{otherwise.} \end{cases}$$

- (a) For  $x = 0, 1, 2$ , we have

$$f_1(x) = \sum_{y=0}^3 f(x, y) = \frac{1}{30}(4x + 6) = \frac{1}{15}(2x + 3).$$

Similarly, for  $y = 0, 1, 2, 3$ , we have

$$f_2(y) = \sum_{x=0}^2 f(x, y) = \frac{1}{30}(3 + 3y) = \frac{1}{10}(1 + y).$$

- (b)  $X$  and  $Y$  are not independent because it is not true that  $f(x, y) = f_1(x)f_2(y)$  for all possible values of  $x$  and  $y$ .

- (a) For  $0 \leq x \leq 2$ , we have

$$f_1(x) = \int_0^1 f(x, y) dy = \frac{1}{2}.$$

Also,  $f_1(x) = 0$  for  $x$  outside the interval  $0 \leq x \leq 2$ . Similarly, for  $0 \leq y \leq 1$ ,

$$f_2(y) = \int_0^2 f(x, y) dx = 3y^2.$$

Also,  $f_2(y) = 0$  for  $y$  outside the interval  $0 \leq y \leq 1$ .

- (b)  $X$  and  $Y$  are independent because  $f(x, y) = f_1(x)f_2(y)$  for  $-\infty < x < \infty$  and  $-\infty < y < \infty$ .
- (c) We have

$$\Pr\left(X < 1 \text{ and } Y \geq \frac{1}{2}\right) = \int_0^1 \int_{1/2}^1 f(x, y) dx dy$$

$$\begin{aligned}
&= \int_0^1 \int_{1/2}^1 f_1(x) f_2(y) dx dy \\
&= \int_0^1 f_1(x) dx \int_{1/2}^1 f_2(y) dy = \Pr(X < 1) \Pr\left(Y > \frac{1}{2}\right).
\end{aligned}$$

Therefore, by the definition of the independence of two events (Definition 2.2.1), the two given events are independent.

We can also reach this answer, without carrying out the above calculation, by reasoning as follows: Since the random variables  $X$  and  $Y$  are independent, and since the occurrence or nonoccurrence of the event  $\{X < 1\}$  depends on the value of  $X$  only while the occurrence or nonoccurrence of the event  $\{Y \geq 1/2\}$  depends on the value of  $Y$  only, it follows that these two events must be independent.

4. (a) The region where  $f(x, y)$  is non-zero is the shaded region in Fig. S.3.26. It can be seen that the

Figure S.3.26: Figure for Exercise 4a of Sec. 3.5.

possible values of  $X$  are confined to the interval  $-1 \leq X \leq 1$ . Hence,  $f_1(x) = 0$  for values of  $x$  outside this interval. For  $-1 \leq x \leq 1$ , we have

$$f_1(x) = \int_0^{1-x^2} f(x, y) dy = \frac{15}{4}x^2(1-x^2).$$

Similarly, it can be seen from the sketch that the possible values of  $Y$  are confined to the interval  $0 \leq Y \leq 1$ . Hence,  $f_2(y) = 0$  for values of  $y$  outside this interval. For  $0 \leq y \leq 1$ , we have

$$f_2(y) = \int_{-(1-y)^{1/2}}^{(1-y)^{1/2}} f(x, y) dx = \frac{5}{2}(1-y)^{3/2}.$$

- (b)  $X$  and  $Y$  are not independent because  $f(x, y) \neq f_1(x)f_2(y)$ .

5. (a) Since  $X$  and  $Y$  are independent,

$$f(x, y) = \Pr(X = x \text{ and } Y = y) = \Pr(X = x) \Pr(Y = y) = p_x p_y.$$

$$(b) \Pr(X = Y) = \sum_{i=0}^3 f(i, i) = \sum_{i=0}^3 p_i^2 = 0.3.$$

$$(c) \Pr(X > Y) = f(1, 0) + f(2, 0) + f(3, 0) + f(2, 1) + f(3, 1) + f(3, 2) = 0.35.$$

6. (a) Since  $X$  and  $Y$  are independent

$$f(x, y) = f_1(x) f_2(y) = g(x)g(y) = \begin{cases} \frac{9}{64}x^2y^2 & \text{for } 0 \leq x \leq 2, 0 \leq y \leq 2 \\ 0 & \text{otherwise.} \end{cases}$$

- (b) Since  $X$  and  $Y$  have a continuous joint distribution,  $\Pr(X = Y) = 0$ .

(c) Since  $X$  and  $Y$  are independent random variables with the same probability distribution, it must be true that  $\Pr(X > Y) = \Pr(Y > X)$ . Since  $\Pr(X = Y) = 0$ , it therefore follows that  $\Pr(X > Y) = 1/2$ .

(d)  $\Pr(X + Y \leq 1) = \Pr(\text{shaded region in sketch})$

$$= \int_0^1 \int_0^{1-y} f(x, y) dx dy = \frac{1}{1280}.$$

Figure S.3.27: Figure for Exercise 6d of Sec. 3.5.

7. Since  $f(x, y) = 0$  outside a rectangle and  $f(x, y)$  can be factored as in Eq. (3.5.7) inside the rectangle (use  $h_1(x) = 2x$  and  $h_2(y) = \exp(-y)$ ), it follows that  $X$  and  $Y$  are independent.
8. Although  $f(x, y)$  can be factored as in Eq. (3.5.7) inside the triangle where  $f(x, y) > 0$ , the fact that  $f(x, y) > 0$  inside a triangle, rather than a rectangle, implies that  $X$  and  $Y$  cannot be independent. (Note that  $y \geq 0$  should have appeared as part of the condition for  $f(x, y) > 0$  in the statement of the exercise.) For example, to factor  $f(x, y)$  as in Eq. (3.5.7) we write  $f(x, y) = g_1(x)g_2(y)$ . Since  $f(1/3, 1/4) = 2$  and  $f(1/6, 3/4) = 3$ , it must be that  $g_1(1/3) > 0$  and  $g_2(3/4) > 0$ . However, since  $f(1/3, 3/4) = 0$ , it must be that either  $g_1(1/3) = 0$  or  $g_2(3/4) = 0$ . These facts contradict each other, hence  $f$  cannot have a factorization as in (3.5.7).
9. (a) Since  $f(x, y)$  is constant over the rectangle  $S$  and the area of  $S$  is 6 units, it follows that  $f(x, y) = 1/6$  inside  $S$  and  $f(x, y) = 0$  outside  $S$ . Next, for  $0 \leq x \leq 2$ ,

$$f_1(x) = \int_{-\infty}^{\infty} f(x, y) dy = \int_1^4 \frac{1}{6} dy = \frac{1}{2}.$$

Also,  $f_1(x) = 0$  otherwise. Similarly, for  $1 \leq y \leq 4$ ,

$$f_2(y) = \int_0^2 \frac{1}{6} dx = \frac{1}{3}.$$

Also,  $f_2(y) = 0$  otherwise. Thus, the marginal distribution of both  $X$  and  $Y$  are uniform distributions.

- (b) Since  $f(x, y) = f_1(x)f_2(y)$  for all values of  $x$  and  $y$ , it follows that  $X$  and  $Y$  are independent.
10. (a)  $f(x, y)$  is constant over the circle  $S$  in Fig. S.3.28. The area of  $S$  is  $\pi$  units, and it follows that  $f(x, y) = 1/\pi$  inside  $S$  and  $f(x, y) = 0$  outside  $S$ . Next, the possible values of  $x$  range from  $-1$  to  $1$ . For any value of  $x$  in this interval,  $f(x, y) > 0$  only for values of  $y$  between  $-(1 - x^2)^{1/2}$  and  $(1 - x^2)^{1/2}$ . Hence, for  $-1 \leq x \leq 1$ ,

$$f_1(x) = \int_{-(1-x^2)^{1/2}}^{(1-x^2)^{1/2}} \frac{1}{\pi} dy = \frac{2}{\pi}(1 - x^2)^{1/2}.$$

Also,  $f_1(x) = 0$  otherwise. By symmetry, the random variable  $Y$  will have the same marginal p.d.f. as  $X$ .

Figure S.3.28: Figure for Exercise 10 of Sec. 3.5.

- (b) Since  $f(x, y) \neq f_1(x)f_2(y)$ ,  $X$  and  $Y$  are not independent.

The conclusions found in this exercise in which  $X$  and  $Y$  have a uniform distribution over a circle should be contrasted with the conclusions found in Exercise 9, in which  $X$  and  $Y$  had a uniform distribution over a rectangle with sides parallel to the axes.

11. Let  $X$  and  $Y$  denote the arrival times of the two persons, measured in terms of the number of minutes after 5 P.M. Then  $X$  and  $Y$  each have the uniform distribution on the interval  $(0, 60)$  and they are independent. Therefore, the joint p.d.f. of  $X$  and  $Y$  is

$$f(x, y) = \begin{cases} \frac{1}{3600} & \text{for } 0 < x < 60, 0 < y < 60, \\ 0 & \text{otherwise.} \end{cases}$$

We must calculate  $\Pr(|X - Y| < 10)$ , which is equal to the probability that the point  $(X, Y)$  lies in the shaded region in Fig. S.3.29. Since the joint p.d.f. of  $X$  and  $Y$  is constant over the entire square, this

Figure S.3.29: Figure for Exercise 11 of Sec. 3.5.

probability is equal to (area of shaded region)/3600. The area of the shaded region is 1100. Therefore, the required probability is  $1100/3600 = 11/36$ .

12. Let the rectangular region be  $R = \{(x, y) : x_0 < x < x_1, y_0 < y < y_1\}$  with  $x_0$  and/or  $y_0$  possibly  $-\infty$  and  $x_1$  and/or  $y_1$  possibly  $\infty$ . For the “if” direction, assume that  $f(x, y) = h_1(x)h_2(y)$  for all  $(x, y)$  that satisfy  $f(x, y) > 0$ . Then define

$$h_1^*(x) = \begin{cases} h_1(x) & \text{if } x_0 < x < x_1, \\ 0 & \text{otherwise.} \end{cases}$$

$$h_2^*(y) = \begin{cases} h_2(y) & \text{if } y_0 < y < y_1, \\ 0 & \text{otherwise.} \end{cases}$$

Then  $h_1^*(x)h_2^*(y) = h_1(x)h_2(y) = f(x, y)$  for all  $(x, y) \in R$  and  $h_1^*(x)h_2^*(y) = 0 = f(x, y)$  for all  $(x, y) \notin R$ . Hence  $f(x, y) = h_1^*(x)h_2^*(y)$  for all  $(x, y)$ , and  $X$  and  $Y$  are independent.

For the “only if” direction, assume that  $X$  and  $Y$  are independent. According to Theorem 3.5.5,  $f(x, y) = h_1(x)h_2(y)$  for all  $(x, y)$ . Then  $f(x, y) = h_1(x)h_2(y)$  for all  $(x, y) \in R$ .

13. Since  $f(x, y) = f(y, x)$  for all  $(x, y)$ , it follows that the marginal p.d.f.’s will be the same. Each of those marginals will equal the integral of  $f(x, y)$  over the other variable. For example, to find  $f_1(x)$ , note that for each  $x$ , the values of  $y$  such that  $f(x, y) > 0$  form the interval  $[-\sqrt{1-x^2}, \sqrt{1-x^2}]$ . Then, for  $-1 \leq x \leq 1$ ,

$$\begin{aligned} f_1(x) &= \int f(x, y) dy \\ &= \int_{-\sqrt{1-x^2}}^{\sqrt{1-x^2}} kx^2 y^2 dy \\ &= kx^2 \frac{y^3}{3} \Big|_{y=-\sqrt{1-x^2}}^{\sqrt{1-x^2}} \\ &= 2kx^2(1-x^2)^{3/2}/3. \end{aligned}$$

14. The set in Fig. 3.12 is not rectangular, so  $X$  and  $Y$  are *not* independent.
15. (a) Figure S.3.30 shows the region where  $f(x, y) > 0$  as the union of two shaded rectangles. Although the region is not a rectangle, it is a *product set*. That is, it has the form  $\{(x, y) : x \in A, y \in B\}$  for two sets  $A$  and  $B$  of real numbers.

Figure S.3.30: Region of positive p.d.f. for Exercise 15a of Sec. 3.5.

(b) The marginal p.d.f. of  $X$  is

$$f_1(x) = \int_0^1 f(x, y) dy = \begin{cases} \frac{1}{3} & \text{if } 1 < x < 3, \\ \frac{1}{6} & \text{if } 6 < x < 8. \end{cases}$$

The marginal p.d.f. of  $Y$  is

$$f_2(y) = \int_1^3 \frac{1}{3} dx + \int_6^8 \frac{1}{6} dx = 1,$$

for  $0 < y < 1$ . The distribution of  $Y$  is the uniform distribution on the interval  $[0, 1]$ .

(c) The product of the two marginal p.d.f.'s is

$$f_1(x)f_2(y) = \begin{cases} \frac{1}{3} & \text{if } 1 < x < 3 \text{ and } 0 < y < 1, \\ \frac{1}{6} & \text{if } 6 < x < 8 \text{ and } 0 < y < 1, \\ 0 & \text{otherwise,} \end{cases}$$

which is the same as  $f(x, y)$ , hence the two random variables are independent. Although the region where  $f(x, y) > 0$  is not a rectangle, it is a product set as we saw in part (a). Although it is sufficient in Theorem 3.5.6 for the region where  $f(x, y) > 0$  to be a rectangle, it is necessary that the region be a product set. Technically, it is necessary that there is a version of the p.d.f. that is strictly positive on a product set. For continuous joint distributions, one can set the p.d.f. to arbitrary values on arbitrary one-dimensional curves without changing it's being a joint p.d.f.

## 3.6 Conditional Distributions

### Commentary

When introducing conditional distributions given continuous random variables, it is important to stress that we are not conditioning on a set of 0 probability, even if the popular notation makes it appear that way. The note on page 146 can be helpful for students who understand two-variable calculus. Also, Exercise 25 in Sec. 3.11 can provide additional motivation for the idea that the conditional distribution of  $X$  given  $Y = y$  is really a surrogate for the conditional distribution of  $X$  given that  $Y$  is close to  $y$ , but we don't wish to say precisely how close. Exercise 26 in Sec. 3.11 (the Borel paradox) brings home the point that conditional distributions really are not conditional on the probability 0 events such as  $\{Y = y\}$ .

Also, it is useful to stress that conditional distributions behave just like distributions. In particular, conditional probabilities can be calculated from conditional p.f.'s and conditional p.d.f.'s in the same way that probabilities are calculated from p.f.'s and p.d.f.'s. Also, be sure to advertise that all future concepts and theorems will have conditional versions that behave just like the marginal versions.

### Solutions to Exercises

- We begin by finding the marginal p.d.f. of  $Y$ . The set of  $x$  values for which  $f(x, y) > 0$  is the interval  $[-(1 - y^2)^{1/2}, (1 - y^2)^{1/2}]$ . So, the marginal p.d.f. of  $Y$  is, for  $-1 \leq y \leq 1$ ,

$$f_2(y) = \int_{-(1-y^2)^{1/2}}^{(1-y^2)^{1/2}} kx^2y^2 dx = \frac{ky^2}{3}x^3 \Big|_{x=-(1-y^2)^{1/2}}^{(1-y^2)^{1/2}} = \frac{2k}{3}y^2(1-y^2)^{3/2},$$

and 0 otherwise. The conditional p.d.f. of  $X$  given  $Y = y$  is the ratio of the joint p.d.f. to the marginal p.d.f. just found.

$$g_1(x|y) = \begin{cases} \frac{3x^2}{2(1-y^2)^{3/2}} & \text{for } -(1-y^2)^{1/2} \leq x \leq (1-y^2)^{1/2}, \\ 0 & \text{otherwise.} \end{cases}$$

2. (a) We have  $\Pr(\text{Junior}) = 0.04 + 0.20 + 0.09 = 0.33$ . Therefore,

$$\Pr(\text{Never} \mid \text{Junior}) = \frac{\Pr(\text{Junior and Never})}{\Pr(\text{Junior})} = \frac{0.04}{0.33} = \frac{4}{33}.$$

- (b) The only way we can use the fact that a student visited the museum three times is to classify the student as having visited more than once. We have

$$\Pr(\text{More than once}) = 0.04 + 0.04 + 0.09 + 0.10 = 0.27.$$

Therefore,

$$\begin{aligned}\Pr(\text{Senior} \mid \text{More than once}) &= \frac{\Pr(\text{Senior and More than once})}{\Pr(\text{More than once})} \\ &= \frac{0.10}{0.27} = \frac{10}{27}.\end{aligned}$$

3. The joint p.d.f. of  $X$  and  $Y$  is positive for all points inside the circle  $S$  shown in the sketch. Since the area of  $S$  is  $9\pi$  and the joint p.d.f. of  $X$  and  $Y$  is constant over  $S$ , this joint p.d.f. must have the form:

$$f(x, y) = \begin{cases} \frac{1}{9\pi} & \text{for } (x, y) \in S, \\ 0 & \text{otherwise.} \end{cases}$$

Figure S.3.31: Figure for Exercise 3 of Sec. 3.6.

It can be seen from Fig. S.3.31 that the possible values of  $X$  lie between  $-2$  and  $4$ . Therefore, for  $-2 < x < 4$ ,

$$f_1(x) = \int_{-2-[9-(x-1)^2]^{1/2}}^{-2+[9-(x-1)^2]^{1/2}} \frac{1}{9\pi} dy = \frac{2}{9\pi}[9 - (x - 1)^2]^{1/2}.$$

- (a) It follows that for  $-2 < x < 4$  and  $-2 - [9 - (x - 1)^2]^{1/2} < y < -2 + [9 - (x - 1)^2]^{1/2}$ ,

$$g_2(y \mid x) = \frac{f(x, y)}{f_1(x)} = \frac{1}{2}[9 - (x - 1)^2]^{-1/2}.$$

- (b) When  $X = 2$ , it follows from part (a) that

$$g_2(y \mid x = 2) = \begin{cases} \frac{1}{2\sqrt{8}} & \text{for } -2 - \sqrt{8} < y < -2 + \sqrt{8} \\ 0 & \text{otherwise.} \end{cases}$$

Therefore,

$$\Pr(Y > 0 \mid X = 2) = \int_0^{-2+\sqrt{8}} g_2(y \mid x = 2) dy = \frac{-2 + \sqrt{8}}{2\sqrt{8}} = \frac{2 - \sqrt{2}}{4}.$$

4. (a) For  $0 \leq y \leq 1$ , the marginal p.d.f. of  $y$  is

$$f_2(y) = \int_0^1 f(x, y) dx = c \left( \frac{1}{2} + y^2 \right).$$

Therefore, for  $0 \leq x \leq 1$  and  $0 \leq y \leq 1$ , the conditional p.d.f. of  $X$  given that  $Y = y$  is

$$g_1(x \mid y) = \frac{f(x, y)}{f_2(y)} = \frac{x + y^2}{\frac{1}{2} + y^2}.$$

It should be noted that it was not necessary to evaluate the constant  $c$  in order to determine this conditional p.d.f.

- (b) When  $Y = 1/2$ , it follows from part (a) that

$$g_1\left(x \mid y = \frac{1}{2}\right) = \begin{cases} \frac{4}{3} \left(x + \frac{1}{4}\right) & \text{for } 0 \leq x \leq 1, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore,

$$\Pr\left(X < \frac{1}{2} \mid Y = \frac{1}{2}\right) = \int_0^{\frac{1}{2}} g_1\left(x \mid y = \frac{1}{2}\right) dx = \frac{1}{3}.$$

5. (a) The joint p.d.f.  $f(x, y)$  is given by Eq. (3.6.15) and the marginal p.d.f.  $f_2(y)$  was also given in Example 3.6.10. Hence, for  $0 < y < 1$  and  $0 < x < y$ , we have

$$g_1(x \mid y) = \frac{f(x, y)}{f_2(y)} = \frac{-1}{(1-x) \log(1-y)}.$$

- (b) When  $Y = 3/4$ , it follows from part (a) that

$$g_1\left(x \mid y = \frac{3}{4}\right) = \begin{cases} \frac{1}{(1-x) \log 4} & \text{for } 0 < x < \frac{3}{4}, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore,

$$\Pr\left(X > \frac{1}{2} \mid Y = \frac{3}{4}\right) = \int_{1/2}^{3/4} g_1\left(x \mid y = \frac{3}{4}\right) dx = \frac{\log 4 - \log 2}{\log 4} = \frac{1}{2}.$$

6. Since  $f(x, y) = 0$  outside a rectangle with sides parallel to the  $x$  and  $y$  axes and since  $f(x, y)$  can be factored as in Eq. (3.5.7), with  $g_1(x) = c \sin(x)$  and  $g_2(y) = 1$ , it follows that  $X$  and  $Y$  are independent random variables. Furthermore, for  $0 \leq y \leq 3$ , the marginal p.d.f.  $f_2(y)$  must be proportional to  $g_2(y)$ . In other words,  $f_2(y)$  must be constant for  $0 \leq y \leq 3$ . Hence,  $Y$  has the uniform distribution on the interval  $[0, 3]$  and

$$f_2(y) = \begin{cases} \frac{1}{3} & \text{for } 0 \leq y \leq 3, \\ 0 & \text{otherwise.} \end{cases}$$

- (a) Since  $X$  and  $Y$  are independent, the conditional p.d.f. of  $Y$  for any given value of  $X$  is the same as the marginal p.d.f.  $f_2(y)$ .

(b) Since  $X$  and  $Y$  are independent,

$$\Pr(1 < Y < 2 \mid X = 0.73) = \Pr(1 < Y < 2) = \int_1^2 f_2(y) dy = \frac{1}{3}.$$

7. The joint p.d.f. of  $X$  and  $Y$  is positive inside the triangle  $S$  shown in Fig. S.3.32. It is seen from Fig. S.3.32 that the possible values of  $X$  lie between 0 and 2. Hence, for  $0 < x < 2$ ,

Figure S.3.32: Figure for Exercise 7 of Sec. 3.6.

$$f_1(x) = \int_0^{4-2x} f(x, y) dy = \frac{3}{8}(x-2)^2.$$

(a) It follows that for  $0 < x < 2$  and  $0 < y < 4 - 2x$ ,

$$g_2(y \mid x) = \frac{f(x, y)}{f_1(x)} = \frac{4 - 2x - y}{2(x-2)^2}.$$

(b) When  $X = 1/2$ , it follows from part (a) that

$$g_2\left(y \mid x = \frac{1}{2}\right) = \begin{cases} \frac{2}{9}(3-y) & \text{for } 0 < y < 3, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore,

$$\Pr\left(Y \geq 2 \mid X = \frac{1}{2}\right) = \int_2^3 g_2\left(y \mid x = \frac{1}{2}\right) dy = \frac{1}{9}.$$

8. (a) The answer is

$$\int_0^1 \int_{0.8}^1 f(x, y) dx dy = 0.264.$$

(b) For  $0 \leq y \leq 1$ , the marginal p.d.f. of  $Y$  is

$$f_2(y) = \int_0^1 f(x, y) dx = \frac{2}{5}(1+3y).$$

Hence, for  $0 \leq x \leq 1$  and  $0 \leq y \leq 1$ ,

$$g_1(x \mid y) = \frac{2x+3y}{1+3y}.$$

When  $Y = 0.3$ , it follows that

$$g_1(x \mid y = 0.3) = \frac{2x+0.9}{1.9} \quad \text{for } 0 \leq x \leq 1.$$

Hence,

$$\Pr(X > 0.8 | Y = 0.3) = \int_{0.8}^1 g_1(x | y = 0.3) dx = 0.284.$$

(c) For  $0 \leq x \leq 1$ , the marginal p.d.f. of  $X$  is

$$f_1(x) = \int_0^1 f(x, y) dy = \frac{2}{5} \left( 2x + \frac{3}{2} \right).$$

Hence, for  $0 \leq x \leq 1$  and  $0 \leq y \leq 1$ ,

$$g_2(y | x) = \frac{2x + 3y}{2x + \frac{3}{2}}.$$

When  $X = 0.3$ , it follows that

$$g_2(y | x = 0.3) = \frac{0.6 + 3y}{2.1} \quad \text{for } 0 \leq y \leq 1.$$

Hence,

$$\Pr(Y > 0.8 | X = 0.3) = \int_{0.8}^1 g_2(y | x = 0.3) dy = 0.314.$$

9. Let  $Y$  denote the instrument that is chosen. Then  $\Pr(Y = 1) = \Pr(Y = 2) = 1/2$ . In this exercise the distribution of  $X$  is continuous and the distribution of  $Y$  is discrete. Hence, the joint distribution of  $X$  and  $Y$  is a mixed distribution, as described in Sec. 3.4. In this case, the joint p.f./p.d.f. of  $X$  and  $Y$  is as follows:

$$f(x, y) = \begin{cases} \frac{1}{2} \cdot 2x = x & \text{for } y = 1 \text{ and } 0 < x < 1, \\ \frac{1}{2} \cdot 3x^2 = \frac{3}{2}x^2 & \text{for } y = 2 \text{ and } 0 < x < 1, \\ 0 & \text{otherwise.} \end{cases}$$

- (a) It follows that for  $0 < x < 1$ ,

$$f_1(x) = \sum_{y=1}^2 f(x, y) = x + \frac{3}{2}x^2,$$

and  $f_1(x) = 0$  otherwise.

- (b) For  $y = 1, 2$  and  $0 < x < 1$ , we have

$$\Pr(Y = y | X = x) = g_2(y | x) = \frac{f(x, y)}{f_1(x)}.$$

Hence,

$$\Pr\left(Y = 1 | X = \frac{1}{4}\right) = \frac{f\left(\frac{1}{4}, 1\right)}{f_1\left(\frac{1}{4}\right)} = \frac{\frac{1}{4}}{\frac{1}{4} + \frac{3}{2} \cdot \frac{1}{16}} = \frac{8}{11}.$$

10. Let  $Y = 1$  if a head is obtained when the coin is tossed and let  $Y = 0$  if a tail is obtained. Then  $\Pr(Y = 1 | X = x) = x$  and  $\Pr(Y = 0 | X = x) = 1 - x$ . In this exercise, the distribution of  $X$  is

continuous and the distribution of  $Y$  is discrete. Hence, the joint distribution of  $X$  and  $Y$  is a mixed distribution as described in Sec. 3.4. The conditional p.f. of  $Y$  given that  $X = x$  is

$$g_2(y|x) = \begin{cases} x & \text{for } y = 1, \\ 1-x & \text{for } y = 0, \\ 0 & \text{otherwise.} \end{cases}$$

The marginal p.d.f.  $f_1(x)$  of  $X$  is given in the exercise, and the joint p.f./p.d.f. of  $X$  and  $Y$  is  $f(x,y) = f_1(x)g_2(y|x)$ . Thus, we have

$$f(x,y) = \begin{cases} 6x^2(1-x) & \text{for } 0 < x < 1 \text{ and } y = 1, \\ 6x(1-x)^2 & \text{for } 0 < x < 1 \text{ and } y = 0, \\ 0 & \text{otherwise.} \end{cases}$$

Furthermore, for  $y = 0, 1$ ,

$$\Pr(Y = y) = f_2(y) = \int_0^1 f(x,y) dx.$$

Hence,

$$\Pr(Y = 1) = \int_0^1 6x^2(1-x) dx = \int_0^1 (6x^2 - 6x^3) dx = \frac{1}{2}.$$

(This result could also have been derived by noting that the p.d.f.  $f_1(x)$  is symmetric about the point  $x = 1/2$ .)

It now follows that the conditional p.d.f. of  $X$  given that  $Y = 1$  is, for  $0 < x < 1$ ,

$$g_1(x|y=1) = \frac{f(x,1)}{\Pr(Y=1)} = \frac{6x^2(1-x)}{1/2} = 12x^2(1-x).$$

11. Let  $F_2$  be the c.d.f. of  $Y$ . Since  $f_2$  is continuous at both  $y_0$  and  $y_1$ , we can write, for  $i = 0, 1$ ,

$$\Pr(Y \in A_i) = F_2(y_i + \epsilon) - F_2(y_i - \epsilon) = 2\epsilon f_2(y'_i),$$

where  $y'_i$  is within  $\epsilon$  of  $y_i$ . This last equation follows from the mean value theorem of calculus. So

$$\frac{\Pr(Y \in A_0)}{\Pr(Y \in A_1)} = \frac{f_2(y'_0)}{f_2(y'_1)}. \quad (\text{S.3.1})$$

Since  $f_2$  is continuous,  $\lim_{\epsilon \rightarrow 0} f_2(y'_i) = f_2(y_i)$ , and the limit of (S.3.1) is  $0/f_2(y_1) = 0$ .

12. (a) The joint p.f./p.d.f. of  $X$  and  $Y$  is the product  $f_2(y)g_1(x|y)$ .

$$f(x,y) = \begin{cases} (2y)^x \exp(-3y)/x! & \text{if } y > 0 \text{ and } x = 0, 1, \dots, \\ 0 & \text{otherwise.} \end{cases}$$

The marginal p.f. of  $X$  is obtained by integrating over  $y$ .

$$f_1(x) = \int_0^\infty \frac{(2y)^x}{x!} \exp(-3y) dy = \frac{1}{3} \left(\frac{2}{3}\right)^x,$$

for  $x = 0, 1, \dots$

- (b) The conditional p.d.f. of  $Y$  given  $X = 0$  is the ratio of the joint p.f./p.d.f. to  $f_1(0)$ .

$$g_2(y|0) = \frac{(2y)^0 \exp(-3y)/0!}{(1/3)(2/3)^0} = 3 \exp(-3y),$$

for  $y > 0$ .

- (c) The conditional p.d.f. of  $Y$  given  $X = 1$  is the ratio of the joint p.f./p.d.f. to  $f_1(1)$ .

$$g_2(y|1) = \frac{(2y)^1 \exp(-3y)/1!}{(1/3)(2/3)^1} = 9y \exp(-3y),$$

for  $y > 0$ .

- (d) The ratio of the two conditional p.d.f.'s is

$$\frac{g_2(y|1)}{g_2(y|0)} = \frac{9y \exp(-3y)}{3 \exp(-3y)} = 3y.$$

The ratio is greater than 1 if  $y > 1/3$ . This corresponds to the intuition that if we observe more calls, then we should think the rate is higher.

13. There are four different treatments on which we are asked to condition. The marginal p.f. of treatment  $Y$  is given in the bottom row of Table 3.6 in the text. The conditional p.f. of response given each treatment is the ratio of the two rows above that to the bottom row:

$$\begin{aligned} g_1(x|1) &= \begin{cases} \frac{0.120}{0.267} = 0.4494 & \text{if } x = 0, \\ \frac{0.147}{0.267} = 0.5506 & \text{if } x = 1. \end{cases} \\ g_1(x|2) &= \begin{cases} \frac{0.087}{0.253} = 0.3439 & \text{if } x = 0, \\ \frac{0.166}{0.253} = 0.6561 & \text{if } x = 1. \end{cases} \\ g_1(x|3) &= \begin{cases} \frac{0.146}{0.253} = 0.5771 & \text{if } x = 0, \\ \frac{0.107}{0.253} = 0.4229 & \text{if } x = 1. \end{cases} \\ g_1(x|4) &= \begin{cases} \frac{0.160}{0.227} = 0.7048 & \text{if } x = 0, \\ \frac{0.067}{0.227} = 0.2952 & \text{if } x = 1. \end{cases} \end{aligned}$$

The fourth one looks quite different from the others, especially from the second.

## 3.7 Multivariate Distributions

### Commentary

The material around Definition 3.7.8 and Example 3.7.8 reintroduces the concept of conditionally independent random variables. This concept is important in Bayesian inference, but outside of Bayesian inference, it generally appears only in more advanced applications such as expert systems and latent variable models. If an instructor is going to forego all discussion of Bayesian inference then this material (and Exercises 13 and 14) could be skipped.

### Solutions to Exercises

1. (a) We have

$$\int_0^1 \int_0^1 \int_0^1 f(x_1, d_2, x_3) dx_1 dx_2 dx_3 = 3c.$$

Since the value of this integral must be equal to 1, it follows that  $c = 1/3$ .

- (b) For  $0 \leq x_1 \leq 1$  and  $0 \leq x_3 \leq 1$ ,

$$f_{13}(x_1, x_3) = \int_0^1 f(x_1, x_2, x_3) dx_2 = \frac{1}{3} (x_1 + 1 + 3x_3).$$

- (c) The conditional p.d.f. of  $x_3$  given that  $x_1 = 1/4$  and  $x_2 = 3/4$  is, for  $0 \leq x_3 \leq 1$ ,

$$g_3\left(x_3 \mid x_1 = \frac{1}{4}, x_2 = \frac{3}{4}\right) = \frac{f\left(\frac{1}{4}, \frac{3}{4}, x_3\right)}{f_{12}\left(\frac{1}{4}, \frac{3}{4}\right)} = \frac{7}{13} + \frac{12}{13}x_3.$$

Therefore,

$$\Pr\left(X_3 < \frac{1}{2} \mid X_1 = \frac{1}{4}, X_2 = \frac{3}{4}\right) = \int_0^{\frac{1}{2}} \left(\frac{7}{13} + \frac{12}{13}x_3\right) dx_3 = \frac{5}{13}.$$

2. (a) First, integrate over  $x_1$ . We need to compute  $\int_0^1 cx_1^{1+x_2+x_3}(1-x_1)^{3-x_2-x_3}dx_1$ . The two exponents always add to 4 and each is always at least 1. So the possible pairs of exponents are (1, 3), (2, 2), and (3, 1). By the symmetry of the function, the first and last will give the same value of the integral. In this case, the values are

$$\int_0^1 c[x_1^3 - x_1^4]dx_1 = \frac{c}{4} - \frac{c}{5} = \frac{c}{20}. \quad (\text{S.3.2})$$

In the other case, the integral is

$$\int_0^1 c[x_1^2 - 2x_1^3 + x_1^4]dx_1 = \frac{c}{3} - \frac{2c}{4} + \frac{c}{5} = \frac{c}{30}. \quad (\text{S.3.3})$$

Finally, sum over the possible  $(x_2, x_3)$  pairs. The mapping between  $(x_2, x_3)$  values and the exponents in the integral is as follows:

$(x_2, x_3)$	Exponents
(0, 0)	(1, 3)
(0, 1)	(2, 2)
(1, 0)	(2, 2)
(1, 1)	(3, 1)

Summing over the four possible  $(x_2, x_3)$  pairs gives the sum of  $c/6$ , so  $c = 6$ .

- (b) The marginal joint p.f. of  $(X_2, X_3)$  is given by setting  $c = 6$  in (S.3.2) and (S.3.3) and using the above table.

$$f_{23}(x_2, x_3) = \begin{cases} 0.3 & \text{if } (x_2, x_3) \in \{(0, 0), (1, 1)\}, \\ 0.2 & \text{if } (x_2, x_3) \in \{(1, 0), (0, 1)\}. \end{cases}$$

- (c) The conditional p.d.f. of  $X_1$  given  $X_2 = 1$  and  $X_3 = 1$  is  $1/0.3$  times the joint p.f./p.d.f. evaluated at  $x_2 = x_3 = 1$ :

$$g_1(x_1|1, 1) = \begin{cases} 20x_1^3(1-x_1) & \text{if } 0 < x_1 < 1, \\ 0 & \text{otherwise.} \end{cases}$$

3. The p.d.f. should be positive for all  $x_i > 0$  not just for all  $x_i > 1$  as stated in early printings. This will match the answers in the back of the text.

(a) We have

$$\int_0^\infty \int_0^\infty \int_0^\infty f(x_1, x_2, x_3) dx_1 dx_2 dx_3 = \frac{1}{6}c.$$

Since the value of this integral must be equal to 1, it follows that  $c = 6$ . If one used  $x_i > 1$  instead, then the integral would equal  $\exp(-6)/6$ , so that  $c = 6\exp(6)$ .

(b) For  $x_1 > 0, x_3 > 0$ ,

$$f_{13}(x_1, x_3) \int_0^\infty f(x_1, x_2, x_3) dx_2 = 3 \exp[-(x_1 + 3x_3)].$$

If one used  $x_i > 1$  instead, then for  $x_1 > 1$  and  $x_3 > 1$ ,  $f_{13}(x_1, x_3) = 3 \exp(-x_1 - 3x_3 + 4)$ .

(c) It is helpful at this stage to recognize that the random variables  $X_1, X_2$ , and  $X_3$  are independent because their joint p.d.f.  $f(x_1, x_2, x_3)$  can be factored as in Eq. (3.7.7); i.e., for  $x_i > 0$  ( $i = 1, 2, 3$ ),

$$f(x_1, x_2, x_3) = (\exp(-x_1)) = (2 \exp(-x_2))(3 \exp(-x_3)).$$

It follows that

$$\Pr(X_1 < 1 | X_2 = 2, X_3 = 1) = \Pr(X_1 < 1) = \int_0^1 f_1(x_1) dx_1 = \int_0^1 \exp(-x_1) dx_1 = 1 - \frac{1}{e}.$$

This answer could also be obtained without explicitly using the independence of  $X_1, X_2$ , and  $X_3$  by calculating first the marginal joint p.d.f.

$$f_{23}(x_2, x_3) = \int_0^\infty f(x_1, x_2, x_3) dx_1,$$

then calculating the conditional p.d.f.

$$g_1(x_1 | x_2 = 2, x_3 = 1) = \frac{f(x_1, 2, 1)}{f_{2,3}(2, 1)},$$

and finally calculating the probability

$$\Pr(X_1 < 1 | X_2 = 2, X_3 = 1) = \int_0^1 g_1(x_1 | x_2 = 2, x_3 = 1) dx_1.$$

If one used  $x_i > 1$  instead, then the probability in this part is 0.

4. The joint p.d.f.  $f(x_1, x_2, x_3)$  is constant over the cube  $S$ . Since

$$\iiint_S dx_1 dx_2 dx_3 = \int_0^1 \int_0^1 \int_0^1 dx_1 dx_2 dx_3 = 1,$$

it follows that  $f(x_1, x_2, x_3) = 1$  for  $(x_1, x_2, x_3) \in S$ . Hence, the probability of any subset of  $S$  will be equal to the volume of that subset.

- (a) The set of points such that  $(x_1 - 1/2)^2 + (x_2 - 1/2)^2 + (x_3 - 1/2)^2 \leq 1/4$  is a sphere of radius  $1/2$  with center at the point  $(1/2, 1/2, 1/2)$ . Hence, this sphere is entirely contained within the cube  $S$ . Since the volume of any sphere is  $4\pi r^3/3$ , the volume of this sphere, and also its probability, is  $4\pi(1/2)^3/3 = \pi/6$ .
- (b) The set of points such that  $x_1^2 + x_2^2 + x_3^2 \leq 1$  is a sphere of radius 1 with center at the origin  $(0, 0, 0)$ . Hence, the volume of this sphere is  $4\pi/3$ . However, only one octant of this sphere, the octant in which all three coordinates are nonnegative, lies in  $S$ . Hence, the volume of the intersection of the sphere with the set  $S$ , and also its probability, is  $\frac{1}{8} \cdot \frac{4}{3}\pi = \frac{1}{6}\pi$ .

5. (a) The probability that all  $n$  independent components will function properly is the product of their individual probabilities and is therefore equal to  $\prod_{i=1}^n p_i$ .
- (b) The probability that all  $n$  independent components will not function properly is the product of their individual probabilities of not functioning properly and is therefore equal to  $\prod_{i=1}^n (1 - p_i)$ . The probability that at least one component will function properly is  $1 - \prod_{i=1}^n (1 - p_i)$ .
6. Since the  $n$  random variables  $x_1, \dots, x_n$  are i.i.d. and each has the p.f.  $f$ , the probability that a particular variable  $X_i$  will be equal to a particular value  $x$  is  $f(x)$ , and the probability that all  $n$  variables will be equal to a particular value  $x$  is  $[f(x)]^n$ . Hence, the probability that all  $n$  variables will be equal, without any specification of their common value, is  $\sum_x [f(x)]^n$ .
7. The probability that a particular variable  $X_i$  will lie in the interval  $(a, b)$  is  $p = \int_a^b f(x) dx$ . Since the variables  $X_1, \dots, X_n$  are independent, the probability that exactly  $i$  of these variables will lie in the interval  $(a, b)$  is  $\binom{n}{i} p^i (1 - p)^{n-i}$ . Therefore, the required probability is

$$\sum_{i=k}^n \binom{n}{i} p^i (1 - p)^{n-i}.$$

8. For any given value  $x$  of  $X$ , the random variables  $Y_1, \dots, Y_n$  are i.i.d., each with the p.d.f.  $g(y|x)$ . Therefore, the conditional joint p.d.f. of  $Y_1, \dots, Y_n$  given that  $X = x$  is

$$h(y_1, \dots, y_n | x) = g(y_1 | x) \dots g(y_n | x) = \begin{cases} \frac{1}{x^n} & \text{for } 0 < y_i < x, i = 1, \dots, n, \\ 0 & \text{otherwise.} \end{cases}$$

The joint p.d.f. of  $X$  and  $Y_1, \dots, Y_n$  is, therefore,

$$f(x)h(y_1, \dots, y_n | x) = \begin{cases} \frac{1}{n!} \exp(-x) & \text{for } 0 < y_i < x \quad (i = 1, \dots, n), \\ 0 & \text{otherwise.} \end{cases}$$

This joint p.d.f. is positive if and only if each  $y_i > 0$  and  $x$  is greater than every  $y_i$ . In other words,  $x$  must be greater than  $m = \max\{y_1, \dots, y_n\}$ .

- (a) For  $y_1 > 0$  ( $i = 1, \dots, n$ ), the marginal joint p.d.f. of  $Y_1, \dots, Y_n$  is
- $$g_0(y_1, \dots, y_n) = \int_{-\infty}^{\infty} f(x)h(y_1, \dots, y_n | x) dx = \int_m^{\infty} \frac{1}{n!} \exp(-x) dx = \frac{1}{n!} \exp(-m).$$
- (b) For  $y_i > 0$  ( $i = 1, \dots, n$ ), the conditional p.d.f. of  $X$  given that  $Y_i = y_i$  ( $i = 1, \dots, n$ ) is
- $$g_1(x | y_1, \dots, y_n) = \frac{f(x)h(y_1, \dots, y_n | x)}{g_0(y_1, \dots, y_n)} = \begin{cases} \exp(-(x - m)) & \text{for } x > m, \\ 0 & \text{otherwise.} \end{cases}$$
9. (a) Since  $X_i = X$  for  $i = 1, 2$ , we know that  $X_i$  has the same distribution as  $X$ . Since  $X$  has a continuous distribution, then so does  $X_i$  for  $i = 1, 2$ .
- (b) We know that  $\Pr(X_1 = X_2) = 1$ . Let  $A = \{(x_1, x_2) : x_1 = x_2\}$ . Then  $\Pr((X_1, X_2) \in A) = 1$ . However, for every function  $f$ ,  $\int_A \int f(x_1, x_2) dx_1 dx_2 = 0$ . So there is no possible joint p.d.f.

10. The marginal p.d.f. of  $Z$  is  $2 \exp(-2z)$ , for  $z > 0$ . The coordinates of  $\mathbf{X}$  are conditionally i.i.d. given  $Z = z$  with p.d.f.  $z \exp(-zx)$ , for  $x > 0$ . This makes the joint p.d.f. of  $(Z, \mathbf{X})$  equal to  $2z^5 \exp(-z[2 + x_1 + \dots + x_5])$  for all variables positive. The marginal joint p.d.f. of  $\mathbf{X}$  is obtained by integrating  $z$  out of this.

$$f_2(\mathbf{x}) = \int_0^\infty 2z^5 \exp(-z[2 + x_1 + \dots + x_5]) dz = \frac{240}{(2 + x_1 + \dots + x_5)^6}, \text{ for all } x_i > 0.$$

Here, we use the formula  $\int_0^\infty y^k \exp(-y) dy = k!$  from Exercise 12 in Sec. 3.6. The conditional p.d.f. of  $Z$  given  $\mathbf{X} = (x_1, \dots, x_5)$  is then

$$g_1(z|\mathbf{x}) = \frac{(2 + x_1 + \dots + x_5)^6}{120} z^5 \exp(-z[2 + x_1 + \dots + x_5]),$$

for  $z > 0$ .

11. Since  $X_1, \dots, X_n$  are independent, their joint p.f., p.d.f., or p.f./p.d.f. factors as

$$f(x_1, \dots, x_n) = f_1(x_1) \cdots f_n(x_n),$$

where each  $f_i$  is a p.f. or p.d.f. If we sum or integrate over all  $x_j$  such that  $j \notin \{i_1, \dots, i_k\}$  we obtain the joint p.f., p.d.f., or p.f./p.d.f. of  $X_{i_1}, \dots, X_{i_k}$  equal to  $f_{i_1}(x_{i_1}) \cdots f_{i_k}(x_{i_k})$ , which is factored in a way that makes it clear that  $X_{i_1}, \dots, X_{i_k}$  are independent.

12. Let  $h(\mathbf{y}, \mathbf{w})$  be the marginal joint p.d.f. of  $\mathbf{Y}$  and  $\mathbf{W}$ , and let  $h_2(\mathbf{w})$  be the marginal p.d.f. of  $\mathbf{w}$ . Then

$$\begin{aligned} h(\mathbf{y}, \mathbf{w}) &= \int f(\mathbf{y}, \mathbf{z}, \mathbf{w}) d\mathbf{z}, \\ h_2(\mathbf{w}) &= \int \int f(\mathbf{y}, \mathbf{z}, \mathbf{w}) d\mathbf{z} d\mathbf{y}, \\ g_1(\mathbf{y}, \mathbf{z}|\mathbf{w}) &= \frac{f(\mathbf{y}, \mathbf{z}, \mathbf{w})}{h_2(\mathbf{w})}, \\ g_2(\mathbf{y}|\mathbf{w}) &= \frac{h(\mathbf{y}, \mathbf{w})}{h_2(\mathbf{w})} = \frac{\int f(\mathbf{y}, \mathbf{z}, \mathbf{w}) d\mathbf{z}}{h_2(\mathbf{w})} = \int g_1(\mathbf{y}, \mathbf{z}|\mathbf{w}) d\mathbf{z}. \end{aligned}$$

13. Let  $f(x_1, x_2, x_3, z)$  be the joint p.d.f. of  $(X_1, X_2, X_3, Z)$ . Let  $f_{12}(x_1, x_2)$  be the marginal joint p.d.f. of  $(X_1, X_2)$ . The conditional p.d.f. of  $X_3$  given  $(X_1, X_2) = (x_1, x_2)$  is

$$\frac{\int f(x_1, x_2, x_3, z) dz}{f_{12}(x_1, x_2)} = \frac{\int g(x_1|z) g(x_2|z) g(x_3|z) f_0(z) dz}{f_{12}(x_1, x_2)} = \int g(x_3|z) \frac{g(x_1|z) g(x_2|z) f_0(z)}{f_{12}(x_1, x_2)} dz.$$

According to Bayes' theorem for random variables, the fraction in this last integral is  $g_0(z|x_1, x_2)$ . Using the specific formulas in the text, we can calculate the last integral as

$$\begin{aligned} &\int_0^\infty z \exp(-zx_3) \frac{1}{2} (2 + x_1 + x_2)^3 z^2 \exp(-z(2 + x_1 + x_2)) dx \\ &= \frac{(2 + x_1 + x_2)^3}{2} \int_0^\infty z^3 \exp(-z(2 + x_1 + x_2 + x_3)) dz \\ &= \frac{(2 + x_1 + x_2)^3}{2} \frac{6}{(2 + x_1 + x_2 + x_3)^4} = \frac{3(2 + x_1 + x_2)^3}{(2 + x_1 + x_2 + x_3)^4}. \end{aligned}$$

The joint p.d.f. of  $(X_1, X_2, X_3)$  can be computed in a manner similar to the joint p.d.f. of  $(X_1, X_2)$  and it is

$$f_{123}(x_1, x_2, x_3) = \frac{12}{(2 + x_1 + x_2 + x_3)^4}.$$

The ratio of  $f_{123}(x_1, x_2, x_3)$  to  $f_{12}(x_1, x_2)$  is the conditional p.d.f. calculated above.

14. (a) We can substitute  $x_1 = 5$  and  $x_2 = 7$  in the conditional p.d.f. computed in Exercise 13.

$$g_3(x_3|5, 7) = \frac{3(2 + 5 + 7)^3}{(2 + 5 + 7 + x_3)^4} = \frac{8232}{(14 + x_3)^4},$$

for  $x_3 > 0$ .

- (b) The conditional probability we want is the integral of the p.d.f. above from 3 to  $\infty$ .

$$\int_3^\infty \frac{8232}{(14 + x_3)^4} dx_3 = -\frac{2744}{(14 + x_3)^3} \Big|_{x_3=3}^\infty = 0.5585.$$

In Example 3.7.9, we computed the marginal probability  $\Pr(X_3 > 3) = 0.4$ . Now that we have observed two service times that are both longer than 3, namely 5 and 7, we think that the probability of  $X_3 > 3$  should be larger.

15. Let  $A$  be an arbitrary  $n$ -dimensional set. Because  $\Pr(W = c) = 1$ , we have

$$\Pr((X_1, \dots, X_n) \in A, W = w) = \begin{cases} \Pr(X_1, \dots, X_n) \in A) & \text{if } w = c, \\ 0 & \text{otherwise.} \end{cases}$$

It follows that

$$\Pr((X_1, \dots, X_n) \in A | W = w) = \begin{cases} \Pr(X_1, \dots, X_n) \in A) & \text{if } w = c, \\ 0 & \text{otherwise.} \end{cases}$$

Hence the conditional joint distribution of  $X_1, \dots, X_n$  given  $W$  is the same as the unconditional joint distribution of  $X_1, \dots, X_n$ , which is the distribution of independent random variables.

## 3.8 Functions of a Random Variable

### Commentary

A brief discussion of simulation appears at the end of this section. This can be considered a teaser for the more detailed treatment in Chapter 12. Simulation is becoming a very important tool in statistics and applied probability. Even those instructors who prefer not to cover Chapter 12 have the option of introducing the topic here for the benefit of students who will need to study simulation in more detail in another course.

If you wish to use the statistical software  $R$ , then the function `runif` will be most useful. For the purposes of this section, `runif(n)` will return  $n$  pseudo-uniform random numbers on the interval  $[0, 1]$ . Of course, either `n` must be assigned a value before expecting  $R$  to understand `runif(n)`, or one must put an explicit value of `n` into the function. The following two options both produce 1,000 pseudo-uniform random numbers and store them in an object called `unums`:

- `unums=runif(1000)`
- `n=1000`  
`unums=runif(n)`

**Solutions to Exercises**

1. The inverse transformation is  $x = (1 - y)^{1/2}$ , whose derivative is  $-(1 - y)^{-1/2}/2$ . The p.d.f. of  $Y$  is then

$$g(y) = f([1 - y]^{1/2})(1 - y)^{-1/2}/2 = \frac{3}{2}(1 - y)^{1/2},$$

for  $0 < y < 1$ .

2. For each possible value of  $x$ , we have the following value of  $y = x^2 - x$ :

$x$	$y$
-3	12
-2	6
-1	2
0	0
1	0
2	2
3	6

Since the probability of each value of  $X$  is  $1/7$ , it follows that the p.f.  $g(y)$  is as follows:

$y$	$g(y)$
0	$\frac{2}{7}$
2	$\frac{2}{7}$
6	$\frac{2}{7}$
12	$\frac{1}{7}$

3. It is seen from Fig. S.3.33 that as  $x$  varies over the interval  $0 < x < 2$ ,  $y$  varies over the interval

Figure S.3.33: Figure for Exercise 3 of Sec. 3.8.

$0 < y \leq 1$ . Therefore, for  $0 < y \leq 1$ ,

$$\begin{aligned} G(y) &= \Pr(Y \leq y) = \Pr[X(2 - X) \leq y] = \Pr(X^2 - 2X \geq -y) \\ &= \Pr(X^2 - 2X + 1 \geq 1 - y) = \Pr[(X - 1)^2 \geq 1 - y] \\ &= \Pr(X - 1 \leq -\sqrt{1 - y}) + \Pr(X - 1 \geq \sqrt{1 - y}) \\ &= \Pr(X \leq 1 - \sqrt{1 - y}) + \Pr(X \geq 1 + \sqrt{1 - y}) \\ &= \int_0^{1-\sqrt{1-y}} \frac{1}{2}x dx + \int_{1+\sqrt{1-y}}^2 \frac{1}{2}x dx \end{aligned}$$

$$= 1 - \sqrt{1-y}.$$

It follows that, for  $0 < y < 1$ ,

$$g(y) = \frac{dG(y)}{dy} = \frac{1}{2(1-y)^{1/2}}.$$

4. The function  $y = 4 - x^3$  is strictly decreasing for  $0 < x < 2$ . When  $x = 0$ , we have  $y = 4$ , and when  $x = 2$  we have  $y = -4$ . Therefore, as  $x$  varies over the interval  $0 < x < 2$ ,  $y$  varies over the interval  $-4 < y < 4$ . The inverse function is  $x = (4-y)^{1/3}$  and

$$\frac{dx}{dy} = -\frac{1}{3}(4-y)^{-2/3}.$$

Therefore, for  $-4 < y < 4$ ,

$$g(y) = f[(4-y)^{1/3}] \cdot \left| \frac{dx}{dy} \right| = \frac{1}{2}(4-y)^{1/3} \cdot \frac{1}{3}(4-y)^{-2/3} = \frac{1}{6}(4-y)^{1/3}.$$

5. If  $y = ax + b$ , the inverse function is  $x = (y-b)/a$  and  $dx/dy = 1/a$ . Therefore,

$$g(y) = f\left[\frac{1}{a}(y-b)\right] \left| \frac{dx}{dy} \right| = \frac{1}{|a|} f\left(\frac{y-b}{a}\right).$$

6.  $X$  lies between 0 and 2 if and only if  $Y$  lies between 2 and 8. Therefore, it follows from Exercise 3 that for  $2 < y < 8$ ,

$$g(y) = \frac{1}{3}f\left(\frac{y-2}{3}\right) = \frac{1}{3} \cdot \frac{1}{2} \cdot \frac{y-2}{3} = \frac{1}{18}(y-2).$$

7. (a) If  $y = x^2$ , then as  $x$  varies over the interval  $(0, 1)$ ,  $y$  also varies over the interval  $(0, 1)$ . Also,  $x = y^{1/2}$  and  $dx/dy = y^{-1/2}/2$ . Hence, for  $0 < y < 1$ ,

$$g(y) = f(y^{1/2}) \left| \frac{dx}{dy} \right| = 1 \cdot \frac{1}{2}y^{-1/2} = \frac{1}{2}y^{-1/2}.$$

- (b) If  $y = -x^3$ , then as  $x$  varies over the interval  $(0, 1)$ ,  $y$  varies over the interval  $(-1, 0)$ . Also,  $x = -y^{1/3}$  and  $dx/dy = -y^{-2/3}/3$ . Hence, for  $-1 < y < 0$ ,

$$g(y) = f(-y^{1/3}) \left| \frac{dx}{dy} \right| = \frac{1}{3} |y|^{-2/3}.$$

- (c) If  $y = x^{1/2}$ , then as  $x$  varies over the interval  $(0, 1)$ ,  $y$  also varies over the interval  $(0, 1)$ . Also,  $x = y^2$  and  $dx/dy = 2y$ . Hence, for  $0 < y < 1$ ,  $g(y) = f(y^2)2y = 2y$ .

8. As  $x$  varies over all positive values,  $y$  also varies over all positive values. Also,  $x = y^2$  and  $dx/dy = 2y$ . Therefore, for  $y > 0$ ,

$$g(y) = f(y^2)(2y) = 2y \exp(-y^2).$$

9. The c.d.f.  $G(y)$  corresponding to the p.d.f.  $g(y)$  is, for  $0 < y < 2$ ,

$$G(y) = \int_0^y g(t)dt = \int_0^y \frac{3}{8}t^2 dt = \frac{1}{8}y^3.$$

We know that the c.d.f. of the random variable  $Y = G^{-1}(X)$  will be  $G$ . We must therefore determine the inverse function  $G^{-1}$ . If  $X = G(Y) = Y^3/8$  then  $Y = G^{-1}(X) = 2X^{1/3}$ . It follows that  $Y = 2X^{1/3}$ .

10. For  $0 < x < 2$ , the c.d.f. of  $X$  is

$$F(x) = \int_0^x f(t)dt = \int_0^x \frac{1}{2}t dt = \frac{1}{4}x^2.$$

Therefore, by the probability integral transformation, we know that  $U = F(X) = X^2/4$  will have the uniform distribution on the interval  $[0, 1]$ . Since  $U$  has this uniform distribution, we know from Exercise 8 that  $Y = 2U^{1/3}$  will have the required p.d.f.  $g$ . Therefore, the required transformation is  $Y = 2U^{1/3} = 2(X^2/4)^{1/3} = (2X^2)^{1/3}$ .

11. We can use the probability integral transformation if we can find the inverse of the c.d.f. The c.d.f. is, for  $0 < y < 1$ ,

$$G(y) = \int_{-\infty}^y g(t)dt = \frac{1}{2} \int_0^y (2t + 1)dt = \frac{1}{2}(y^2 + y).$$

The inverse of this function can be found by setting  $G(y) = p$  and solving for  $y$ .

$$\frac{1}{2}(y^2 + y) = p; \quad y^2 + y - 2p = 0; \quad y = \frac{-1 + (1 + 8p)^{1/2}}{2}.$$

So, we should generate four independent uniform pseudo-random variables  $P_1, P_2, P_3, P_4$  and let  $Y_i = [-1 + (1 + 8P_i)^{1/2}]/2$  for  $i = 1, 2, 3, 4$ .

12. Let  $X$  have the uniform distribution on  $[0, 1]$ , and let  $F$  be a c.d.f. Let  $F^{-1}(p)$  be defined as the smallest  $x$  such that  $F(x) \geq p$ . Define  $Y = F^{-1}(X)$ . We need to show that  $\Pr(Y \leq y) = F(y)$  for all  $y$ . First, suppose that  $y$  is the unique  $x$  such that  $F(x) = F(y)$ . Then  $Y \leq y$  if and only if  $X \leq F(y)$ . Since  $X$  has a uniform distribution  $\Pr(X \leq F(y)) = F(y)$ . Next, suppose that  $F(x) = F(y)$  for all  $x$  in the interval  $[a, b]$  of  $[a, b]$  with  $b > a$ , and suppose that  $F(x) < F(y)$  for all  $x < a$ . Then  $F^{-1}(X) \leq y$  if and only if  $X \leq F(a) = F(y)$ . Once again  $\Pr(X \leq F(y)) = F(y)$ .

13. The inverse transformation is  $z = 1/t$  with derivative  $-1/t^2$ . the p.d.f. of  $T$  is

$$g(t) = f(1/t)/t^2 = 2 \exp(-2/t)/t^2,$$

for  $t > 0$ .

14. Let  $Y = cX + d$ . The inverse transformation is  $x = (y - d)/c$ . Assumethat  $c > 0$ . The derivative of the inverse is  $1/c$ . The p.d.f. of  $Y$  is

$$g(y) = f([y - d]/c)/c = [c(b - a)]^{-1}, \text{ for } a \leq (y - d)/c \leq b.$$

It is easy to see that  $a \leq (y - d)/c \leq b$  if and only if  $ca + d \leq y \leq cb + d$ , so  $g$  is the p.d.f. of the uniform distribution on the interval  $[ca + d, cb + d]$ . If  $c < 0$ , the distribution of  $Y$  would be uniform on the interval  $[cb + d, ca + d]$ . If  $c = 0$ , the distribution of  $Y$  is degenerate at the value  $d$ , i.e.,  $\Pr(Y = d) = 1$ .

15. Let  $F$  be the c.d.f. of  $X$ . First, find the c.d.f. of  $Y$ , namely, for  $y > 0$ ,

$$\Pr(Y \leq y) = \Pr(X^2 \leq y) = \Pr(-y^{1/2} \leq X \leq y^{1/2}) = F(y^{1/2}) - F(-y^{1/2}).$$

Now, the p.d.f. of  $Y$  is the derivative of the above expression, namely,

$$g(y) = \frac{d}{dy}[F(y^{1/2}) - F(-y^{1/2})] = \frac{f(y^{1/2})}{2y^{1/2}} + \frac{f(-y^{1/2})}{2y^{1/2}}.$$

This equals the expression in the exercise.

16. Because  $0 < X < 1$  with probability 1, squaring  $X$  produces smaller values. There are wide intervals of values of  $X$  that produce small values of  $X^2$  but the values of  $X$  that produce large values of  $X^2$  are more limited. For example, to get  $Y \in [0.9, 1]$ , you need  $X \in [0.9487, 1]$ , whereas to get  $Y \in [0, 0.1]$  (an interval of the same length), you need  $X \in [0, 0.3162]$ , a much bigger set.
17. (a) According to the problem description,  $Y = 0$  if  $X \leq 100$ ,  $Y = X - 100$  if  $100 < X \leq 5100$ , and  $Y = 5000$  if  $X > 5100$ . So,  $Y = r(X)$ , where

$$r(x) = \begin{cases} 0 & \text{if } x \leq 100, \\ x - 100 & \text{if } 100 < x \leq 5100, \\ 5000 & \text{if } x > 5100. \end{cases}$$

- (b) Let  $G$  be the c.d.f. of  $Y$ . Then  $G(y) = 0$  for  $y < 0$ , and  $G(y) = 1$  for  $y \geq 5000$ . For  $0 \leq y < 5000$ ,

$$\begin{aligned} \Pr(Y \leq y) &= \Pr(r(X) \leq y) \\ &= \Pr(X \leq y + 100) \\ &= \int_0^{y+100} \frac{dx}{(1+x)^2} \\ &= 1 - \frac{1}{y+101}. \end{aligned}$$

In summary,

$$G(y) = \begin{cases} 0 & \text{if } y < 0, \\ 1 - \frac{1}{y+101} & \text{if } 0 \leq y < 5000, \\ 1 & \text{if } y \geq 5000. \end{cases}$$

- (c) There is positive probability that  $Y = 5000$ , but the rest of the distribution of  $Y$  is spread out in a continuous manner between 0 and 5000.

## 3.9 Functions of Two or More Random Variables

### Commentary

The material in this section can be very difficult, even for students who have studied calculus. Many textbooks at this level avoid the topic of general bivariate and multivariate transformations altogether. If an instructor wishes to avoid discussion of Jacobians and multivariate transformations, it might still be useful to introduce convolution, and the extremes of a random sample. The text is organized so that these topics appear early in the section, before any discussion of Jacobians. In the remainder of the text, the method of Jacobians is used in the following places:

- The proof of Theorem 5.8.1, the derivation of the beta distribution p.d.f.
- The proof of Theorem 5.10.1, the derivation of the joint p.d.f. of the bivariate normal distribution.
- The proof of Theorem 8.3.1, the derivation of the joint distribution of the sample mean and sample variance from a random sample of normal random variables.
- The proof of Theorem 8.4.1, the derivation of the p.d.f. of the  $t$  distribution.

### Solutions to Exercises

1. The joint p.d.f. of  $X_1$  and  $X_2$  is

$$f(x_1, x_2) = \begin{cases} 1 & \text{for } 0 < x_1 < 1, 0 < x_2 < 1, \\ 0 & \text{otherwise.} \end{cases}$$

By Eq. (3.9.5), the p.d.f. of  $Y$  is

$$g(y) = \int_{-\infty}^{\infty} f(y - z, z) dz.$$

The integrand is positive only for  $0 < y - z < 1$  and  $0 < z < 1$ . Therefore, for  $0 < y \leq 1$  it is positive only for  $0 < z < y$  and we have

$$g(y) = \int_0^y 1 \cdot dz = y.$$

For  $1 < y < 2$ , the integrand is positive only for  $y - 1 < z < 1$  and we have

$$g(y) = \int_{y-1}^1 1 \cdot dz = 2 - y.$$

2. Let  $f$  be the p.d.f. of  $Y = X_1 + X_2$  found in Exercise 1, and let  $Z = Y/2$ . The inverse of this transformation is  $y = 2z$  with derivative 2. The p.d.f. of  $Z$  is

$$g(z) = 2f(2z) = \begin{cases} 4z & \text{for } 0 < z < 1/2, \\ 4(1-z) & \text{for } 1/2 < z < 1, \\ 0 & \text{otherwise.} \end{cases}$$

3. The inverse transformation is:

$$\begin{aligned} x_1 &= y_1, \\ x_2 &= y_2/y_1, \\ x_3 &= y_3/y_2. \end{aligned}$$

Furthermore, the set  $S$  where  $0 < x_i < 1$  for  $i = 1, 2, 3$  corresponds to the set  $T$  where  $0 < y_3 < y_2 < y_1 < 1$ . We also have

$$J = \det \begin{bmatrix} \frac{\partial x_1}{\partial y_1} & \frac{\partial x_1}{\partial y_2} & \frac{\partial x_1}{\partial y_3} \\ \frac{\partial x_2}{\partial y_1} & \frac{\partial x_2}{\partial y_2} & \frac{\partial x_2}{\partial y_3} \\ \frac{\partial x_3}{\partial y_1} & \frac{\partial x_3}{\partial y_2} & \frac{\partial x_3}{\partial y_3} \end{bmatrix} = \det \begin{bmatrix} 1 & 0 & 0 \\ -\frac{y_2}{y_1^2} & \frac{1}{y_1} & 0 \\ 0 & -\frac{y_3}{y_2^2} & \frac{1}{y_2} \end{bmatrix} = \frac{1}{y_1 y_2}.$$

Therefore, for  $0 < y_3 < y_2 < y_1 < 1$ , the joint p.d.f. of  $Y_1, Y_2$ , and  $Y_3$  is

$$\begin{aligned} g(y_1, y_2, y_3) &= f\left(y_1, \frac{y_2}{y_1}, \frac{y_3}{y_2}\right) |J| \\ &= 8y_1 \frac{y_2}{y_1} \frac{y_3}{y_2} \frac{1}{y_1 y_2} = \frac{8y_3}{y_1 y_2}. \end{aligned}$$

4. As a convenient device, let  $Z = X_1$ . Then the transformation from  $X_1$  and  $X_2$  to Y and Z is a one-to-one transformation between the set S where  $0 < x_1 < 1$  and  $0 < x_2 < 1$  and the set T where  $0 < y < z < 1$ . The inverse transformation is

$$\begin{aligned}x_1 &= z, \\x_2 &= \frac{y}{z}.\end{aligned}$$

Therefore,

$$J = \det \begin{bmatrix} \frac{\partial x_1}{\partial y} & \frac{\partial x_1}{\partial z} \\ \frac{\partial x_2}{\partial y} & \frac{\partial x_2}{\partial z} \end{bmatrix} = \det \begin{bmatrix} 0 & 1 \\ \frac{1}{z} & -\frac{y}{z^2} \end{bmatrix} = -\frac{1}{z}.$$

For  $0 < y < z < 1$ , the joint p.d.f. of Y and Z is

$$g(y, z) = f\left(z, \frac{y}{z}\right) |J| = \left(z + \frac{y}{z}\right) \left(\frac{1}{z}\right).$$

It follows that for  $0 < y < 1$ , the marginal p.d.f. of Y is

$$g_1(y) = \int_y^1 g(y, z) dz = 2(1 - y).$$

5. As a convenient device let  $Y = X_2$ . Then the transformation from  $X_1$  and  $X_2$  to Y and Z is a one-to-one transformation between the set S where  $0 < x_1 < 1$  and  $0 < x_2 < 1$  and the set T where  $0 < y < 1$  and  $0 < yz < 1$ . The inverse transformation is

$$\begin{aligned}x_1 &= yz, \\x_2 &= y.\end{aligned}$$

Therefore,

$$J = \det \begin{bmatrix} z & y \\ 1 & 0 \end{bmatrix} = -y.$$

The region where the p.d.f. of  $(Z, Y)$  is positive is in Fig. S.3.34. For  $0 < y < 1$  and  $0 < yz < 1$ , the

Figure S.3.34: The region where the p.d.f. of  $(Z, Y)$  is positive in Exercise 5 of Sec. 3.9.

joint p.d.f. of Y and Z is

$$g(y, z) = f(yz, y) |J| = (yz + y)(y).$$

It follows that for  $0 < z \leq 1$ , the marginal p.d.f. of  $Z$  is

$$g_2(z) = \int_0^1 g(y, z) dy = \frac{1}{3}(z + 1).$$

Also, for  $z > 1$ ,

$$g_2(z) = \int_0^{\frac{1}{z}} g(y, z) dy = \frac{1}{3z^3}(z + 1).$$

6. By Eq. (3.9.5) (with a change in notation),

$$g(z) = \int_{-\infty}^{\infty} f(z - t, t) dt \quad \text{for } -\infty < z < \infty.$$

However, the integrand is positive only for  $0 \leq z - t \leq t \leq 1$ . Therefore, for  $0 \leq z \leq 1$ , it is positive only for  $z/2 \leq t \leq z$  and we have

$$g(z) = \int_{z/2}^z 2z dt = z^2.$$

For  $1 < z < 2$ , the integrand is positive only for  $z/2 \leq t \leq 1$  and we have

$$g(z) = \int_{z/2}^z 2z dt = z(2 - z).$$

7. Let  $Z = -X_2$ . Then the p.d.f. of  $Z$  is

$$f_2(z) = \begin{cases} \exp(z) & \text{for } z < 0, \\ 0 & \text{for } z \geq 0. \end{cases}$$

Since  $X_1$  and  $Z$  are independent, the joint p.d.f. of  $X_1$  and  $Z$  is

$$f(x_1, z) = \begin{cases} \exp(-(x - z)) & \text{for } x > 0, z < 0, \\ 0 & \text{otherwise.} \end{cases}$$

It now follows from Eq. (3.9.5) that the p.d.f. of  $Y = X_1 - X_2 = X_1 + Z$  is

$$g(y) = \int_{-\infty}^{\infty} f(y - z, z) dz.$$

The integrand is positive only for  $y - z > 0$  and  $z < 0$ . Therefore, for  $y \leq 0$ ,

$$g(y) = \int_{-\infty}^y \exp(-(y - 2z)) dz = \frac{1}{2} \exp(y).$$

Also, for  $y > 0$ ,

$$g(y) = \int_{-\infty}^0 \exp(-(y - 2z)) dz = \frac{1}{2} \exp(-y).$$

8. We have

$$\begin{aligned}\Pr(Y_n \geq 0.99) &= 1 - \Pr(Y_n < 0.99) \\ &= 1 - \Pr(\text{All } n \text{ observations} < 0.99) \\ &= 1 - (0.99)^n.\end{aligned}$$

Next,  $1 - (0.99)^n \geq 0.95$  if and only if

$$\begin{aligned}(0.99)^n \leq 0.05 &\quad \text{or} \quad n \log(0.99) \leq \log(0.05) \\ &\quad \text{or} \quad n \geq \frac{\log(0.05)}{\log(0.99)} \approx 298.1.\end{aligned}$$

So,  $n \geq 299$  is needed.

9. It was shown in this section that the joint c.d.f. of  $Y_1$  and  $Y_n$  is, for  $-\infty < y_1 < y_n < \infty$ ,

$$G(y_1, y_n) = [F(y_n)]^n - [F(y_n) - F(y_1)]^n.$$

Since  $F(y) = y$  for the given uniform distribution, we have

$$\Pr(Y_1 \leq 0.1, Y_n \leq 0.8) = G(0.1, 0.8) = (0.8)^n - (0.7)^n.$$

10.  $\Pr(Y_1 \leq 0.1 \text{ and } Y_n \geq 0.8)$

$$= \Pr(Y_1 \leq 0.1) - \Pr(Y_1 \leq 0.1 \text{ and } Y_n \leq 0.8).$$

It was shown in this section that the p.d.f. of  $Y_1$  is

$$G_1(y) = 1 - [1 - F(y)]^n.$$

Therefore,  $\Pr(Y_1 \leq 0.1) = G_1(0.1) = 1 - (0.9)^n$ . Also, by Exercise 9,

$$\Pr(Y_1 \leq 0.1 \text{ and } Y_n \leq 0.8) = (0.8)^n - (0.7)^n.$$

Therefore,

$$\Pr(Y_1 \leq 0.1 \text{ and } Y_n \geq 0.8) = 1 - (0.9)^n - (0.8)^n + (0.7)^n.$$

11. The required probability is equal to

$$\Pr\left(\text{All } n \text{ observations} < \frac{1}{3}\right) + \Pr\left(\text{All } n \text{ observations} > \frac{1}{3}\right) = \left(\frac{1}{3}\right)^n + \left(\frac{2}{3}\right)^n.$$

This exercise could also be solved by using techniques similar to those used in Exercise 10.

12. The p.d.f.  $h_1(w)$  of  $W$  was derived in Example 3.9.8. Therefore,

$$\begin{aligned}\Pr(W > 0.9) &= \int_{0.9}^1 h_1(w) dw = \int_{0.9}^1 n(n-1)w^{n-2}(1-w)dw \\ &= 1 - n(0.9)^{n-1} + (n-1)(0.9)^n.\end{aligned}$$

13. If  $X$  has the uniform distribution on the interval  $[0, 1]$ , then  $aX + b$  ( $a > 0$ ) has the uniform distribution on the interval  $[b, a + b]$ . Therefore,  $8X - 3$  has the uniform distribution on the interval  $[-3, 5]$ . It follows that if  $X_1, \dots, X_n$  form a random sample from the uniform distribution on the interval  $[0, 1]$ , then the  $n$  random variables  $8X_1 - 3, \dots, 8X_n - 3$  will have the same joint distribution as a random sample from the uniform distribution on the interval  $[-3, 5]$ .

Next, it follows that if the range of the sample  $X_1, \dots, X_n$  is  $W$ , then the range of the sample  $8X_1 - 3, \dots, 8X_n - 3$  will be  $8W$ . Therefore, if  $W$  is the range of a random sample from the uniform distribution on the interval  $[0, 1]$ , then  $Z = 8W$  will have the same distribution as the range of a random sample from the uniform distribution on the interval  $[-3, 5]$ .

The p.d.f.  $h(w)$  of  $W$  was given in Example 3.9.8. Therefore, the p.d.f.  $f(z)$  of  $Z = 8W$  is

$$g(z) = h\left(\frac{z}{8}\right) \cdot \frac{1}{8} = \frac{n(n-1)}{8} \left(\frac{z}{8}\right)^{n-2} \left(1 - \frac{z}{8}\right),$$

for  $-3 < z < 5$ .

This p.d.f.  $g(z)$  could also have been derived from first principles as in Example 3.9.8.

14. Following the hint given in this exercise, we have

$$\begin{aligned} G(y) &= \Pr(\text{At least } n-1 \text{ observations are } \leq y) \\ &= \Pr(\text{Exactly } n-1 \text{ observations are } \leq y) + \Pr(\text{All } n \text{ observations are } \leq y) \\ &= ny^{n-1}(1-y) + y^n = ny^{n-1} - (n-1)y^n. \end{aligned}$$

Therefore, for  $0 < y < 1$ ,

$$\begin{aligned} g(y) &= n(n-1)y^{n-2} - n(n-1)y^{n-1} \\ &= n(n-1)y^{n-2}(1-y). \end{aligned}$$

It is a curious result that for this uniform distribution, the p.d.f. of  $Y$  is the same as the p.d.f. of the range  $W$ , as given in Example 3.9.8. There actually is intuition to support those two distributions being the same.

15. For any  $n$  sets of real numbers  $A_1, \dots, A_n$ , we have

$$\begin{aligned} \Pr(Y_1 \in A_1, \dots, Y_n \in A_n) &= \Pr[r_1(X_1) \in A_1, \dots, r_n(X_n) \in A_n] \\ &= \Pr[r_1(X_1) \in A_1] \dots \Pr[r_n(X_n) \in A_n] \\ &= \Pr(Y_1 \in A_1) \dots \Pr(Y_n \in A_n). \end{aligned}$$

Therefore,  $Y_1, \dots, Y_n$  are independent by Definition 3.5.2.

16. If  $f$  factors in the form given in this exercise, then there must exist a constant  $c > 0$  such that the marginal joint p.d.f. of  $X_1$  and  $X_2$  is

$$f_{12}(x_1, x_2) = cg(x_1, x_2) \quad \text{for } (x_1, x_2) \in R^2,$$

the marginal joint p.d.f. of  $X_3, X_4$ , and  $X_5$  is

$$f_{345}(x_3, x_4, x_5) = \frac{1}{c}h(x_3, x_4, x_5) \quad \text{for } (x_3, x_4, x_5) \in R^3,$$

and, therefore, for every point  $(x_1 \dots, x_5) \in R^5$  we have

$$f(x_1, \dots, x_5) = f_{12}(x_1, x_2)f_{345}(x_3, x_4, x_5).$$

It now follows that for any sets of real numbers  $A_1$  and  $A_2$ ,

$$\begin{aligned} \Pr(Y_1 \in A_1 \text{ and } Y_2 \in A_2) &= \int \dots \int_{\substack{r_1(x_1, x_2) \in A_1 \text{ and} \\ r_2(x_3, x_4, x_5) \in A_2}} f(x_1, \dots, x_5) dx_1 \dots dx_5 \\ &= \int_{r_1(x_1, x_2) \in A_1} \int_{r_2(x_3, x_4, x_5) \in A_2} f_{12}(x_1, x_2) dx_1 dx_2 \int \int_{r_2(x_3, x_4, x_5) \in A_2} f_{345}(x_3, x_4, x_5) dx_3 dx_4 dx_5 \\ &= \Pr(Y_1 \in A_1)\Pr(Y_2 \in A_2). \end{aligned}$$

Therefore, by definition,  $Y_1$  and  $Y_2$  are independent.

17. We need to transform  $(X, Y)$  to  $(Z, W)$ , where  $Z = XY$  and  $W = Y$ . The joint p.d.f. of  $(X, Y)$  is

$$f(x, y) = \begin{cases} y \exp(-xy)f_2(y) & \text{if } x > 0, \\ 0 & \text{otherwise.} \end{cases}$$

The inverse transformation is  $x = z/w$  and  $y = w$ . The Jacobian is

$$J = \det \begin{pmatrix} 1/w & -z/w^2 \\ 0 & 1 \end{pmatrix} = \frac{1}{w}.$$

The joint p.d.f. of  $(Z, W)$  is

$$g(z, w) = f(z/w, w)/w = w \exp(-z)f_2(w)/w = \exp(-z)f_2(w), \text{ for } z > 0.$$

This is clearly factored in the appropriate way to show that  $Z$  and  $W$  are independent. Indeed, if we integrate  $g(z, w)$  over  $w$ , we obtain the marginal p.d.f. of  $Z$ , namely  $g_1(z) = \exp(-z)$ , for  $z > 0$ . This is the same as the function in (3.9.18).

18. We need to transform  $(X, Y)$  to  $(Z, W)$ , where  $Z = X/Y$  and  $W = Y$ . The joint p.d.f. of  $(X, Y)$  is

$$f(x, y) = \begin{cases} 3x^2 f_2(y)/y^3 & \text{if } x > 0, \\ 0 & \text{otherwise.} \end{cases}$$

The inverse transformation is  $x = zw$  and  $y = w$ . The Jacobian is

$$J = \det \begin{pmatrix} w & z \\ 0 & 1 \end{pmatrix} = w.$$

The joint p.d.f. of  $(Z, W)$  is

$$g(z, w) = f(zw, w)w = 3z^2 w^2 f_2(w)w/w^3 = 3z^2 f_2(w), \text{ for } 0 < z < 1.$$

This is clearly factored in the appropriate way to show that  $Z$  and  $W$  are independent. Indeed, if we integrate  $g(z, w)$  over  $w$ , we obtain the marginal p.d.f. of  $Z$ , namely  $g_1(z) = 3z^2$ , for  $0 < z < 1$ .

19. This is a convolution. Let  $g$  be the p.d.f. of  $Y$ . By (3.9.5) we have, for  $y > 0$ ,

$$\begin{aligned} g(y) &= \int f(y-z)f(z)dx \\ &= \int_0^y e^{z-y}e^{-z}dz \\ &= ye^{-y}. \end{aligned}$$

Clearly,  $g(y) = 0$  for  $y < 0$ , so the p.d.f. of  $Y$  is

$$g(y) = \begin{cases} ye^{-y} & \text{for } y > 0, \\ 0 & \text{otherwise.} \end{cases}$$

20. Let  $f_1$  stand for the marginal p.d.f. of  $X_1$ , namely  $f_1(x) = \int f(x, x_2)dx_2$ . With  $a_2 = 0$  and  $a_1 = a$  in (3.9.2) we get

$$\begin{aligned} g(y) &= \int_{-\infty}^{\infty} f\left(\frac{y-b}{a}, x_2\right) \frac{1}{|a|} dx_2 \\ &= \frac{1}{|a|} f_1\left(\frac{y-b}{a}\right), \end{aligned}$$

which is the same as (3.8.1).

21. Transforming to  $Z_1 = X_1/X_2$  and  $Z_2 = X_1$  has the inverse  $X_1 = Z_2$  and  $X_2 = Z_2/Z_1$ . The set of values where the joint p.d.f. of  $Z_1$  and  $Z_2$  is positive is where  $0 < z_2 < 1$  and  $0 < z_2/z_1 < 1$ . This can be written as  $0 < z_2 < \min\{1, z_1\}$ . The Jacobian is the determinant of the matrix

$$\begin{pmatrix} 0 & 1 \\ -z_2/z_1^2 & 1/z_1 \end{pmatrix},$$

which is  $|z_2/z_1^2|$ . The joint p.d.f. of  $Z_1$  and  $Z_2$  is then

$$g(z_1, z_2) = \left| \frac{z_2}{z_1^2} \right| 4z_2 \frac{z_2}{z_1} = 4z_2^3 z_1^3,$$

for  $0 < z_2 < \min\{1, z_1\}$ . Integrating  $z_2$  out of this yields, for  $z_1 > 0$ ,

$$\begin{aligned} g_1(z_1) &= \int_0^{\min\{1, z_1\}} 4 \frac{z_2^3}{z_1^3} dz_2 \\ &= \frac{\min\{z_1, 1\}^4}{z_1^3} \\ &= \begin{cases} z_1 & \text{if } z_1 < 1, \\ z_1^{-3} & \text{if } z_1 \geq 1. \end{cases} \end{aligned}$$

This is the same thing we got in Example 3.9.11.

## 3.10 Markov Chains

### Commentary

Instructors can discuss this section at any time that they find convenient or they can omit it entirely. Instructors who wish to cover Sec. 12.5 (Markov chain Monte Carlo) and who wish to give some theoretical justification for the methodology will want to discuss some of this material before covering Sec. 12.5. On the other hand, one could cover Sec. 12.5 and skip the justification for the methodology without introducing Markov chains at all.

Students may notice the following property, which is exhibited in some of the exercises at the end of this section: Suppose that the Markov chain is in a given state  $s_i$  at time  $n$ . Then the probability of being in a particular state  $s_j$  a few periods later, say at time  $n+3$  or  $n+4$ , is approximately the same for each possible given state  $s_i$  at time  $n$ . For example, in Exercise 2, the probability that it will be sunny on Saturday is approximately the same regardless of whether it is sunny or cloudy on the preceding Wednesday, three days earlier. In Exercise 5, for given probabilities on Wednesday, the probability that it will be cloudy on Friday is approximately the same as the probability that it will be cloudy on Saturday. In Exercise 7, the probability that the student will be on time on the fourth day of class is approximately the same regardless of whether he was late or on time on the first day of class. In Exercise 10, the probabilities for  $n=3$  and  $n=4$ , are generally similar. In Exercise 11, the answers in part (a) and part (b) are almost identical.

This property is a reflection of the fact that for many Markov chains, the  $n$ th power of the transition matrix  $\mathbf{P}^n$  will converge, as  $n \rightarrow \infty$ , to a matrix for which all the elements in any given column are equal. For example, in Exercise 2, the matrix  $\mathbf{P}^n$  converges to the following matrix:

$$\begin{bmatrix} \frac{2}{3} & \frac{1}{3} \\ \frac{2}{3} & \frac{1}{3} \\ \frac{2}{3} & \frac{1}{3} \\ \frac{2}{3} & \frac{1}{3} \end{bmatrix}.$$

This type of convergence is an example of Theorem 3.10.4. This theorem, and analogs for more complicated Markov chains, provide the justification of the Markov chain Monte Carlo method introduced in Sec. 12.5.

### Solutions to Exercises

1. The transition matrix for this Markov chain is

$$\mathbf{P} = \begin{bmatrix} \frac{1}{3} & \frac{2}{3} \\ \frac{2}{3} & \frac{1}{3} \\ \frac{2}{3} & \frac{1}{3} \\ \frac{2}{3} & \frac{1}{3} \end{bmatrix}.$$

- (a) If we multiply the initial probability vector by this matrix we get

$$\mathbf{v}\mathbf{P} = \left( \frac{1}{3}, \frac{1}{3}, \frac{1}{3}, \frac{1}{3} \right) \mathbf{P} = \left( \frac{1}{2}, \frac{1}{2} \right).$$

- (b) The two-step transition matrix is  $\mathbf{P}^2$ , namely

$$\begin{bmatrix} \frac{1}{3} \cdot \frac{1}{3} + \frac{2}{3} \cdot \frac{2}{3} & \frac{1}{3} \cdot \frac{2}{3} + \frac{2}{3} \cdot \frac{1}{3} \\ \frac{2}{3} \cdot \frac{1}{3} + \frac{1}{3} \cdot \frac{2}{3} & \frac{2}{3} \cdot \frac{2}{3} + \frac{1}{3} \cdot \frac{1}{3} \end{bmatrix} = \begin{bmatrix} \frac{5}{9} & \frac{4}{9} \\ \frac{4}{9} & \frac{5}{9} \end{bmatrix}.$$

2. (a) 0.4, the lower right corner of the matrix.

(b)  $(0.7)(0.7) = 0.49.$

(c) The probability that it will be cloudy on the next three days is  $(0.4)(0.4)(0.4) = 0.064.$  The desired probability is  $1 - 0.064 = 0.936.$

3. Saturday is three days after Wednesday, so we first compute

$$\mathbf{P}^3 = \begin{bmatrix} 0.667 & 0.333 \\ 0.666 & 0.334 \end{bmatrix}.$$

Therefore, the answers are (a) 0.667 and (b) 0.666.

4. (a) From Exercise 3, the probability that it will be sunny on Saturday is 0.667. Therefore, the answer is  $(0.667)(0.7) = 0.4669.$

(b) From Exercise 3, the probability that it will be sunny on Saturday is 0.666. Therefore, the answer is  $(0.666)(0.7) = 0.4662.$

5. Let  $\mathbf{v} = (0.2, 0.8).$

(a) The answer will be the second component of the vector  $\mathbf{v}\mathbf{P}.$  We easily compute  $\mathbf{v}\mathbf{P} = (0.62, 0.38),$  so the probability is 0.38.

(b) The answer will be the second component of  $\mathbf{v}\mathbf{P}^2.$  We can compute  $\mathbf{v}\mathbf{P}^2$  by multiplying  $\mathbf{v}\mathbf{P}$  by  $\mathbf{P}$  to get  $(0.662, 0.338),$  so the probability is 0.338.

(c) The answer will be the second component of  $\mathbf{v}\mathbf{P}^3.$  Since  $\mathbf{v}\mathbf{P}^3 = (0.6662, 0.3338),$  the answer is 0.3338.

6. In this exercise (and the next two) the transition matrix  $\mathbf{P}$  is

		Late	On time
		0.2	0.8
Late	Late	0.2	0.8
	On time	0.5	0.5

(a)  $(0.8)(0.5)(0.5) = 0.2$

(b)  $(0.5)(0.2)(0.2) = 0.02.$

7. Using the matrix in Exercise 6, it is found that

$$\mathbf{P}^3 = \begin{bmatrix} 0.368 & 0.632 \\ 0.395 & 0.605 \end{bmatrix}.$$

Therefore, the answers are (a) 0.632 and (b) 0.605.

8. Let  $\mathbf{v} = (0.7, 0.3).$

(a) The answer will be the first component of the vector  $\mathbf{v}\mathbf{P}.$  We can easily compute  $\mathbf{v}\mathbf{P} = (0.29, 0.71),$  so the answer is 0.29.

(b) The answer will be the second component of the vector  $\mathbf{v}\mathbf{P}^3.$  We compute  $\mathbf{v}\mathbf{P}^3 = (0.3761, 0.6239),$  so the answer is 0.6239.

9. (a) It is found that

$$\mathbf{P}^2 = \begin{bmatrix} \frac{3}{16} & \frac{7}{16} & \frac{2}{16} & \frac{4}{16} \\ 0 & 1 & 0 & 0 \\ \frac{3}{8} & \frac{1}{8} & \frac{2}{8} & \frac{2}{8} \\ \frac{4}{16} & \frac{6}{16} & \frac{3}{16} & \frac{3}{16} \end{bmatrix}.$$

The answer is given by the element in the third row and second column.

- (b) The answer is the element in the first row and third column of  $\mathbf{P}^3$ , namely 0.125.

10. Let  $\mathbf{v} = \left( \frac{1}{8}, \frac{1}{4}, \frac{3}{8}, \frac{1}{4} \right)$ .

- (a) The probabilities for  $s_1, s_2, s_3$ , and  $s_4$  will be the four components of the vector  $\mathbf{v}\mathbf{P}$ .
- (b) The required probabilities will be the four components of  $\mathbf{v}\mathbf{P}^2$ .
- (c) The required probabilities will be the four components of  $\mathbf{v}\mathbf{P}^3$ .

11. The transition matrix for the states  $A$  and  $B$  is

$$\begin{bmatrix} \frac{1}{3} & \frac{2}{3} \\ \frac{2}{3} & \frac{1}{3} \end{bmatrix}.$$

It is found that

$$\mathbf{P}^4 = \begin{bmatrix} \frac{41}{81} & \frac{40}{81} \\ \frac{40}{81} & \frac{41}{81} \end{bmatrix}.$$

Therefore, the answers are (a)  $\frac{40}{81}$  and (b)  $\frac{41}{81}$ .

12. (a) Using the transition probabilities stated in the exercise, we construct

$$\mathbf{P} = \begin{bmatrix} 0.0 & 0.2 & 0.8 \\ 0.6 & 0.0 & 0.4 \\ 0.5 & 0.5 & 0.0 \end{bmatrix}.$$

- (b) It is found that

$$\mathbf{P}^2 = \begin{bmatrix} 0.52 & 0.40 & 0.08 \\ 0.20 & 0.32 & 0.48 \\ 0.30 & 0.10 & 0.60 \end{bmatrix}.$$

Let  $\mathbf{v} = \left( \frac{1}{3}, \frac{1}{3}, \frac{1}{3} \right)$ . The probabilities that  $A, B$ , and  $C$  will have the ball are equal to the three components of  $\mathbf{v}\mathbf{P}^2$ . Since the third component is largest, it is most likely that  $C$  will have the ball at time  $n + 2$ .

13. The states are triples of possible outcomes:  $(HHH)$ ,  $(HHT)$ ,  $(HTH)$ , etc. There are a total of eight such triples. The conditional probabilities of the possible values of the outcomes on trials  $(n-1, n, n+1)$  given all trials up to time  $n$  depend only on the trials  $(n-2, n-1, n)$  and not on  $n$  itself, hence we have a Markov chain with stationary transition probabilities. Every row of the transition matrix has the following form except the two corresponding to  $(HHH)$  and  $(TTT)$ . Let  $a, b, c$  stand for three arbitrary elements of  $\{H, T\}$ , not all equal. The row for  $(abc)$  has 0 in every column except for the two columns  $(abH)$  and  $(abT)$ , which have  $1/2$  in each. In the  $(HHH)$  row, every column has 0 except the  $(HHT)$  column, which has 1. In the  $(TTT)$  row, every column has 0 except the  $(TTH)$  column which has 1.
14. Since we switch a pair of balls during each operation, there are always three balls in box  $A$  during this process. There are a total of nine red balls available, so there are four possible states of the proposed Markov chain, 0, 1, 2, 3, each state giving the number of red balls in box  $A$ . The possible compositions of box  $A$  after the  $n$ th operation clearly depend only on the composition after the  $n-1$ st operation, so we have a Markov chain. Also, balls are drawn at random during each operation, so the probabilities of transition depend only on the current state. Hence, the transition probabilities are stationary. If there are currently 0 red balls in box  $A$ , then we shall certainly remove a green ball. The probability that we get a red ball from box  $B$  is  $9/10$ , otherwise we stay in state 0. So, the first row of  $\mathbf{P}$  is  $(1/10, 9/10, 0, 0)$ . If we start with 1 red ball, then we remove that ball with probability  $1/3$ . We replace whatever we draw with a red ball with probability  $8/10$ . So we can either go to state 0 (probability  $1/3 \times 2/10$ ), stay in state 1 (probability  $1/3 \times 8/10 + 2/3 \times 2/10$ ), or go to state 2 (probability  $2/3 \times 8/10$ ). The second row of  $\mathbf{P}$  is  $(1/15, 2/5, 8/15, 0)$ . If we start with 2 red balls, we remove one with probability  $2/3$  and we replace it with red with probability  $7/10$ . So, the third row of  $\mathbf{P}$  is  $(0, 1/5, 17/30, 7/30)$ . If we start with 3 red balls, we certainly remove one and we replace it by red with probability  $6/10$ , so the fourth row of  $\mathbf{P}$  is  $(0, 0, 2/5, 3/5)$ .
15. We are asked to verify the numbers in the second and fifth rows of the matrix in Example 3.10.6. For the second row, the parents have genotypes  $AA$  and  $Aa$ , so that the only possible offspring are  $AA$  and  $Aa$ . Each of these occurs with probability  $1/2$  because they are determined by which allele comes from the  $Aa$  parent. Since the two offspring in the second generation are independent, we will get  $\{AA, AA\}$  with probability  $(1/2)^2 = 1/4$  and we will get  $\{Aa, Aa\}$  with probability  $1/4$  also. The remaining probability,  $1/2$ , is the probability of  $\{AA, Aa\}$ . For the fifth row, the parent have genotypes  $Aa$  and  $aa$ . The only possible offspring are  $Aa$  and  $aa$ . Indeed, the situation is identical to the second row with  $a$  and  $A$  switched. The resulting probabilities are also the same after this same switch.
16. We have to multiply the initial probability vector into the transition matrix and do the arithmetic. For the first coordinate, we obtain

$$\frac{1}{16} \times 1 + \frac{1}{4} \times 0.25 + \frac{1}{4} \times 0.0625 = \frac{9}{64}.$$

The other five elements are calculated in a similar fashion. The resulting vector is

$$\left( \frac{9}{64}, \frac{3}{16}, \frac{1}{32}, \frac{5}{16}, \frac{3}{16}, \frac{9}{64} \right).$$

17. (a) We are asked to find the conditional distribution of  $X_n$  given  $X_{n-1} = \{Aa, aa\}$  and  $X_{n+1} = \{AA, aa\}$ . For each possible state  $x_n$ , we can find

$$\begin{aligned} & \Pr(X_n = x_n | X_{n-1} = \{Aa, aa\}, X_{n+1} = \{AA, aa\}) \\ &= \frac{\Pr(X_n = x_n, X_{n+1} = \{AA, aa\} | X_{n-1} = \{Aa, aa\})}{\Pr(X_{n+1} = \{AA, aa\} | X_{n-1} = \{Aa, aa\})}. \end{aligned} \tag{S.3.4}$$

The denominator is 0.0313 from the 2-step transition matrix in Example 3.10.9. The numerator is the product of two terms from the 1-step transition matrix: one from  $\{Aa, aa\}$  to  $x_n$  and the other from  $x_n$  to  $\{AA, aa\}$ . These products are as follows:

	$x_n$					
	$\{AA, AA\}$	$\{AA, Aa\}$	$\{AA, aa\}$	$\{Aa, Aa\}$	$\{Aa, aa\}$	$\{aa, aa\}$
	0	0	0	$0.25 \times 0.125$	0	0

Plugging these into (S.3.4) gives

$$\Pr(X_n = \{Aa, Aa\} | X_{n+1} = \{Aa, aa\}, X_{n+2} = \{AA, aa\}) = 1,$$

and all other states have probability 0.

(b) This time, we want

$$\begin{aligned} & \Pr(X_n = x_n | X_{n-1} = \{Aa, aa\}, X_{n+1} = \{aa, aa\}) \\ &= \frac{\Pr(X_n = x_n, X_{n+1} = \{aa, aa\} | X_{n-1} = \{Aa, aa\})}{\Pr(X_{n+1} = \{aa, aa\} | X_{n-1} = \{Aa, aa\})}. \end{aligned}$$

The denominator is 0.3906. The numerator products and their ratios to the denominator are:

$x_n$	$\{AA, AA\}$	$\{AA, Aa\}$	$\{AA, aa\}$	$\{Aa, Aa\}$	$\{Aa, aa\}$	$\{aa, aa\}$
Numerator	0	0	0	$0.25 \times 0.0625$	$0.5 \times 0.25$	$0.25 \times 1$
Ratio	0	0	0	0.0400	0.3200	0.6400

This time, we get

$$\Pr(X_n = x_n | X_{n-1} = \{Aa, aa\}, X_{n+1} = \{Aa, Aa\}) = \begin{cases} 0.04 & \text{if } x_n = \{Aa, Aa\}, \\ 0.32 & \text{if } x_n = \{Aa, aa\}, \\ 0.64 & \text{if } x_n = \{aa, aa\}, \end{cases}$$

and all others are 0.

18. We can see from the 2-step transition matrix that it is possible to get from every non-absorbing state into each of the absorbing states in two steps. So, no matter what non-absorbing state we start in, the probability is one that we will eventually end up in one of absorbing states. Hence, no distribution with positive probability on any non-absorbing state can be a stationary distribution.
19. The matrix  $\mathbf{G}$  and its inverse are

$$\begin{aligned} \mathbf{G} &= \begin{pmatrix} -0.3 & 1 \\ 0.6 & 1 \end{pmatrix}, \\ \mathbf{G}^{-1} &= -\frac{10}{9} \begin{pmatrix} 1 & -1 \\ -0.6 & -0.3 \end{pmatrix}. \end{aligned}$$

The bottom row of  $\mathbf{G}^{-1}$  is  $(2/3, 1/3)$ , the unique stationary distribution.

20. The argument is essentially the same as in Exercise 18. All probability in non-absorbing states eventually moves into the absorbing states after sufficiently many transitions.

## 3.11 Supplementary Exercises

### Solution to Exercises

1. We can calculate the c.d.f. of  $Z$  directly.

$$\begin{aligned} F(z) &= \Pr(Z \leq z) = \Pr(Z = X) \Pr(X \leq z) + \Pr(Z = Y) \Pr(Y \leq z) \\ &= \frac{1}{2} \Pr(X \leq z) + \frac{1}{2} \Pr(Y \leq z) \end{aligned}$$

The graph is in Fig. S.3.35.

Figure S.3.35: Graph of c.d.f. for Exercise 1 of Sec. 3.11.

2. Let  $x_1, \dots, x_k$  be the finitely many values for which  $f_1(x) > 0$ . Since  $X$  and  $Y$  are independent, the conditional distribution of  $Z = X + Y$  given  $X = x$  is the same as the distribution of  $x + Y$ , which has the p.d.f.  $f_2(z - x)$ , and the c.d.f.  $F_2(z - x)$ . By the law of total probability the c.d.f. of  $Z$  is  $\sum_{i=1}^k F_2(z - x_i)f_1(x_i)$ . Notice that this is a weighted average of continuous functions of  $z$ ,  $F_2(z - x_i)$  for  $i = 1, \dots, k$ , hence it is a continuous function. The p.d.f. of  $Z$  can easily be found by differentiating the c.d.f. to obtain  $\sum_{i=1}^k f_2(z - x_i)f_1(x_i)$ .
3. Since  $F(x)$  is continuous and differentiable everywhere except at the points  $x = 0, 1$ , and  $2$ ,

Figure S.3.36: Graph of c.d.f. for Exercise 3 of Sec. 3.11.

$$f(x) = \frac{dF(x)}{dx} \begin{cases} \frac{2}{5} & \text{for } 0 < x < 1, \\ \frac{3}{5} & \text{for } 1 < x < 2, \\ 0 & \text{otherwise.} \end{cases}$$

4. Since  $f(x)$  is symmetric with respect to  $x = 0$ ,  $F(0) = Pr(X \leq 0) = 0.5$ . Hence,

$$\int_0^{x_0} f(x) dx = \frac{1}{2} \int_0^{x_0} \exp(-x) dx = .4.$$

It follows that  $\exp(-x_0) = .2$  and  $x_0 = \log 5$ .

5.  $X_1$  and  $X_2$  have the uniform distribution over the square, which has area 1. The area of the quarter circle in Fig. S.3.37, which is the required probability, is  $\pi/4$ .

Figure S.3.37: Region for Exercise 5 of Sec. 3.11.

6. (a)  $\Pr(X \text{ divisible by } n) = f(n) + f(2n) + f(3n) + \dots = \sum_{x=1}^{\infty} \frac{1}{c(p)} \frac{1}{(nx)^p} = \frac{1}{n^p}$ .  
 (b) By part (a),  $\Pr(X \text{ even}) = 1/2^p$ . Therefore,  $\Pr(X \text{ odd}) = 1 - 1/2^p$ .

7.

$$\begin{aligned}\Pr(X_1 + X_2 \text{ even}) &= \Pr(X_1 \text{ even}) \Pr(X_2 \text{ even}) + \Pr(X_1 \text{ odd}) \Pr(X_2 \text{ odd}) \\ &= \left(\frac{1}{2^p}\right) \left(\frac{1}{2^p}\right) + \left(1 - \frac{1}{2^p}\right) \left(1 - \frac{1}{2^p}\right) \\ &= 1 - \frac{1}{2^{p-1}} + \frac{1}{2^{2p-1}}.\end{aligned}$$

8. Let  $G(x)$  denote the c.d.f. of the time until the system fails, let  $A$  denote the event that component 1 is still operating at time  $x$ , and let  $B$  denote the event that at least one of the other three components is still operating at time  $x$ . Then

$$1 - G(x) = \Pr(\text{System still operating at time } x) = \Pr(A \cap B) = \Pr(A) \Pr(B) = [1 - F(x)][1 - F^3(x)].$$

$$\text{Hence, } G(x) = F(x)[1 + F^2(x) - F^3(x)].$$

9. Let  $A$  denote the event that the tack will land with its point up on all three tosses. Then  $\Pr(A | X = x) = x^3$ . Hence,

$$\Pr(A) = \int_0^1 x^3 f(x) dx = \frac{1}{10}.$$

10. Let  $Y$  denote the area of the circle. Then  $Y = \pi X^2$ , so the inverse transformation is

$$x = (y/\pi)^{1/2} \quad \text{and} \quad \frac{dx}{dy} = \frac{1}{2(\pi y)^{1/2}}.$$

Also, if  $0 < x < 2$ , then  $0 < y < 4\pi$ . Thus,

$$g(y) = \frac{1}{16(\pi y)^{1/2}} \left[ 3 \left( \frac{y}{\pi} \right)^{1/2} + 1 \right] \quad \text{for } 0 < y < 4\pi$$

and  $g(y) = 0$  otherwise.

11.  $F(x) = 1 - \exp(-2x)$  for  $x > 0$ . Therefore, by the probability integral transformation,  $F(X)$  will have the uniform distribution on the interval  $[0, 1]$ . Therefore,

$$Y = 5F(X) = 5(1 - \exp(-2X))$$

will have the uniform distribution on the interval  $[0, 5]$ .

It might be noted that if  $Z$  has the uniform distribution on the interval  $[0, 1]$ , then  $1 - Z$  has the same uniform distribution. Therefore,

$$Y = 5[1 - F(X)] = 5\exp(-2X)$$

will also have the uniform distribution on the interval  $[0, 5]$ .

12. This exercise, in different words, is exactly the same as Exercise 7 of Sec. 1.7 and, therefore, the solution is the same.
13. Only in (c) and (d) is the joint p.d.f. of  $X$  and  $Y$  positive over a rectangle with sides parallel to the axes, so only in (c) and (d) is there the possibility of  $X$  and  $Y$  being independent. Since the uniform density is constant, it can be regarded as being factored in the form of Eq. (3.5.7). Hence,  $X$  and  $Y$  are independent in (c) and (d).
14. The required probability  $p$  is the probability of the shaded area in Fig. S.3.38. Therefore,

Figure S.3.38: Figure for Exercise 14 of Sec. 3.11.

$$p = 1 - \Pr(A) = 1 - \int_0^{1/2} \int_0^y f_1(x) f_2(y) dx dy = 1 - 1/3 = 2/3.$$

15. This problem is similar to Exercise 11 of Sec. 3.5, but now we have Fig. S.3.39. The area of the shaded region is now  $550 + 787.5 = 1337.5$ . Hence, the required probability is  $\frac{1337.5}{3600} = .3715$

16. For  $0 < x < 1$ ,

$$f_1(x) = \int_x^1 2(x+y) dy = 1 + 2x - 3x^2.$$

$$\text{Therefore, } \Pr\left(X < \frac{1}{2}\right) = \int_0^{1/2} f_1(x) dx = \frac{1}{2} + \frac{1}{4} - \frac{1}{8} = \frac{5}{8}.$$

Finally, for  $0 < x, y < 1$ ,

$$g_2(y | x) = \frac{f(x, y)}{f_1(x)} = \frac{2(x+y)}{1 + 2x - 3x^2}.$$

Figure S.3.39: Figure for Exercise 15 of Sec. 3.11.

17.  $f(x, y) = f(x) g(y | x) = \frac{9y^2}{x}$  for  $0 < y < x < 1$ .

Hence,

$$f_2(y) = \int_y^1 f(x, y) dx = -9y^2 \log(y) \quad \text{for } 0 < y < 1$$

and

$$g_1(x | y) = \frac{f(x, y)}{f_2(y)} = -\frac{1}{x \log(y)} \quad \text{for } 0 < y < x < 1.$$

18.  $X$  and  $Y$  have the uniform distribution over the region shown in Fig. S.3.40. The area of this region is

Figure S.3.40: Region for Exercise 18 of Sec. 3.11.

4. The area in the second plus the fourth quadrants is 1. Therefore, the area in the first plus the third quadrants is 3, and

$$\Pr(XY > 0) = \frac{3}{4}.$$

Furthermore, for any value of  $x$  ( $-1 < x < 1$ ), the conditional distribution of  $Y$  given that  $X = x$  will be a uniform distribution over the interval  $[x - 1, x + 1]$ . Hence,

$$g_2(y|x) = \begin{cases} \frac{1}{2} & \text{for } x - 1 < y < x + 1, \\ 0 & \text{otherwise.} \end{cases}$$

19.

$$\begin{aligned} f_1(x) &= \int_x^1 \int_y^1 6 \, dz \, dy = 3 - 6x + 3x^2 = 3(1-x)^2 \quad \text{for } 0 < x < 1, \\ f_2(y) &= \int_0^y \int_y^1 6 \, dz \, dx = 6y(1-y) \quad \text{for } 0 < y < 1. \\ f_3(z) &= \int_0^z \int_0^y 6 \, dx \, dy = 3z^2 \quad \text{for } 0 < z < 1. \end{aligned}$$

20. Since  $f(x, y, z)$  can be factored in the form  $g(x, y)h(z)$  it follows that  $Z$  is independent of the random variables  $X$  and  $Y$ . Hence, the required conditional probability is the same as the unconditional probability  $\Pr(3X > Y)$ . Furthermore, it follows from the factorization just given that the marginal p.d.f.  $h(z)$  is constant for  $0 < z < 1$ . Thus, this constant must be 1 and the marginal joint p.d.f. of  $X$  and  $Y$  must be simply  $g(x, y) = 2$ , for  $0 < x < y < 1$ . Therefore,

$$\Pr(3X > Y) = \int_0^1 \int_{y/3}^y 2 \, dx \, dy = \frac{2}{3}.$$

The range of integration is illustrated in Fig. S.3.41.

Figure S.3.41: Range of integration for Exercise 20 of Sec. 3.11.

21. (a)  $f(x, y) = \begin{cases} \exp(-(x+y)) & \text{for } x > 0, y > 0, \\ 0 & \text{otherwise.} \end{cases}$

Also,  $x = uv$  and  $y = (1-u)v$ , so

$$J = \begin{vmatrix} v & u \\ -v & 1-u \end{vmatrix} = v > 0.$$

Therefore,

$$g(u, v) = f(uv, [1-u]v) | J | = \begin{cases} v \exp(-v) & \text{for } 0 < u < 1, v > 0, \\ 0 & \text{otherwise.} \end{cases}$$

- (b) Because  $g$  can be appropriately factored (the factor involving  $u$  is constant) and it is positive over an appropriate rectangle, it follows that  $U$  and  $V$  are independent.
22. Here,  $x = uv$  and  $y = v$ , so

$$J = \begin{vmatrix} v & u \\ 0 & 1 \end{vmatrix} = v > 0.$$

Therefore,

$$g(u, v) = f(uv, v) |J| = \begin{cases} 8uv^3 & \text{for } 0 \leq u \leq 1, 0 \leq v \leq 1, \\ 0 & \text{otherwise.} \end{cases}$$

$X$  and  $Y$  are not independent because  $f(x, y) > 0$  over a triangle, not a rectangle. However, it can be seen that  $U$  and  $V$  are independent.

23. Here,  $f(x) = \frac{dF(x)}{dx} = \exp(-x)$  for  $x > 0$ . It follows from the results in Sec. 3.9 that

$$g(y_1, y_n) = n(n-1)(\exp(-y_1) - \exp(-y_n))^{n-2} \exp(-(y_1 + y_n))$$

for  $0 < y_1 < y_n$ . Also, the marginal p.d.f. of  $Y_n$  is

$$g_n(y_n) = n(1 - \exp(-y_n))^{n-1} \exp(-y_n) \quad \text{for } y_n > 0.$$

Hence,

$$h(y_1 | y_n) = \frac{(n-1)(\exp(-y_1) - \exp(-y_n))^{n-2} \exp(-y_1)}{(1 - \exp(-y_n))^{n-1}} \quad \text{for } 0 < y_1 < y_n.$$

24. As in Example 3.9.7, let  $W = Y_n - Y_1$  and  $Z = Y_1$ . The joint p.d.f.  $g(w, z)$  of  $(W, Z)$  is, for  $0 < w < 1$  and  $0 < z < 1 - w$ ,

$$g(w, z) = 24[(w+z)^2 - z^2] z (w+z) = 24 w (2z^3 + 3wz^2 + w^2z),$$

and 0 otherwise. Hence, the p.d.f. of the range is, for  $0 < w < 1$ ,

$$h(w) = \int_0^{1-w} g(w, z) dz = 12w(1-w)^2.$$

25. (a) Let  $f_2$  be the marginal p.d.f. of  $Y$ . We approximate

$$\Pr(y - \epsilon < Y \leq y + \epsilon) = \int_{y-\epsilon}^{y+\epsilon} f_2(t) dt \approx 2\epsilon f_2(y).$$

- (b) For each  $s$ , we approximate

$$\int_{y-\epsilon}^{y+\epsilon} f(s, t) dt \approx 2\epsilon f(s, y).$$

Using this, we can approximate

$$\Pr(X \leq x, y - \epsilon < Y \leq y + \epsilon) = \int_{-\infty}^x \int_{y-\epsilon}^{y+\epsilon} f(s, t) dt ds \approx 2\epsilon \int_{-\infty}^x f(s, y) ds.$$

(c) Taking the ratio of the approximation in part (b) to the approximation in part (a), we obtain

$$\begin{aligned}\Pr(X \leq x | y - \epsilon < Y \leq y + \epsilon) &= \frac{\Pr(X \leq x, y - \epsilon < Y \leq y + \epsilon)}{\Pr(y - \epsilon < Y \leq y + \epsilon)} \\ &\approx \frac{\int_{-\infty}^x f(s, y) ds}{f_2(y)} \\ &= \int_{-\infty}^x g_1(s|y) ds.\end{aligned}$$

26. (a) Let  $Y = X_1$ . The transformation is  $Y = X_1$  and  $Z = X_1 - X_2$ . The inverse is  $x_1 = y$  and  $x_2 = y - z$ . The Jacobian has absolute value 1. The joint p.d.f. of  $(Y, Z)$  is

$$g(y, z) = \exp(-y - (y - z)) = \exp(-2y + z),$$

for  $y > 0$  and  $z < y$ .

(b) The marginal p.d.f. of  $Z$  is

$$\int_{\max\{0, z\}}^{\infty} \exp(-2y + z) dy = \frac{1}{2} \exp(z) \exp(-2 \max\{0, z\}) = \frac{1}{2} \begin{cases} \exp(-z) & \text{if } z \geq 0, \\ \exp(z) & \text{if } z < 0. \end{cases}$$

The conditional p.d.f. of  $Y = X_1$  given  $Z = 0$  is the ratio of these two with  $z = 0$ , namely

$$g_1(x_1|0) = 2 \exp(-2x_1), \text{ for } x_1 > 0.$$

(c) Let  $Y = X_1$ . The transformation is now  $Y = X_1$  and  $W = X_1/X_2$ . The inverse is  $x_1 = y$  and  $x_2 = y/w$ . The Jacobian is

$$J = \det \begin{pmatrix} 1 & 0 \\ 1/w & -y/w^2 \end{pmatrix} = -\frac{y}{w^2}.$$

The joint p.d.f. of  $(Y, W)$  is

$$g(y, w) = \exp(-y - y/w)y/w^2 = y \exp(-y(1 + 1/w))/w^2,$$

for  $y, w > 0$ .

(d) The marginal p.d.f. of  $W$  is

$$\int_0^{\infty} y \exp(-y(1 + 1/w))/w^2 dy = \frac{1}{w^2(1 + 1/w)^2} = \frac{1}{(1 + w)^2},$$

for  $w > 0$ . The conditional p.d.f. of  $Y = X_1$  given  $W = 1$  is the ratio of these two with  $w = 1$ , namely

$$h_1(x_1|1) = 4x_1 \exp(-2x_1), \text{ for } x_1 > 0.$$

(e) The conditional p.d.f.  $g_1$  in part (b) is supposed to be the conditional p.d.f. of  $X_1$  given that  $Z$  is close to 0, that is, that  $|X_1 - X_2|$  is small. The conditional p.d.f.  $h_1$  in part (d) is supposed to be the conditional p.d.f. of  $X_1$  given that  $W$  is close to 1, that is, that  $|X_1/X_2 - 1|$  is small. The sets of  $(x_1, x_2)$  values such that  $|x_1 - x_2|$  is small and that  $|x_1/x_2 - 1|$  is small are drawn in Fig. S.3.42. One can see how the two sets, although close, are different enough to account for different conditional distributions.

27. The transition matrix is as follows:

		Players in game $n + 1$		
		$(A, B)$	$(A, C)$	$(B, C)$
Players in game $n$	$(A, B)$	0	0.3	0.7
	$(A, C)$	0.6	0	0.4
	$(B, C)$	0.8	0.2	0

Figure S.3.42: Boundaries of the two regions where  $|x_1 - x_2| < 0.1$  and  $|x_1/x_2 - 1| < 0.1$  in Exercise 26e of Sec. 3.11.

28. If  $A$  and  $B$  play in the first game, then there are the following two sequences of outcomes which result in their playing in the fourth game:

- i)  $A$  beats  $B$  in the first game,  $C$  beats  $A$  in the second game,  $B$  beats  $C$  in the third game;
- ii)  $B$  beats  $A$  in the first game,  $C$  beats  $B$  in the second game,  $A$  beats  $C$  in the third game.

The probability of the first sequence is  $(0.3)(0.4)(0.8) = 0.096$ . The probability of the second sequence is  $(0.7)(0.2)(0.6) = 0.084$ . Therefore, the overall probability that  $A$  and  $B$  will play again in the fourth game is 0.18. The same sort of calculations show that this answer will be the same if  $A$  and  $C$  play in the first game or if  $B$  and  $C$  play in the first game.

29. The matrix  $\mathbf{G}$  and its inverse are

$$\begin{aligned}\mathbf{G} &= \begin{pmatrix} -1.0 & 0.3 & 1.0 \\ 0.6 & -1.0 & 1.0 \\ 0.8 & 0.2 & 1.0 \end{pmatrix}, \\ \mathbf{G}^{-1} &= \begin{pmatrix} -0.5505 & -0.4587 & 0.5963 \\ 0.0917 & -0.8257 & 0.7339 \\ 0.4220 & 0.2018 & 0.3761 \end{pmatrix}.\end{aligned}$$

The bottom row of  $\mathbf{G}^{-1}$  is the unique stationary distribution,  $(0.4220, 0.2018, 0.3761)$ .

## Expectation

### 4.1 The Expectation of a Random Variable

#### Commentary

It is useful to stress the fact that the expectation of a random variable depends only on the distribution of the random variable. Every two random variables with the same distribution will have the same mean. This also applies to variance (Sec. 4.3), other moments and m.g.f. (Sec. 4.4), and median (Sec. 4.5). For this reason, one often refers to means, variance, quantiles, etc. of a distribution rather than of a random variable. One need not even have a random variable in mind in order to calculate the mean of a distribution.

#### Solutions to Exercises

1. The mean of  $X$  is

$$E(X) = \int x f(x) dx = \int_a^b \frac{x}{b-a} dx = \frac{b^2 - a^2}{2(b-a)} = \frac{a+b}{2}.$$

$$2. E(X) = \frac{1}{100}(1 + 2 + \dots + 100) = \frac{1}{100} \frac{(100)(101)}{2} = 50.5.$$

3. The total number of students is 50. Therefore,

$$E(X) = 18\left(\frac{20}{50}\right) + 19\left(\frac{22}{50}\right) + 20\left(\frac{4}{50}\right) + 21\left(\frac{3}{50}\right) + 25\left(\frac{1}{50}\right) = 18.92.$$

4. There are eight words in the sentence and they are each equally probable. Therefore, the possible values of  $X$  and their probabilities are as follows:

$x$	$f(x)$
2	1/8
3	5/8
4	1/8
9	1/8

It follows that  $E(X) = 2\left(\frac{1}{8}\right) + 3\left(\frac{5}{8}\right) + 4\left(\frac{1}{8}\right) + 9\left(\frac{1}{8}\right) = 3.75$ .

5. There are 30 letters and they are each equally probable:

2 letters appear in the only two-letter word;

15 letters appear in three-letter words;

4 letters appear in the only four-letter word;

9 letters appear in the only nine-letter word.

Therefore, the possible values of  $Y$  and their probabilities are as follows:

$y$	$g(y)$
2	2/30
3	15/30
4	4/30
9	9/30

$$E(Y) = 2\left(\frac{2}{30}\right) + 3\left(\frac{15}{30}\right) + 4\left(\frac{4}{30}\right) + 9\left(\frac{9}{30}\right) = 4.867.$$

$$6. E\left(\frac{1}{X}\right) = \int_0^1 \frac{1}{x} \cdot 2x dx = 2.$$

$$7. E\left(\frac{1}{X}\right) = \int_0^1 \frac{1}{x} dx = -\lim_{x \rightarrow 0} \log(x) = \infty. \text{ Since the integral is not finite, } E\left(\frac{1}{X}\right) \text{ does not exist.}$$

$$8. E(XY) = \int_0^1 \int_0^x xy \cdot 12y^2 dy dx = \frac{1}{2}.$$

9. If  $X$  denotes the point at which the stick is broken, then  $X$  has the uniform distribution on the interval  $[0, 1]$ . If  $Y$  denotes the length of the longer piece, then  $Y = \max\{X, 1 - X\}$ . Therefore,

$$E(Y) = \int_0^1 \max(x, 1 - x) dx = \int_0^{1/2} (1 - x) dx + \int_{1/2}^1 x dx = \frac{3}{4}.$$

10. Since  $\alpha$  has the uniform distribution on the interval  $[-\pi/2, \pi/2]$ , the p.d.f. of  $\alpha$  is

$$f(\alpha) = \begin{cases} \frac{1}{\pi} & \text{for } -\frac{\pi}{2} < \alpha < \frac{\pi}{2}, \\ 0 & \text{otherwise.} \end{cases}$$

Figure S.4.1: Figure for Exercise 10 of Sec. 4.1.

Also,  $Y = \tan(\alpha)$ . Therefore, the inverse transformation is  $\alpha = \tan^{-1} Y$  and  $d\alpha/dy = 1/(1+y^2)$ . As  $\alpha$  varies over the interval  $(-\pi/2, \pi/2)$ ,  $Y$  varies over the entire real line. Therefore, for  $-\infty < y < \infty$ , the p.d.f. of  $Y$  is

$$g(y) = f(\tan^{-1} y) \frac{1}{1+y^2} = \frac{1}{\pi(1+y^2)}.$$

11. The p.d.f.'s of  $Y_1$  and  $Y_n$  were found in Sec. 3.9. For the given uniform distribution, the p.d.f. of  $Y_1$  is

$$g_1(y) = \begin{cases} n(1-y)^{n-1} & \text{for } 0 < y < 1, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore,

$$E(Y_1) = \int_0^1 y n(1-y)^{n-1} dy = \frac{1}{n+1}.$$

The p.d.f. of  $Y_n$  is

$$g_n(y) = \begin{cases} ny^{n-1} & \text{for } 0 < y < 1, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore,

$$E(Y_n) = \int_0^1 y \cdot ny^{n-1} dy = \frac{n}{n+1}.$$

12. It follows from the probability integral transformation that the joint distribution of  $F(X_1), \dots, F(X_n)$  is the same as the joint distribution of a random sample from the uniform distribution on the interval  $[0, 1]$ . Since  $F(Y_1)$  is the smallest of these values and  $F(Y_n)$  is the largest, the distributions of these variables will be the same as the distributions of the smallest and the largest values in a random sample from the uniform distribution on the interval  $[0, 1]$ . Therefore,  $E[F(Y_1)]$  and  $E[F(Y_n)]$  will be equal to the values found in Exercise 11.
13. Let  $p = \Pr(X = 300)$ . Then  $E(X) = 300p + 100(1-p) = 200p + 100$ . For risk-neutrality, we need  $E(X) = 110 * (1.058) = 116.38$ . Setting  $200p + 100 = 116.38$  yields  $p = 0.0819$ . The option has a value of 150 if  $X = 300$  and it has a value of 0 if  $X = 100$ , so the mean of the option value is  $150p = 12.285$ . The present value of this amount is  $12.285/1.058 = 11.61$ , the risk-neutral price of the option.
14. For convenience, we shall not use dollar signs in these calculations.

- (a) We need to check the investor's net worth at the end of the year in four situations:
- i.  $X = 180$  and she makes the transactions
  - ii.  $X = 180$  and she doesn't make the transactions
  - iii.  $X = 260$  and she makes the transactions
  - iv.  $X = 260$  and she doesn't make the transactions

Since we don't know the investor's entire net worth, we shall only calculate it relative to all other investments. This means that we only need to pretend as if the investor had one share of the stock worth 200. We don't care what else she has. We need to show that cases (i) and (ii) lead to the same net worth and that cases (iii) and (iv) lead to the same net worth. In case (ii), her net worth will change by  $-20$ . In case (iv), her net worth will change by  $60$ . In case (i), nobody will exercise the options. So she will sell the three extra shares for 180 each (total 540) and pay the loan of 519.24 plus interest 20.77 for a net 0.01 loss. Plus her one original share of stock has lost 20 and her net worth has changed a total of  $-20.01$ , which is the same as case (i) except for the accumulated rounding error. In case (iii), the options will be exercised, and she will receive 800 for four shares of the stock. She will have to pay back the loan of 519.24 plus 20.77 in interest for a net gain of 259.99. But she no longer has the one share of stock that was worth 200, so her change in net worth is 59.99, the same as case (iv) to within the same one cent of rounding.

- (b) If the option price is  $x < 20.19$ , then the investor only receives  $4x$  for selling the options, but still needs to pay 600 for the three shares, so she must borrow  $600 - 4x$ . The rest of the calculations proceed just as in part (a) but we must replace 519.24 by  $600 - 4x$ , and the interest 20.77 must be replaced by  $0.04(600 - 4x)$ . That is, to pay back the loan with interest, she must pay  $624 - 4.16x$  instead of 540.01. So she pays an additional  $83.99 - 4.16x$  relative to the situation in case (a) regardless of what happens to the stock price.
  - (c) This situation is the same as part (b) except now the value of  $83.99 - 4.16x$  is negative instead of positive, so the investor pays back less and hence makes additional profit rather than suffers additional loss.
15. The value of the option is 0 if  $X = 260$  and it is 40 if  $X = 180$ , so the expected value of the option is  $40(1 - p) = 40 \times 0.65 = 26$ . The present value of this amount is  $26/1.04 = 25$ .
16. If  $f$  is the p.f. of  $X$ , and  $Y = |X|$ , then for  $y \geq 0$ ,  $\Pr(Y = y) = \Pr(X = y) + \Pr(X = -y)$ . In Example 4.1.4,  $\Pr(X = y) = \Pr(X = -y) = 1/[2y(y + 1)]$ , and this makes  $\Pr(Y = y)$  the p.f. in Example 4.1.5.

## 4.2 Properties of Expectations

### Commentary

Be sure to stress the fact that Theorem 4.2.6 on the expected value of a product of random variables has the condition that the random variables are independent. This section ends with a derivation for the expectation of a nonnegative discrete random variable. Although this method has theoretical interest, it is not central to the rest of the text.

### Solutions to Exercises

1. The random variable  $Y$  is equal to  $10(R - 1.5)$  in dollars. The mean of  $Y$  is  $10[E(R) - 1.5]$ . From Exercise 1 in Sec. 4.1, we know that  $E(R) = (-3 + 7)/2 = 2$ , so  $E(Y) = 5$ .
2.  $E(2X_1 - 3X_2 + X_3 - 4) = 2E(X_1) - 3E(X_2) + E(X_3) - 4 = 2(5) - 3(5) + 5 - 4 = -4$ .
- 3.

$$\begin{aligned} E[(X_1 - 2X_2 + X_3)^2] &= E(X_1^2 + 4X_2^2 + X_3^2 - 4X_1X_2 + 2X_1X_3 - 4X_2X_3) \\ &= E(X_1^2) + 4E(X_2^2) + E(X_3^2) - 4E(X_1X_2) \\ &\quad + 2E(X_1X_3) - 4E(X_2X_3). \end{aligned}$$

Since  $X_1, X_2$ , and  $X_3$  are independent,

$$E(X_i X_j) = E(X_i)E(X_j) \quad \text{for } i \neq j.$$

Therefore, the above expectation can be written in the form:

$$E(X_1^2) + 4E(X_2^2) + E(X_3^2) - 4E(X_1)E(X_2) + 2E(X_1)E(X_3) - 4E(X_2)E(X_3).$$

Also, since each  $X_i$  has the uniform distribution on the interval  $[0, 1]$ , then  $E(X_i) = \frac{1}{2}$  and

$$E(X_i^2) = \int_0^1 x^2 dx = \frac{1}{3}.$$

Hence, the desired expectation has the value  $1/2$ .

4. The area of the rectangle is  $XY$ . Since  $X$  and  $Y$  are independent,  $E(XY) = E(X)E(Y)$ . Also,  $E(X) = 1/2$  and  $E(Y) = 7$ . Therefore,  $E(XY) = 7/2$ .
5. For  $i = 1, \dots, n$ , let  $Y_i = 1$  if the observation  $X_i$  falls within the interval  $(a, b)$ , and let  $Y_i = 0$  otherwise. Then  $E(Y_i) = \Pr(Y_i = 1) = \int_a^b f(x)dx$ . The total number of observations that fall within the interval  $(a, b)$  is  $Y_1 + \dots + Y_n$ , and

$$E(Y_1 + \dots + Y_n) = E(Y_1) + \dots + E(Y_n) = n \int_a^b f(x)dx.$$

6. Let  $X_i = 1$  if the  $i$ th jump of the particle is one unit to the right and let  $X_i = -1$  if the  $i$ th jump is one unit to the left. Then, for  $i = 1, \dots, n$ ,

$$E(X_i) = (-1)p + (1)(1-p) = 1 - 2p.$$

The position of the particle after  $n$  jumps is  $X_1 + \dots + X_n$ , and

$$E(X_1 + \dots + X_n) = E(X_1) + \dots + E(X_n) = n(1 - 2p).$$

7. For  $i = 1, \dots, n$ , let  $X_i = 2$  if the gambler's fortune is doubled on the  $i$ th play of the game and let  $X_i = 1/2$  if his fortune is cut in half on the  $i$ th play. Then

$$E(X_i) = 2\left(\frac{1}{2}\right) + \left(\frac{1}{2}\right)\left(\frac{1}{2}\right) = \frac{5}{4}.$$

After the first play of the game, the gambler's fortune will be  $cX_1$ , after the second play it will be  $(cX_1)X_2$ , and by continuing in this way it is seen that after  $n$  plays the gambler's fortune will be  $cX_1 \dots X_n$ . Since  $X_1, \dots, X_n$  are independent,

$$E(cX_1 \dots X_n) = cE(X_1) \dots E(X_n) = c\left(\frac{5}{4}\right)^n.$$

8. It follows from Example 4.2.4 that

$$E(X) = 8\left(\frac{10}{25}\right) = \frac{16}{5}.$$

Since  $Y = 8 - X$ ,  $E(Y) = 8 - E(X) = \frac{24}{5}$ . Finally,  $E(X - Y) = E(X) - E(Y) = -\frac{8}{5}$ .

9. We know that  $E(X) = np$ . Since  $Y = n - X$ ,  $E(X - Y) = E(2X - n) = 2E(X) - n = n(2p - 1)$ .
10. (a) Since the probability of success on any trial is  $p = 1/2$ , it follows from the material presented at the end of this section that the expected number of tosses is  $1/p = 2$ .
- (b) The number of tails that will be obtained is equal to the total number of tosses minus one (the final head). Therefore, the expected number of tails is  $2 - 1 = 1$ .
11. We shall use the notation presented in the hint for this exercise. It follows from part (a) of Exercise 10 that  $E(X_i) = 2$  for  $i = 1, \dots, k$ . Therefore,

$$E(X) = E(X_1) + \dots + E(X_k) = 2k.$$

12. (a) We need the p.d.f. of  $X = 54R_1 + 110R_2$  where  $R_1$  has the uniform distribution on the interval  $[-10, 20]$  and  $R_2$  has the uniform distribution on the interval  $[-4.5, 10]$ . We can rewrite  $X$  as  $X_1 + X_2$  where  $X_1 = 54R_1$  has the uniform distribution on the interval  $[-540, 1080]$  and  $X_2 = 110R_2$  has the uniform distribution on the interval  $[-495, 1100]$ . Let  $f_i$  be the p.d.f. of  $X_i$  for  $i = 1, 2$ , and use the same technique as in Example 3.9.5. First, compute

$$f_1(z)f_2(x - z) = \begin{cases} 3.87 \times 10^{-7} & \text{for } -540 \leq z \leq 1080 \text{ and } -495 \leq x - z \leq 1100, \\ 0 & \text{otherwise.} \end{cases}$$

We need to integrate this over  $z$  for each fixed  $x$ . The set of  $x$  for which the function above is ever positive is the interval  $[-1035, 2180]$ . For  $-1035 \leq x < 560$ , we must integrate  $z$  from  $-540$  to  $x + 495$ . For  $560 \leq x < 585$ , we must integrate  $z$  from  $x - 1100$  to  $x + 495$ . For  $585 \leq x \leq 2180$ , we must integrate  $z$  from  $x - 1100$  to  $1080$ . The resulting integral is

$$g(x) = \begin{cases} 3.87 \times 10^{-7}x + 4.01 \times 10^{-4} & \text{for } -1035 \leq x < 560, \\ 6.17 \times 10^{-4} & \text{for } 560 \leq x < 585, \\ 8.44 \times 10^{-4} - 3.87 \times 10^{-7}x & \text{for } 585 \leq x \leq 2180. \end{cases}$$

- (b) We need the negative of the 0.03 quantile. For  $-1035 \leq x \leq 560$ , the c.d.f. of  $X$  is

$$F(x) = \frac{3.87 \times 10^{-7}(x^2 - 1035^2)}{2} + 4.01 \times 10^{-4}(x + 1035).$$

This function is a second degree polynomial in  $x$ . To be sure that the 0.03 quantile is between  $-1035$  and  $560$ , we compute  $F(-1035) = 0$  and  $F(560) = 0.493$ , which assures us that the 0.03 quantile is in this range. Setting  $F(x) = 0.03$  and solving for  $x$  using the quadratic formula yields  $x = -642.4$ , so VaR is  $642.4$ .

13. Use Taylor's theorem with remainder to write

$$g(X) = g(\mu) + (X - \mu)g'(\mu) + \frac{(X - \mu)^2}{2}g''(Y), \quad (\text{S.4.1})$$

where  $\mu = E(X)$  and  $Y$  is between  $X$  and  $\mu$ . Take the mean of both sides of (S.4.1). We get

$$E[g(X)] = g(\mu) + 0 + E\left(\frac{(X - \mu)^2}{2}g''(Y)\right).$$

The random variable whose mean is on the far right is nonnegative, hence the mean is nonnegative and  $E[g(X)] \geq g(\mu)$ .

## 4.3 Variance

### Commentary

Be sure to stress the fact that Theorem 4.3.5 on the variance of a sum of random variables has the condition that the random variables are independent.

### Solutions to Exercises

1. We found in Exercise 1 of Sec. 4.1 that  $E(X) = (0 + 1)/2 = 1/2$ . We can find

$$E(X^2) = \int_0^1 x^2 dx = \frac{1}{3}.$$

So  $\text{Var}(X) = 1/3 - (1/2)^2 = 1/12$ .

2. The p.f. of  $X$  and the value of  $E(X)$  were determined in Exercise 4 of Sec. 4.1. From the p.f. given there we also find that

$$E(X^2) = 2^2\left(\frac{1}{8}\right) + 3^2\left(\frac{5}{8}\right) + 4^2\left(\frac{1}{8}\right) + 9^2\left(\frac{1}{8}\right) = \frac{73}{4}.$$

Therefore,  $\text{Var}(X) = E(X^2) - [E(X)]^2 = \frac{73}{4} - \left(\frac{15}{4}\right)^2 = \frac{67}{16}$ .

3. The p.d.f. of this distribution is

$$f(x) = \begin{cases} \frac{1}{b-a} & \text{for } a < x < b, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore,  $E(X) = \frac{b+a}{2}$  and

$$E(X^2) = \int_a^b x^2 \frac{1}{b-a} dx = \frac{b^3 - a^3}{3(b-a)} = \frac{1}{3}(b^2 + ab + a^2).$$

It follows that  $\text{Var}(X) = E(X^2) - [E(X)]^2 = \frac{1}{12}(b-a)^2$ .

4.  $E[X(X-1)] = E(X^2 - X) = E(X^2) - \mu = \text{Var}(X) + [E(X)]^2 - \mu = \sigma^2 + \mu^2 - \mu$ .
5.  $E[(X-c)^2] = E(X^2) - 2cE(X) + c^2 = \text{Var}(X) + [E(X)]^2 - 2c\mu + c^2 = \sigma^2 + \mu^2 - 2c\mu + c^2 = \sigma^2 + (\mu-c)^2$ .
6. Since  $E(X) = E(Y)$ ,  $E(X-Y) = 0$ . Therefore,

$$E[(X-Y)^2] = \text{Var}(X-Y) = \text{Var}[X+(-Y)].$$

Since  $X$  and  $-Y$  are independent, it follows that

$$E[(X-Y)^2] = \text{Var}(X) + \text{Var}(-Y) = \text{Var}(X) + \text{Var}(Y).$$

7. (a) Since  $X$  and  $Y$  are independent,  $\text{Var}(X-Y) = \text{Var}(X) + \text{Var}(Y) = 3 + 3 = 6$ .
- (b)  $\text{Var}(2X-3Y+1) = 2^2 \text{Var}(X) + 3^2 \text{Var}(Y) = 4(3) + 9(3) = 39$ .

8. Consider a p.d.f. of the form

$$f(x) = \begin{cases} c\frac{1}{x^3} & \text{for } x \geq 1, \\ 0 & \text{for } x < 1. \end{cases}$$

Here,

$$E(X) = \int_1^\infty c\frac{1}{x^2}dx < \infty$$

but

$$E(X^2) = \int_1^\infty c\frac{1}{x}dx \quad \text{is not finite.}$$

Therefore,  $E(X)$  is finite but  $E(X^2)$  is not. Therefore,  $\text{Var}(X)$  is not finite.

9. The mean of  $X$  is  $(n+1)/2$ , and the mean of  $X^2$  is  $\sum_{k=1}^n k^2/n = (n+1)(2n+1)/6$ . So,

$$\text{Var}(X) = \frac{(n+1)(2n+1)}{6} - \frac{(n+1)^2}{4} = \frac{n^2 - 1}{12}.$$

10. The example efficient portfolio has  $s_1 = 524.7$ ,  $s_2 = 609.7$ , and  $s_3 = 39250$ .

- (a) We know that  $R_1$  has a mean of 6 and a variance of 55, while  $R_2$  has a mean of 4 and a variance of 28. Since we are assuming that  $R_i$  has the uniform distribution on the interval  $[a_i, b_i]$  for  $i = 1, 2$ , we know that

$$\begin{aligned} E(R_i) &= \frac{a_i + b_i}{2}, \\ \text{Var}(R_i) &= \frac{(b_i - a_i)^2}{12}. \end{aligned}$$

(See Exercise 1 of this section for the variance of a uniform distribution.) For  $i = 1$ , we set  $(a_1 + b_1)/2 = 6$  and  $(b_1 - a_1)^2/12 = 55$ . The solution is  $a_1 = -6.845$  and  $b_1 = 18.845$ . For  $i = 2$ , we set  $(a_2 + b_2)/2 = 4$  and  $(b_2 - a_2)^2/12 = 28$ . The solution is  $a_2 = -5.165$  and  $b_2 = 13.165$ .

- (b) Let  $X_1 = s_1 R_1$  and  $X_2 = s_2 R_2$ . Then the distribution of  $X_1$  is the uniform distribution on the interval  $[-3591.6, 9888.0]$ , and  $X_2$  has the uniform distribution on the interval  $[-3149.1, 8026.7]$ . The value of the return on the portfolio is  $Y = X_1 + X_2 + 1413$ . We need to find the 0.03 quantile of  $Y$ . As in Exercise 12 of Sec. 4.2, the p.d.f. of  $Y$  will be linear for the lowest values of  $y$ . Those values are  $-5327.7 \leq y < 5848.1$ . The line is  $g(y) = 6.638 \times 10^{-9}y + 3.537 \times 10^{-5}$ . In this range, the c.d.f. is

$$G(y) = \frac{6.638 \times 10^{-9}}{2}(y^2 - 5327.7^2) + 3.537 \times 10^{-5}(y + 5327.7).$$

Since  $G(-5327.7) = 0$  and  $G(5848.1) = 0.4146$ , we know that the 0.03 quantile is in this range. Setting  $G(y) = 0.03$ , we find  $y = -2321.9$ . So VaR is 2321.9.

11. The quantile function of  $X$  can be found from Example 3.3.8 with  $a = 0$  and  $b = 1$ . It is  $F^{-1}(p) = p$ . So, the IQR is  $0.75 - 0.25 = 0.5$ .

12. The c.d.f. is  $F(x) = 1 - \exp(-x)$ , for  $x > 0$  and  $F(x) = 0$  for  $x \leq 0$ . The quantile function is  $F^{-1}(p) = -\log(1-p)$ . So, the 0.25 and 0.75 quantiles are respectively  $-\log(0.75) = 0.2877$  and  $-\log(0.25) = 1.3863$ . The IQR is then  $1.3863 - 0.2877 = 1.0986$ .
13. From Table 3.1, we find the 0.25 and 0.75 quantiles of the distribution of  $X$  to be 1 and 2 respectively. This makes the IQR equal to  $2 - 1 = 1$ .
14. The result will follow from the following general result: If  $x$  is the  $p$  quantile of  $X$  and  $a > 0$ , then  $ax$  is the  $p$  quantile of  $Y = aX$ . To prove this, let  $F$  be the c.d.f. of  $X$ . Note that  $x$  is the greatest lower bound on the set  $C_p = \{z : F(z) \geq p\}$ . Let  $G$  be the c.d.f. of  $Y$ , then  $G(z) = F(z/a)$  because  $Y \leq z$  if and only if  $aX \leq z$  if and only if  $X \leq z/a$ . The  $p$  quantile of  $Y$  is the greatest lower bound on the set

$$D_p = \{y : G(y) \geq p\} = \{y : F(y/a) \geq p\} = \{az : F(z) \geq p\} = aC_p,$$

where the third equality follows from the fact that  $F(y/a) \geq p$  if and only if  $y = za$  where  $F(z) \geq p$ . The greatest lower bound on  $aC_p$  is  $a$  times the greatest lower bound on  $C_p$  because  $a > 0$ .

## 4.4 Moments

### Commentary

The moment generating function (m.g.f.) is a challenging topic that is introduced in this section. The m.g.f. is used later in the text to outline a proof of the central limit theorem (Sec. 6.3). It is also used in a few places to show that certain sums of random variables have particular distributions (e.g., Poisson, Bernoulli, exponential). If students are not going to study the proofs of these results, one could skip the material on moment generating functions.

### Solutions to Exercises

1. Since the uniform p.d.f. is symmetric with respect to its mean  $\mu = (a+b)/2$ , it follows that  $E[(X-\mu)^5] = 0$ .
2. The mean of  $X$  is  $(b+a)/2$ , so the  $2k$ th central moment of  $X$  is the mean of  $(X - [b+a]/2)^{2k}$ . Note that  $Y = X - [b+a]/2$  has the uniform distribution on the interval  $[-(b-a)/2, (b-a)/2]$ . Also,  $Z = 2Y/(b-a)$  has the uniform distribution on the interval  $[-1, 1]$ . So  $E(Y^{2k}) = [(b-a)/2]^{2k} E(Z^{2k})$ .

$$E(Z^{2k}) = \int_{-1}^1 \frac{z^{2k}}{2} dz = \frac{1}{2k+1}.$$

So, the  $2k$ th central moment of  $X$  is  $[(b-a)/2]^{2k}/(2k+1)$ .

3.  $E[(X-\mu)^3] = E[(X-1)^3] = E(X^3 - 3X^2 + 3X - 1) = 5 - 3(2) + 3(1) - 1 = 1$ .
4. Since  $\text{Var}(X) \geq 0$  and  $\text{Var}(X) = E(X^2) - [E(X)]^2$ , it follows that  $E(X^2) \geq [E(X)]^2$ . The second part of the exercise follows from Theorem 4.3.3.
5. Let  $Y = (X-\mu)^2$ . Then by Exercise 4,

$$E(Y^2) = E[(X-\mu)^4] \geq [E(Y)]^2 = [\text{Var}(X)]^2 = \sigma^4.$$

6. Since

$$f(x) = \begin{cases} \frac{1}{b-a} & \text{for } a < x < b, \\ 0 & \text{otherwise,} \end{cases}$$

then

$$\psi(t) = \int_a^b \exp(tx) \frac{1}{b-a} dx.$$

Therefore, for  $t \neq 0$ ,

$$\psi(t) = \frac{\exp(tb) - \exp(ta)}{t(b-a)}.$$

As always,  $\psi(0) = 1$ .

7.  $\psi'(t) = \frac{1}{4}(3\exp(t) - \exp(-t))$  and  $\psi''(t) = \frac{1}{4}(3\exp(t) + \exp(-t))$ . Therefore,  $\mu = \psi'(0) = 1/2$  and  $\sigma^2 = \psi''(0) - \mu^2 = 1 - \left(\frac{1}{2}\right)^2 = \frac{3}{4}$ .
8.  $\psi'(t) = (2t+3)\exp(t^2 + 3t)$  and  $\psi''(t) = (2t+3)^2\exp(t^2 + 3t) + 2\exp(t^2 + 3t)$ . Therefore,  $\mu = \psi'(0) = 3$  and  $\sigma^2 = \psi''(0) - \mu^2 = 11 - (3)^2 = 2$ .
9.  $\psi'_2(t) = c\psi'_1(t)\exp(c[\psi_1(t) - 1])$  and  $\psi''_2(t) = \{[c\psi'_1(t)]^2 + c\psi''_1(t)\}\exp(c[\psi_1(t) - 1])$ . We know that  $\psi_1(0) = 1$ ,  $\psi'_1(0) = \mu$ , and  $\psi''_1(0) = \sigma^2 + \mu^2$ .

Therefore,  $E(Y) = \psi'_2(0) = c\mu$  and

$$\text{Var}(Y) = \psi''_2(0) - [E(Y)]^2 = \{(c\mu)^2 + c(\sigma^2 + \mu^2)\} - (c\mu)^2 = c(\sigma^2 + \mu^2).$$

10. The m.g.f. of  $Z$  is

$$\begin{aligned} \psi_1(t) &= E(\exp(tZ)) = E[\exp(t(2X - 3Y + 4))] \\ &= \exp(4t)E(\exp(2tX)\exp(-3ty)) \\ &= \exp(4t)E(\exp(2tX))E(\exp(-3tY)) \quad (\text{since } X \text{ and } Y \text{ are independent}) \\ &= \exp(4t)\psi(2t)\psi(-3t) \\ &= \exp(4t)\exp(4t^2 + 6t)\exp(9t^2 - 9t) \\ &= \exp(13t^2 + t). \end{aligned}$$

11. If  $X$  can take only a finite number of values  $x_1, \dots, x_k$  with probabilities  $p_1, \dots, p_k$ , respectively, then the m.g.f. of  $X$  will be

$$\psi(t) = p_1 \exp(tx_1) + p_2 \exp(tx_2) + \cdots + p_k \exp(tx_k).$$

By matching this expression for  $\psi(t)$  with the expression given in the exercise, it can be seen that  $X$  can take only the three values 1, 4, and 8, and that  $f(1) = 1/5$ ,  $f(4) = 2/5$ , and  $f(8) = 2/5$ .

12. We shall first rewrite  $\psi(t)$  as follows:

$$\psi(t) = \frac{4}{6} \exp(0) + \frac{1}{6} \exp(t) + \frac{1}{6} \exp(-t).$$

By reasoning as in Exercise 11, it can now be seen that  $X$  can take only the three values 0, 1, and  $-1$ , and that  $f(0) = 4/6$ ,  $f(1) = 1/6$ , and  $f(-1) = 1/6$ .

13. The m.g.f. of a Cauchy random variable would be

$$\psi(t) = \int_{-\infty}^{\infty} \frac{\exp(tx)}{\pi(1+x^2)} dx. \quad (\text{S.4.2})$$

If  $t > 0$ ,  $\lim_{x \rightarrow \infty} \exp(tx)/(1+x^2) = \infty$ , so the integral in Eq. (S.4.2) is infinite. Similarly, if  $t < 0$ ,  $\lim_{x \rightarrow -\infty} \exp(tx)/(1+x^2) = \infty$ , so the integral is still infinite. Only for  $t = 0$  is the integral finite, and that value is  $\psi(0) = 1$  as it is for every random variable.

14. The m.g.f. is

$$\psi(t) = \int_1^{\infty} \frac{\exp(tx)}{x^2} dx.$$

If  $t \leq 0$ ,  $\exp(tx)$  is bounded, so the integral is finite. If  $t > 0$ , then  $\lim_{x \rightarrow \infty} \exp(tx)/x^2 = \infty$ , and the integral is infinite.

15. Let  $X$  have a discrete distribution with p.f.  $f(x)$ . Assume that  $E(|X|^a) < \infty$  for some  $a > 0$ . Let  $0 < b < a$ . Then

$$\begin{aligned} E(|X|^b) &= \sum_x |x|^b f(x) = \sum_{|x| \leq 1} |x|^b f(x) + \sum_{|x| > 1} |x|^b f(x) \\ &\leq 1 + \sum_{|x| > 1} |x|^a f(x) \leq 1 + E(|X|^a) < \infty, \end{aligned}$$

where the first inequality follows from the fact that  $0 \leq |x|^b \leq 1$  for all  $|x| \leq 1$  and  $|x|^b < |x|^a$  for all  $|x| > 1$ . The next-to-last inequality follows from the fact that the final sum is only part of the sum that makes up  $E(|X|^a)$ .

16. Let  $Z = n - X$ . It is easy to see that  $Z$  has the same distribution as  $Y$  since, if  $X$  is the number of successes in  $n$  independent Bernoulli trials with probability of success  $p$ , then  $Z$  is the number of failures and the probability of failure is  $1 - p$ . It is known from Theorem 4.3.5 that  $\text{Var}(Z) = \text{Var}(X)$ , which also equals  $\text{Var}(Y)$ . Also  $E(Z) = n - E(X)$ , so  $Z - E(Z) = n - X - n + E(X) = E(X) - X$ . Hence the third central moment of  $Z$  is the negative of the third central moment of  $X$  and the skewnesses are negatives of each other.

17. We already computed the mean  $\mu = 1$  and variance  $\sigma^2 = 1$  in Example 4.4.3. Using the m.g.f., the third moment is computed from the third derivative:

$$\psi'''(t) = \frac{6}{(1-t)^4}.$$

The third moment is 6. The third central moment is

$$E([X - 1]^3) = E(X^3) - 3E(X^2) + 3E(X) - 1 = 6 - 6 + 3 - 1 = 2.$$

The skewness is then  $2/1 = 2$ .

## 4.5 The Mean and the Median

### Solutions to Exercises

1. The  $1/2$  quantile defined in Definition 3.3.2 applies to a continuous random variable whose c.d.f. is one-to-one. The  $1/2$  quantile is then  $x_0 = F^{-1}(1/2)$ . That is,  $F(x_0) = 1/2$ . In order for a number  $m$  to be a median as defined in this section, it must be that  $\Pr(X \leq m) \geq 1/2$  and  $\Pr(X \geq m) \geq 1/2$ . If  $X$  has a continuous distribution, then  $\Pr(X \leq m) = F(m)$  and  $\Pr(X \geq m) = 1 - F(m)$ . Since  $F(x_0) = 1/2$ ,  $m = x_0$  is a median.
2. In this example,  $\sum_{x=1}^6 f(x) = 21c$ . Therefore,  $c = 1/21$ . Since  $\Pr(X \leq 5) = 15/21$  and  $\Pr(X \geq 5) = 11/21$ , it follows that 5 is a median and it can be verified that it is the unique median.
3. A median  $m$  must satisfy the equation

$$\int_0^m \exp(-x) dx = \frac{1}{2}.$$

Therefore,  $1 - \exp(-m) = 1/2$ . It follows that  $m = \log 2$  is the unique median of this distribution.

4. Let  $X$  denote the number of children per family. Then

$$\Pr(X \leq 2) = \frac{21 + 40 + 42}{153} \geq \frac{1}{2}$$

and

$$\Pr(X \geq 2) = \frac{42 + 27 + 23}{153} \geq \frac{1}{2}.$$

Therefore, 2 is the unique median. Since all families with 4 or more children are in the upper half of the distribution no matter how many children they have (so long as it is at least 4), it doesn't matter how they are distributed among the values 4, 5, .... Next, let  $Y = \min\{X, 4\}$ , that is  $Y$  is the number of children per family if we assume that all families with more than 4 children have exactly 4. We can compute the mean of  $Y$  as

$$E(Y) = \frac{1}{153} (0 \times 21 + 1 \times 40 + 2 \times 42 + 3 \times 27 + 4 \times 23) = 1.941.$$

5. The p.d.f. of  $X$  will be  $h(x) = [f(x) + g(x)]/2$  for  $-\infty < x < \infty$ . Therefore,

$$E(X) = \frac{1}{2} \int_{-\infty}^{\infty} x[f(x) + g(x)]dx = \frac{1}{2}(\mu_f + \mu_g).$$

Since  $\int_{-\infty}^1 h(x)dx = \int_0^1 \frac{1}{2}f(x)dx = \frac{1}{2}$  and  $\int_2^{\infty} h(x)dx = \int_2^4 \frac{1}{2}g(x)dx = \frac{1}{2}$ , it follows that every value of  $m$  in the interval  $1 \leq m \leq 2$  will be a median.

6. (a) The required value is the mean  $E(X)$ , and

$$E(X) = \int_0^1 x \cdot 2x dx = \frac{2}{3}.$$

- (b) The required value is the median  $m$ , where

$$\int_0^m 2x \, dx = \frac{1}{2}.$$

Therefore,  $m = 1/\sqrt{2}$ .

7. (a) The required value is  $E(X)$ , and

$$E(X) = \int_0^1 x \left( x + \frac{1}{2} \right) dx = \frac{7}{12}.$$

- (b) The required value is the median  $m$ , where

$$\int_0^m \left( x + \frac{1}{2} \right) dx = \frac{1}{2}.$$

Therefore,  $m = (\sqrt{5} - 1)/2$ .

8.  $E[(X - d)^4] = E(X^4) - 4E(X^3)d + 6E(X^2)d^2 - 4E(X)d^3 + d^4$ . Since the distribution of  $X$  is symmetric with respect to 0,

$$E(X) = E(X^3) = 0.$$

Therefore,

$$E[(X - d)^4] = E(X^4) + 6E(X^2)d^2 + d^4.$$

For any given nonnegative values of  $E(X^4)$  and  $E(X^2)$ , this is a polynomial of fourth degree in  $d$  and it is a minimum when  $d = 0$ .

9. (a) The required point is the mean  $E(X)$ , and

$$E(X) = (0.2)(-3) + (0.1)(-1) + (0.1)(0) + (0.4)(1) + (0.2)(2) = 0.1.$$

- (b) The required point is the median  $m$ . Since  $\Pr(X \leq 1) = 0.8$  and  $\Pr(X \geq 1) = 0.6$ , the point 1 is the unique median.

10. Let  $x_1 < \dots < x_n$  denote the locations of the  $n$  houses and let  $d$  denote the location of the store. We must choose  $d$  to minimize  $\sum_{i=1}^n |x_i - d|$  or equivalently to minimize  $\sum_{i=1}^n |x_i - d|/n$ . This sum can be interpreted as the M.A.E. of  $d$  for a discrete distribution in which each of the  $n$  points  $x_1, \dots, x_n$  has probability  $1/n$ . Therefore,  $d$  should be chosen equal to a median of this distribution. If  $n$  is odd, then the middle value among  $x_1, \dots, x_n$  is the unique median. If  $n$  is even, then any point between the two middle values among  $x_1, \dots, x_n$  (including the two middle values themselves) will be a median.

11. The M.S.E. of any prediction is a minimum when the prediction is equal to the mean of the variable being predicted, and the minimum value of the M.S.E. is then the variance of the variable. It was shown in the derivation of Eq. (4.3.3) that the variance of the binomial distribution with parameters  $n$  and  $p$  is  $np(1-p)$ . Therefore, the minimum M.S.E. that can be attained when predicting  $X$  is  $\text{Var}(X) = 7(1/4)(3/4) = 21/16$  and the minimum M.S.E. that can be attained when predicting  $Y$  is  $\text{Var}(Y) = 5(1/2)(1/2) = 5/4 = 20/16$ . Thus,  $Y$  can be predicted with the smaller M.S.E.

12. (a) The required value is the mean  $E(X)$ . The random variable  $X$  will have the binomial distribution with parameters  $n = 15$  and  $p = 0.3$ . Therefore,  $E(X) = np = 4.5$ .

- (b) The required value is the median of the binomial distribution with parameters  $n = 15$  and  $p = 0.3$ . From the table of this distribution given in the back of the book, it is found that 4 is the unique median.
13. To say that the distribution of  $X$  is symmetric around  $m$ , means that  $X$  and  $2m - X$  have the same distribution. That is,  $\Pr(X \leq x) = \Pr(2m - X \leq x)$  for all  $x$ . This can be rewritten as  $\Pr(X \leq x) = \Pr(X \geq 2m - x)$ . With  $x = m$ , we see that  $\Pr(X \leq m) = \Pr(X \geq m)$ . If  $\Pr(X \leq m) < 1/2$ , then  $\Pr(X \leq m) + \Pr(X > m) < 1$ , which is impossible. Hence  $\Pr(X \leq m) \geq 1/2$  and  $\Pr(X \geq m) \geq 1/2$ , and  $m$  is a median.
14. The Cauchy distribution is symmetric around 0, so 0 is a median by Exercise 13. Since the p.d.f. of the Cauchy distribution is strictly positive everywhere, the c.d.f. will be one-to-one and 0 is the unique median.
15. (a) Since  $a$  is assumed to be a median,  $F(a) = \Pr(X \leq a) \geq 1/2$ . Since  $b > a$  is assumed to be a median  $\Pr(X \geq b) \geq 1/2$ . If  $\Pr(X \leq a) > 1/2$ , then  $\Pr(X \leq a) + \Pr(X \geq b) > 1$ . But  $\{X \leq a\}$  and  $\{X \geq b\}$  are disjoint events, so the sum of their probabilities can't be greater than 1. This means that  $F(a) > 1/2$  is impossible, so  $F(a) = 1/2$ .
- (b) The c.d.f.  $F$  is nondecreasing, so  $A = \{x : F(x) = 1/2\}$  is an interval. Since  $F$  is continuous from the right, the lower endpoint  $c$  of the interval  $A$  must also be in  $A$ . For every  $x$ ,  $\Pr(X \leq x) + \Pr(X \geq x) \geq 1$ . For every  $x \in A$ ,  $\Pr(X \leq x) = 1/2$ , hence it must be that  $\Pr(X \geq x) \geq 1/2$  and  $x$  is a median. Let  $d$  be the upper endpoint of the interval  $A$ . We need to show that  $d$  is also a median. Since  $F$  is not necessarily continuous from the left,  $F(d) > 1/2$  is possible. If  $F(d) = 1/2$ , then  $d \in A$  and  $d$  is a median by the argument just given. If  $F(d) > 1/2$ , then  $\Pr(X = d) = F(d) - 1/2$ . This makes

$$\Pr(X \geq d) = \Pr(X > d) + \Pr(X = d) = 1 - F(d) + F(d) - 1/2 = 1/2.$$

Hence  $d$  is also a median

- (c) If  $X$  has a discrete distribution, then clearly  $F$  must be discontinuous at  $d$  otherwise  $F(x) = 1/2$  even for some  $x > d$  and  $d$  would not be the right endpoint of  $A$ .
16. We know that  $1 = \Pr(X < m) + \Pr(X = m) + \Pr(X > m)$ . Since  $\Pr(X < m) = \Pr(X > m)$ , both  $\Pr(X < m) \leq 1/2$  and  $\Pr(X > m) \leq 1/2$ , otherwise their sum would be more than 1. Since  $\Pr(X < m) \leq 1/2$ ,  $\Pr(X \geq m) = 1 - \Pr(X < m) \geq 1/2$ . Similarly,  $\Pr(X \leq m) = 1 - \Pr(X > m) \geq 1/2$ . Hence  $m$  is a median.
17. As in the previous problem,  $1 = \Pr(X < m) + \Pr(X = m) + \Pr(X > m)$ . Since  $\Pr(X < m) < 1/2$  and  $\Pr(X > m) < 1/2$ , we have  $\Pr(X \geq m) = 1 - \Pr(X < m) > 1/2$  and  $\Pr(X \leq m) = 1 - \Pr(X > m) > 1/2$ . Hence  $m$  is a median. Let  $k > m$ . Then  $\Pr(X \geq k) \leq \Pr(X > m) < 1/2$ , and  $k$  is not a median. Similarly, if  $k < m$ , then  $\Pr(X \leq k) \leq \Pr(X < m) < 1/2$ , and  $k$  is not a median. So,  $m$  is the unique median.
18. Let  $m$  be the  $p$  quantile of  $X$ , and let  $r$  be strictly increasing. Let  $Y = r(X)$  and let  $G(y)$  be the c.d.f. of  $Y$  while  $F(x)$  is the c.d.f. of  $X$ . Since  $Y \leq y$  if and only if  $r(X) \leq y$  if and only if  $X \leq r^{-1}(y)$ , we have  $G(y) = F(r^{-1}(y))$ . The  $p$  quantile of  $Y$  is the smallest element of the set

$$C_p = \{y : G(y) \geq p\} = \{y : F(r^{-1}(y)) \geq p\} = \{r(x) : F(x) \geq p\}.$$

Also,  $m$  is the smallest  $x$  such that  $F(x) \geq p$ . Because  $r$  is strictly increasing, the smallest  $r(x)$  such that  $F(x) \geq p$  is  $r(m)$ . Hence,  $r(m)$  is the smallest number in  $C_p$ .

## 4.6 Covariance and Correlation

### Solutions to Exercises

- The location of the circle makes no difference since it only affects the means of  $X$  and  $Y$ . So, we shall assume that the circle is centered at  $(0,0)$ . As in Example 4.6.5,  $\text{Cov}(X, Y) = 0$ . It follows that  $\rho(X, Y) = 0$  also.
- We shall follow the hint given in this exercise. The relation  $[(X - \mu_X) + (Y - \mu_Y)]^2 \geq 0$  implies that

$$(X - \mu_X)(Y - \mu_Y) \leq \frac{1}{2}[(X - \mu_X)^2 + (Y - \mu_Y)^2].$$

Similarly, the relation  $[(X - \mu_X) - (Y - \mu_Y)]^2 \geq 0$  implies that

$$-(X - \mu_X)(Y - \mu_Y) \leq \frac{1}{2}[(X - \mu_X)^2 + (Y - \mu_Y)^2].$$

Hence, it follows that

$$|(X - \mu_X)(Y - \mu_Y)| \leq \frac{1}{2}[(X - \mu_X)^2 + (Y - \mu_Y)^2].$$

By taking expectations on both sides of this relation, we find that

$$E[|(X - \mu_X)(Y - \mu_Y)|] \leq \frac{1}{2}[\text{Var}(X) + \text{Var}(Y)] < \infty.$$

Since the expectation on the left side of this relation is finite, it follows that

$$\text{Cov}(X, Y) = E[(X - \mu_X)(Y - \mu_Y)]$$

exists and is finite.

- Since the p.d.f. of  $X$  is symmetric with respect to 0, it follows that  $E(X) = 0$  and that  $E(X^k) = 0$  for every odd positive integer  $k$ . Therefore,  $E(XY) = E(X^7) = 0$ . Since  $E(XY) = 0$  and  $E(X)E(Y) = 0$ , it follows that  $\text{Cov}(X, Y) = 0$  and  $\rho(X, Y) = 0$ .
- It follows from the assumption that  $0 < E(X^4) < \infty$ , that  $0 < \sigma_X^2 < \infty$  and  $0 < \sigma_Y^2 < \infty$ . Hence,  $\rho(X, Y)$  is well defined. Since the distribution of  $X$  is symmetric with respect to 0,  $E(X) = 0$  and  $E(X^3) = 0$ . Therefore,  $E(XY) = E(X^3) = 0$ . It now follows that  $\text{Cov}(X, Y) = 0$  and  $\rho(X, Y) = 0$ .
- We have  $E(aX + b) = a\mu_X + b$  and  $E(cY + d) = c\mu_Y + d$ . Therefore,

$$\begin{aligned} \text{Cov}(aX + b, cY + d) &= E[(aX + b - a\mu_X - b)(cY + d - c\mu_Y - d)] \\ &= E[ac(X - \mu_X)(Y - \mu_Y)] = ac \text{Cov}(X, Y). \end{aligned}$$

- By Exercise 5,  $\text{Cov}(U, V) = ac \text{Cov}(X, Y)$ . Also,  $\text{Var}(U) = a^2\sigma_X^2$  and  $\text{Var}(V) = c^2\sigma_Y^2$ . Hence

$$p(U, V) = \frac{ac \text{Cov}(X, Y)}{|a|\sigma_X \cdot |c|\sigma_Y} = \begin{cases} \rho(X, Y) & \text{if } ac > 0, \\ -\rho(X, Y) & \text{if } ac < 0. \end{cases}$$

7. We have  $E(aX + bY + c) = a\mu_X + b\mu_Y + c$ . Therefore,

$$\begin{aligned}\text{Cov}(aX + bY + c, Z) &= E[(aX + bY + c - a\mu_X - b\mu_Y - c)(Z - \mu_Z)] \\ &= E\{[a(X - \mu_X) + b(Y - \mu_Y)](Z - \mu_Z)\} \\ &= aE[(X - \mu_X)(Z - \mu_Z)] + bE[(Y - \mu_Y)(Z - \mu_Z)] \\ &= a\text{Cov}(X, Z) + b\text{Cov}(Y, Z).\end{aligned}$$

8. We have

$$\begin{aligned}\text{Cov}\left(\sum_{i=1}^m a_i X_i, \sum_{j=1}^n b_j Y_j\right) &= E\left[\sum_{i=1}^m a_i (X_i - \mu_{X_i}) \sum_{j=1}^n b_j (Y_j - \mu_{Y_j})\right] \\ &= E\left[\sum_{i=1}^m \sum_{j=1}^n a_i b_j (X_i - \mu_{X_i})(Y_j - \mu_{Y_j})\right] \\ &= \sum_{i=1}^m \sum_{j=1}^n a_i b_j E[(X_i - \mu_{X_i})(Y_j - \mu_{Y_j})] \\ &= \sum_{i=1}^m \sum_{j=1}^n a_i b_j \text{Cov}(X_i, Y_j).\end{aligned}$$

9. Let  $U = X + Y$  and  $V = X - Y$ . Then

$$E(UV) = E[(X + Y)(X - Y)] = E(X^2 - Y^2) = E(X^2) - E(Y^2).$$

Also,

$$E(U)E(V) = E(X + Y)E(X - Y) = (\mu_X + \mu_Y)(\mu_X - \mu_Y) = \mu_X^2 - \mu_Y^2.$$

Therefore,

$$\begin{aligned}\text{Cov}(U, V) &= E(UV) - E(U)E(V) = [E(X^2) - \mu_X^2] - [E(Y^2) - \mu_Y^2] \\ &= \text{Var}(X) - \text{Var}(Y) = 0.\end{aligned}$$

It follows that  $\rho(U, V) = 0$ .

10.  $\text{Var}(X + Y) = \text{Var}(X) + \text{Var}(Y) + 2\text{Cov}(X, Y)$  and  $\text{Var}(X - Y) = \text{Var}(X) + \text{Var}(Y) - 2\text{Cov}(X, Y)$ . Since  $\text{Cov}(X, Y) < 0$ , it follows that

$$\text{Var}(X + Y) < \text{Var}(X - Y).$$

11. For the given values,

$$\begin{aligned}\text{Var}(X) &= E(X^2) - [E(X)]^2 = 10 - 9 = 1, \\ \text{Var}(Y) &= E(Y^2) - [E(Y)]^2 = 29 - 4 = 25, \\ \text{Cov}(X, Y) &= E(XY) - E(X)E(Y) = 0 - 6 = -6.\end{aligned}$$

Therefore,

$$\rho(X, Y) = \frac{-6}{(1)(5)} = -\frac{6}{5}, \text{ which is impossible.}$$

12.

$$\begin{aligned} E(X) &= \int_0^1 \int_0^2 x \cdot \frac{1}{3}(x+y) dy dx = \frac{5}{9}, \\ E(Y) &= \int_0^1 \int_0^2 y \cdot \frac{1}{3}(x+y) dy dx = \frac{11}{9}, \\ E(X^2) &= \int_0^1 \int_0^2 x^2 \cdot \frac{1}{3}(x+y) dy dx = \frac{7}{18}, \\ E(Y^2) &= \int_0^1 \int_0^2 y^2 \cdot \frac{1}{3}(x+y) dy dx = \frac{16}{9}, \\ E(XY) &= \int_0^1 \int_0^2 xy \cdot \frac{1}{3}(x+y) dy dx = \frac{2}{3}. \end{aligned}$$

Therefore,

$$\begin{aligned} \text{Var}(X) &= \frac{7}{18} - \left(\frac{5}{9}\right)^2 = \frac{13}{162}, \\ \text{Var}(Y) &= \frac{16}{9} - \left(\frac{11}{9}\right)^2 = \frac{23}{81}, \\ \text{Cov}(XY) &= \frac{2}{3} - \left(\frac{5}{9}\right)\left(\frac{11}{9}\right) = -\frac{1}{81}. \end{aligned}$$

It now follows that

$$\begin{aligned} \text{Var}(2X - 3Y + 8) &= 4\text{Var}(X) + 9\text{Var}(Y) - (2)(2)(3)\text{Cov}(X, Y) \\ &= \frac{245}{81}. \end{aligned}$$

13.  $\text{Cov}(X, Y) = \rho(X, Y)\sigma_X\sigma_Y = -\frac{1}{6}(3)(2) = -1.$

(a)  $\text{Var}(X + Y) = \text{Var}(X) + \text{Var}(Y) + 2\text{Cov}(X, Y) = 11.$

(b)  $\text{Var}(X - 3Y + 4) = \text{Var}(X) + 9\text{Var}(Y) - (2)(3)\text{Cov}(X, Y) = 51.$

14. (a)  $\text{Var}(X + Y + Z) = \text{Var}(X) + \text{Var}(Y) + \text{Var}(Z) + 2\text{Cov}(X, Y) + 2\text{Cov}(X, Z) + 2\text{Cov}(Y, Z) = 17.$

(b)  $\text{Var}(3X - Y - 2Z + 1) = 9\text{Var}(X) + \text{Var}(Y) + 4\text{Var}(Z) - 6\text{Cov}(X, Y) - 12\text{Cov}(X, Z) + 4\text{Cov}(Y, Z) = 59.$

15. Since each variance is equal to 1 and each covariance is equal to 1/4,

$$\begin{aligned} \text{Var}(X_1 + \dots + X_n) &= \sum_i \text{Var}(X_i) + 2 \sum_{i < j} \text{Cov}(X_i, X_j) \\ &= n(1) + 2 \cdot \frac{n(n-1)}{2} \left(\frac{1}{4}\right) = n + \frac{n(n-1)}{4}. \end{aligned}$$

16. We need the cost to be 6000 dollars, so that  $50s_1 + 30s_2 = 6000$ . We also need the variance to be 0. The variance of  $s_1R_1 + s_2R_2$  is

$$s_1^2 \text{Var}(R_1) + s_2^2 \text{Var}(R_2) + 2s_1s_2 \text{Cov}(R_1, R_2).$$

The variances of  $R_1$  and  $R_2$  are  $\text{Var}(R_1) = 75$  and  $\text{Var}(R_2) = 17.52$ . Since the correlation between  $R_1$  and  $R_2$  is  $-1$ , their covariance is  $-1(75)^{1/2}(17.52)^{1/2} = -36.25$ . To make the variance 0, we need  $75s_1^2 + 17.52s_2^2 - 36.25s_1s_2 = 0$ . This equation can be rewritten  $(75^{1/2}s_1 - 17.52^{1/2}s_2)^2 = 0$ . So, we need to solve the two equations

$$75^{1/2}s_1 - 17.52^{1/2}s_2 = 0, \quad \text{and} \quad 50s_1 + 30s_2 = 6000.$$

The solution is  $s_1 = 53.54$  and  $s_2 = 110.77$ . The reason that such a portfolio is unrealistic is that it has positive mean (1126.2) but zero variance, that is one can earn money with no risk. Such a “money pump” would surely dry up the moment anyone recognized it.

17. Let  $\mu_X = E(X)$  and  $\mu_Y = E(Y)$ . Apply Theorem 4.6.2 with  $U = X - \mu_X$  and  $V = Y - \mu_Y$ . Then (4.6.4) becomes

$$\text{Cov}(X, Y)^2 \leq \text{Var}(X)\text{Var}(Y). \quad (\text{S.4.3})$$

Now  $|\rho(X, Y)| = 1$  is equivalent to equality in (S.4.3). According to Theorem 4.6.2, we get equality in (4.6.4) and (S.4.3) if and only if there exist constants  $a$  and  $b$  such that  $aU + bV = 0$ , that is  $a(X - \mu_X) + b(Y - \mu_Y) = 0$ , with probability 1. So  $|\rho(X, Y)| = 1$  implies  $aX + bY = a\mu_X + b\mu_Y$  with probability 1.

18. The means of  $X$  and  $Y$  are the same since  $f(x, y) = f(y, x)$  for all  $x$  and  $y$ . The mean of  $X$  (and the mean of  $Y$ ) is

$$E(X) = \int_0^1 \int_0^1 x(x+y) dx dy = \int_0^1 \left( \frac{1}{3} + \frac{y}{2} \right) dy = \frac{1}{3} + \frac{1}{4} = \frac{7}{12}.$$

Also,

$$E(XY) = \int_0^1 \int_0^1 xy(x+y) dx dy = \int_0^1 \left( \frac{y}{3} + \frac{y^2}{2} \right) dy = \frac{1}{6} + \frac{1}{6} = \frac{1}{3}.$$

So,

$$\text{Cov}(X, Y) = \frac{1}{3} - \left( \frac{7}{12} \right)^2 = -0.00695.$$

## 4.7 Conditional Expectation

### Solutions to Exercises

1. The M.S.E. after observing  $X = 18$  is  $\text{Var}(P|18) = 19 \times (41 - 18)/[42^2 \times 43] = 0.00576$ . This is about seven percent of the marginal M.S.E.
2. If  $X$  denotes the score of the selected student, then

$$E(X) = E[E(X \mid \text{School})] = (0.2)(80) + (0.3)(76) + (0.5)(84) = 80.8.$$

3. Since  $E(X \mid Y) = c$ , then  $E(X) = E[E(X \mid Y)] = c$  and  $E(XY) = E[E(XY \mid Y)] = E(YE(X \mid Y)) = E(cY) = cE(Y)$ .

Therefore,

$$\text{Cov}(X, Y) = E(XY) - E(X)E(Y) = cE(Y) - cE(Y) = 0.$$

4. Since  $X$  is symmetric with respect to 0,  $E(X^k) = 0$  for every odd integer  $k$ . Therefore,

$$E(X^{2m}Y) = E[E(X^{2m}Y | X)] = E[X^{2m}E(Y | X)] = E[aX^{2m+1} + bX^{2m}] = bE(X^{2m}).$$

Also,

$$E(Y) = E[E(Y | X)] = E(aX + b) = b.$$

It follows that

$$\text{Cov}(X^{2m}, Y) = E(X^{2m}Y) - E(X^{2m})E(Y) = bE(X^{2m}) - bE(X^{2m}) = 0.$$

5. For any given value  $x_{n-1}$  of  $X_{n-1}$ ,  $E(X_n | x_{n-1})$  will be the midpoint of the interval  $(x_{n-1}, 1)$ . Therefore,  $E(X_n | X_{n-1}) = \frac{1+x_{n-1}}{2}$ .

It follows that

$$E(X_n) = E[E(X_n | X_{n-1})] = \frac{1}{2} + \frac{1}{2}E(X_{n-1}).$$

Similarly,  $E(X_{n-1}) = \frac{1}{2} + \frac{1}{2}E(X_{n-2})$ , etc. Since  $E(X_1) = \frac{1}{2}$ , we obtain

$$E(X_n) = \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \cdots + \frac{1}{2^n} = 1 - \frac{1}{2^n}.$$

6. The joint p.d.f. of  $X$  and  $Y$  is

$$f(x, y) = \begin{cases} c & \text{for } x^2 + y^2 < 1, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore, for any given value of  $y$  in the interval  $-1 < y < 1$ , the conditional p.d.f. of  $X$  given that  $Y = y$  will be of the form

$$g(x | y) = \frac{f(x, y)}{f_2(y)} = \begin{cases} \frac{c}{f_2(y)} & \text{for } -\sqrt{1-y^2} < x < \sqrt{1-y^2}, \\ 0 & \text{otherwise.} \end{cases}$$

For each given value of  $y$ , this conditional p.d.f. is a constant over an interval of values of  $x$  symmetric with respect to  $x = 0$ . Therefore,  $E(X | y) = 0$  for each value of  $y$ .

7. The marginal p.d.f. of  $X$  is

$$f_1(x) = \int_0^1 (x+y) dy = x + \frac{1}{2} \quad \text{for } 0 \leq x \leq 1.$$

Therefore, for  $0 \leq x \leq 1$ , the conditional p.d.f. of  $Y$  given that  $X = x$  is

$$g(y | x) = \frac{f(x, y)}{f_1(x)} = \frac{2(x+y)}{2x+1} \quad \text{for } 0 \leq y \leq 1.$$

Hence,

$$\begin{aligned} E(Y | x) &= \int_0^1 \frac{2(xy + y^2)}{2x+1} dy = \frac{3x+2}{3(2x+1)}, \\ E(Y^2 | x) &= \int_0^1 \frac{2(xy^2 + y^3)}{2x+1} dy = \frac{4x+3}{6(2x+1)}, \end{aligned}$$

and

$$\text{Var}(Y | x) = \frac{4x+3}{6(2x+1)} - \left[ \frac{3x+2}{3(2x+1)} \right]^2 = \frac{1}{36} \left[ 3 - \frac{1}{(2x+1)^2} \right].$$

8. The prediction is  $E\left(Y | X = \frac{1}{2}\right) = \frac{7}{12}$  and the M.S.E. is  $\text{Var}\left(Y | X = \frac{1}{2}\right) = \frac{11}{144}$ .

9. The overall M.S.E. is

$$E[\text{Var}(Y | X)] = \int_0^1 \frac{1}{36} \left[ 3 - \frac{1}{(2x+1)^2} \right] f_1(x) dx.$$

It was found in the solution of Exercise 7 that

$$f_1(x) = x + \frac{1}{2} \quad \text{for } 0 \leq x \leq 1.$$

Therefore, it can be found that  $E[\text{Var}(Y | X)] = \frac{1}{12} - \frac{\log 3}{144}$ .

10. It was found in Exercise 9 that when  $Y$  is predicted from  $X$ , the overall M.S.E. is  $\frac{1}{12} - \frac{\log 3}{144}$ . Therefore, the total loss would be

$$\frac{1}{12} - \frac{\log 3}{144} + c.$$

If  $Y$  is predicted without using  $X$ , the M.S.E. is  $\text{Var}(Y)$ . It is found that

$$E(Y) = \int_0^1 \int_0^1 y(x+y) dx dy = \frac{7}{12}$$

and

$$E(Y^2) = \int_0^1 \int_0^1 y^2(x+y) dx dy = \frac{5}{12}.$$

Hence,  $\text{Var}(Y) = \frac{5}{12} - \left(\frac{7}{12}\right)^2 = \frac{11}{144}$ . The total loss when  $X$  is used for predicting  $Y$  will be less than  $\text{Var}(Y)$  if and only if  $c < \frac{\log 3 - 1}{144}$ .

11. Let  $E(Y) = \mu_Y$ . Then

$$\begin{aligned}\text{Var}(Y) &= E[(Y - \mu_Y)^2] = E\{[(Y - E(Y | X)) + (E(Y | X) - \mu_Y)]^2\} \\ &= E\{[Y - E(Y | X)]^2\} + 2E\{[Y - E(Y | X)][E(Y | X) - \mu_Y]\} \\ &\quad + E\{[E(Y | X) - \mu_Y]^2\}.\end{aligned}$$

We shall now consider further each of the three expectations in the final sum. First,

$$E\{[Y - E(Y | X)]^2\} = E(E\{[Y - E(Y | X)]^2 | X\}) = E[\text{Var}(Y | X)].$$

Next,

$$\begin{aligned}E\{[Y - E(Y | X)][E(Y | X) - \mu_Y]\} &= E(E\{[Y - E(Y | X)][E(Y | X) - \mu_Y] | X\}) \\ &= E([E(Y | X) - \mu_Y]E\{Y - E(Y | X) | X\}) \\ &= E([E(Y | X) - \mu_Y] \cdot 0) \\ &= 0.\end{aligned}$$

Finally, since the mean of  $E(Y | X)$  is  $E[E(Y | X)] = \mu_Y$ , we have

$$E\{[E(Y | X) - \mu_Y]^2\} = \text{Var}[E(Y | X)].$$

It now follows that

$$\text{Var}(Y) = E[\text{Var}(Y | X)] + \text{Var}[E(Y | X)].$$

12. Since  $E(Y) = E[E(Y | X)]$ , then

$$E(Y) = aE(X) + b.$$

Also, as found in Example 4.7.7,

$$E(XY) = aE(X^2) + bE(X).$$

By solving these two equations simultaneously for  $a$  and  $b$  we obtain,

$$a = \frac{E(XY) - E(X)E(Y)}{E(X^2) - [E(X)]^2} = \frac{\text{Cov}(X, Y)}{\text{Var}(X)}$$

and

$$b = E(Y) - aE(X).$$

13. (a) The prediction is the mean of  $Y$ :

$$E(Y) = \int_0^1 \int_0^1 y \cdot \frac{2}{5}(2x + 3y) dx dy = \frac{3}{5}.$$

- (b) The prediction is the median  $m$  of  $X$ . The marginal p.d.f. of  $X$  is

$$f_1(x) = \int_0^1 \frac{2}{5}(2x + 3y)dy = \frac{1}{5}(4x + 3) \quad \text{for } 0 \leq x \leq 1.$$

We must have

$$\int_0^m \frac{1}{5}(4x + 3)dx = \frac{1}{2}.$$

$$\text{Therefore, } 4m^2 + 6m - 5 = 0 \text{ and } m = \frac{\sqrt{29} - 3}{4}.$$

14. First,

$$E(XY) = \int_0^1 \int_0^1 xy \cdot \frac{2}{5}(2x + 3y)dx dy = \frac{1}{3}.$$

Next, the marginal p.d.f.  $f_1$  of  $X$  was found in Exercise 13(b). Therefore,

$$E(X) = \int_0^1 xf_1(x)dx = \frac{17}{30}.$$

Furthermore, it was found in Exercise 13(a) that  $E(Y) = 3/5$ . It follows that  $\text{Cov}(X, Y) = 1/3 - (17/30)(3/5) = 17/51 - 17/50 < 0$ . Therefore,  $X$  and  $Y$  are negatively correlated.

15. (a) For  $0 \leq x \leq 1$  and  $0 \leq y \leq 1$ , the conditional p.d.f. of  $Y$  given that  $X = x$  is

$$g(y | x) = \frac{f(x, y)}{f_1(x)} = \frac{2(2x + 3y)}{4x + 3}.$$

When  $X = 0.8$ , the prediction of  $Y$  is

$$E(Y | X = 0.8) = \int_0^1 yg(y | x = 0.8)dy = \int_0^1 \frac{y(1.6 + 3y)}{3.1}dy = \frac{18}{31}.$$

- (b) The marginal p.d.f. of  $Y$  is

$$f_2(y) = \int_0^1 \frac{2}{5}(2x + 3y)dx = \frac{2}{5}(1 + 3y) \quad \text{for } 0 \leq y \leq 1.$$

Therefore, for  $0 \leq x \leq 1$  and  $0 \leq y \leq 1$ , the conditional p.d.f. of  $X$  given that  $Y = y$  is

$$h(x | y) = \frac{f(x, y)}{f_2(y)} = \frac{2x + 3y}{1 + 3y}.$$

When  $Y = 1/3$ , the prediction of  $X$  is the median  $m$  of the conditional p.d.f.  $h(x | y = 1/3)$ . We must have

$$\int_0^{m/2} \frac{2x + 1}{2} dx = \frac{1}{2}.$$

$$\text{Hence, } m^2 + m = 1 \text{ and } m = (\sqrt{5} - 1)/2.$$

16. Rather than repeat the entire proof of Theorem 4.7.3 with the necessary changes, we shall merely point out what changes need to be made. Let  $d(X)$  be a conditional median of  $Y$  given  $X$ . Replace all squared differences by absolute differences. For example  $[Y - d(X)]^2$  becomes  $|Y - d(X)|$ ,  $[Y - d^*(x)]^2$  becomes  $|Y - d^*(x)|$ , and so on. When we refer to Sec. 4.5 near the end of the proof, replace each “M.S.E.” by “M.A.E.” and replace the word “mean” by “median” each time it appears in the last four sentences.

17. Let  $Z = r(X, Y)$ , and let  $(X, Y)$  have joint p.f.  $f(x, y)$ . Also, let  $W = r(x_0, Y)$ , for some possible value  $x_0$  of  $X$ . We need to show that the conditional p.f. of  $Z$  given  $X = x_0$  is the same as the conditional p.f. of  $W$  given  $X = x_0$  for all  $x_0$ .

Let  $f_1(x)$  be the marginal p.f. of  $X$ . For each possible value  $(z, x)$  of  $(Z, X)$ , define  $B_{(z,x)} = \{y : r(x, y) = z\}$ . Then,  $(Z, X) = (z, x)$  if and only if  $X = x$  and  $Y \in B_{(z,x)}$ . The joint p.f. of  $(Z, X)$  is then

$$g(z, x) = \sum_{y \in B_{(z,x)}} f(x, y).$$

The conditional p.f. of  $Z$  given  $X = x_0$  is  $g_1(z|x_0) = g(z, x_0)/f_1(x_0)$  for all  $z$  and all  $x_0$ .

Next, notice that  $(W, X) = (w, x)$  if and only if  $X = x$  and  $w \in B_{(w,x_0)}$ . The joint p.f. of  $(W, X)$  is then

$$h(w, x) = \sum_{y \in B_{(w,x_0)}} f(x, y).$$

The conditional p.f. of  $W$  given  $X = x$  is  $h_1(w|x) = h(w, x)/f_1(x)$ . Now, for  $x = x_0$ , we get  $h_1(w|x_0) = h(w, x_0)/f_1(x_0)$ . But  $h(w, x_0) = g(w, x_0)$  for all  $w$  and all  $x_0$ . Hence  $h_1(w|x_0) = g_1(w|x_0)$  for all  $w$  and all  $x_0$ . This is the desired conclusion.

## 4.8 Utility

### Commentary

It is interesting to have the students in the class determine their own utility functions for any possible gain between, say, 0 dollars and 100 dollars; in the other words, to have each student determine their own function  $U(x)$  for  $0 \leq x \leq 100$ . One method for determining various points on a person's utility function is as follows:

First, notice that if  $U(x)$  is a person's utility function, then the function  $V(x) = aU(x) + b$ , where  $a$  and  $b$  are constants with  $a > 0$ , could also be used as the person's utility function, because for any two gambles  $X$  and  $Y$ , we will have  $E[U(X)] > E[U(Y)]$  if and only if  $E[V(X)] = aE[U(X)] + b > E[V(Y)] = aE[U(Y)] + b$ . Therefore, the function  $V$  reflects exactly the same preferences as  $U$ . The effect of being able to transform a person's utility function in this way by choosing any constants  $a > 0$  and  $b$  is that we can arbitrarily fix the values of the person's utility function at the two points  $x = 0$  and  $x = 100$ , as long as we use values such that  $U(0) < U(100)$ . For convenience, we shall assume that  $U(0) = 0$  and  $U(100) = 100$ .

Now determine a value  $x_1$  such that the person is indifferent between accepting a gamble from which the gain will be either 100 dollars with probability 1/2 or 0 dollars with probability 1/2 and accepting  $x_1$  dollars as a sure thing. For this value  $x_1$ , we must have

$$U(X_1) = \frac{1}{2}U(0) + \frac{1}{2}U(100) = \frac{1}{2} \cdot 0 + \frac{1}{2} \cdot 100 = 50.$$

Hence,  $U(x_1) = 50$ .

Next, we might determine a value  $x_2$  such that the person is indifferent between accepting a gamble from which the gain will be either  $x_1$  dollars with probability 1/2 or 0 dollars with probability 1/2 and accepting  $x_2$  dollars as a sure thing. For this value  $x_2$ , we must have

$$U(x_2) = \frac{1}{2}U(x_1) + \frac{1}{2}U(0) = \frac{1}{2} \cdot 50 + \frac{1}{2} \cdot 0 = 25.$$

Hence,  $U(x_2) = 25$ .

Similarly, we can determine a value  $x_3$  such that the person is indifferent between accepting a gamble from which the gain will be either  $x_1$  dollars with probability 1/2 or 100 dollars with probability 1/2 and accepting  $x_3$  dollars as a sure thing. For this value  $x_3$ , we must have

$$U(x_3) = \frac{1}{2}U(x_1) + \frac{1}{2}U(100) = \frac{1}{2} \cdot 50 + \frac{1}{2} \cdot 100 = 75.$$

Hence,  $U(x_3) = 75$ .

By continuing in this way, arbitrarily many points on a person's utility function can be determined and the curve  $U(x)$  for  $0 \leq x \leq 100$  can then be sketched. The difficulty is in having the person determine the values of  $x_1, x_2, x_3$ , etc., honestly and accurately in a hypothetical situation where he will not actually have to gamble. For this reason, it is necessary to check and recheck the values that are determined. For example, since

$$U(x_1) = 50 = \frac{1}{2}U(x_2) + \frac{1}{2}U(x_3),$$

the person should be indifferent between accepting  $x_1$  dollars as a sure thing and accepting a gamble from which the gain will be either  $x_2$  dollars with probability 1/2 or  $x_3$  dollars with probability 1/2. By repeatedly carrying out checks of this type and allowing the person to adjust his answers, a reasonably accurate representation of a person's utility function can usually be obtained.

## Solutions to Exercises

1. The utility of not buying the ticket is  $U(0) = 0$ . If the decision maker buys the ticket, the utility is  $U(499)$  if the ticket is a winner and  $U(-1)$  if the ticket is a loser. That is the utility is  $499^\alpha$  with probability 0.001 and it is  $-1$  with probability 0.999. The expected utility is then  $0.001 \times 499^\alpha - 0.999$ . The decision maker prefers buying the ticket if this expected utility is greater than 0. Setting the expected utility greater than 0 means  $499^\alpha > 999$ . Taking logarithms of both sides yields  $\alpha > 1.11$ .
- 2.

$$E[U(X)] = \frac{1}{2} \cdot 5^2 + \frac{1}{2} \cdot 25^2 = 325,$$

$$E[U(Y)] = \frac{1}{2} \cdot 10^2 + \frac{1}{2} \cdot 20^2 = 250,$$

$$E[U(Z)] = 15^2 = 225.$$

Hence,  $X$  is preferred.

- 3.

$$E[U(X)] = \frac{1}{2}\sqrt{5} + \frac{1}{2}\sqrt{25} = 3.618,$$

$$E[U(Y)] = \frac{1}{2}\sqrt{10} + \frac{1}{2}\sqrt{20} = 3.817,$$

$$E[U(Z)] = \sqrt{15} = 3.873.$$

Hence,  $Z$  is preferred.

4. For any gamble  $X$ ,  $E[U(X)] = aE(X) + b$ . Therefore, among any set of gambles, the one for which the expected gain is largest will be preferred. We have

$$E(X) = \frac{1}{2} \cdot 5 + \frac{1}{2} \cdot 25 = 15,$$

$$E(Y) = \frac{1}{2} \cdot 10 + \frac{1}{2} \cdot 20 = 15,$$

$$E(Z) = 15.$$

Hence, all three gambles are equally preferred.

5. Since the person is indifferent between the gamble and the sure thing,

$$U(50) = \frac{1}{3}U(0) + \frac{2}{3}U(100) = \frac{1}{3} \cdot 0 + \frac{2}{3} \cdot 1 = \frac{2}{3}.$$

6. Since the person is indifferent between  $X$  and  $Y$ ,  $E[U(X)] = E[U(Y)]$ . Therefore,

$$(0.6)U(-1) + (0.2)U(0) + (0.2)U(2) = (0.9)U(0) + (0.1)U(1).$$

It follows from the given values that  $U(-1) = 23/6$ .

7. For any given values of  $a$ ,

$$E[U(X)] = p \log a + (1-p) \log(1-a).$$

The maximum of this expected utility can be found by elementary differentiation. We have

$$\frac{\partial E[U(X)]}{\partial a} = \frac{p}{a} - \frac{1-p}{1-a}.$$

When this derivative is set equal to 0, we find that  $a = p$ . Since

$$\frac{\partial^2 E[U(X)]}{\partial a^2} = -\frac{p}{a^2} - \frac{1-p}{(1-a)^2} < 0,$$

It follows that  $E[U(X)]$  is a maximum when  $a = p$ .

8. For any given value of  $a$ ,

$$E[U(X)] = pa^{1/2} + (1-p)(1-a)^{1/2}.$$

Therefore,

$$\frac{\partial E[U(X)]}{\partial a} = \frac{p}{2a^{1/2}} - \frac{1-p}{2(1-a)^{1/2}}.$$

When this derivative is set equal to 0, we find that

$$a = \frac{p^2}{p^2 + (1-p)^2}.$$

Since  $\frac{\partial^2 E[U(X)]}{\partial a^2} < 0$ , it follows that  $E[U(X)]$  is a maximum at this value of  $a$ .

Figure S.4.2: Figure for Exercise 9 of Sec. 4.8.

9. For any given value of  $a$ ,

$$E[U(X)] = pa + (1 - p)(1 - a).$$

This is a linear function of  $a$ . If  $p < 1/2$ , it has the form shown in sketch (i) of Fig. S.4.2.

Therefore,  $E[U(X)]$  is a maximum when  $a = 0$ . If  $p > 1/2$ , it has the form shown in sketch (ii) of Fig. S.4.2. Therefore,  $E[U(X)]$  is a maximum when  $a = 1$ . If  $p = 1/2$ , then  $E[U(X)] = 1/2$  for all values of  $a$ .

10. The person will prefer  $X_3$  to  $X_4$  if and only if

$$\begin{aligned} E[U(X_3)] &= (0.3)U(0) + (0.3)U(1) + (0.4)U(2) > E[U(X_4)] \\ &= (0.5)U(0) + (0.5)U(2). \end{aligned}$$

Therefore, the person will prefer  $X_3$  to  $X_4$  if and only if

$$(0.2)U(0) - (0.3)U(1) + (0.1)U(2) < 0.$$

Since the person prefers  $X_1$  to  $X_2$ , we know that

$$\begin{aligned} E[U(X_1)] &= (0.2)U(0) + (0.5)U(1) + (0.3)U(2) > E[U(X_2)] \\ &= (0.4)U(0) + (0.2)U(1) + (0.4)U(2), \end{aligned}$$

which implies that

$$(0.2)U(0) - (0.3)U(1) + (0.1)U(2) < 0.$$

This is precisely the inequality which was needed to conclude that the person will prefer  $X_3$  to  $X_4$ .

11. For any given value of  $b$ ,

$$E[U(X)] = p \log(A + b) + (1 - p) \log(A - b).$$

Therefore,

$$\frac{\partial E[U(X)]}{\partial b} = \frac{p}{A + b} - \frac{1 - p}{A - b}.$$

When this derivative is set equal to 0, we find that

$$b = (2p - 1)A.$$

Since  $\frac{\partial^2 E[U(X)]}{\partial b^2} < 0$ , this value of  $b$  does yield a maximum value of  $E[U(X)]$ . If  $p \geq 1/2$ , this value of  $b$  lies between 0 and  $A$  as required. However, if  $p < 1/2$ , this value of  $b$  is negative and not permissible. In this case, it can be shown that the maximum value of  $E[U(X)]$  for  $0 \leq b \leq A$  occurs when  $b = 0$ ; that is, when the person does not bet at all.

12. For any given value of  $b$ ,

$$E[U(X)] = p(A + b)^{1/2} + (1 - p)(A - b)^{1/2}.$$

Therefore,

$$\frac{\partial E[U(X)]}{\partial b} = \frac{p}{2(A + b)^{1/2}} - \frac{1 - p}{2(A - b)^{1/2}}.$$

When this derivative is set equal to 0, we find that

$$b = \frac{p^2 - (1 - p)^2}{p^2 + (1 - p)^2} A.$$

As in Exercise 11, if  $p \geq 1/2$ , then this value of  $b$  lies in the interval  $0 \leq b \leq A$  and will maximize  $E[U(X)]$ . However, if  $p < 1/2$ , the value of  $b$  in the interval  $0 \leq b \leq A$  for which  $E[U(X)]$  is a maximum is  $b = 0$ .

13. For any given value of  $b$ ,

$$E[U(X)] = p(A + b) + (1 - p)(A - b).$$

This is a linear function of  $b$ . If  $p > 1/2$ , it has the form shown in sketch (i) of Fig. S.4.3 and  $b = A$  is best. If  $p < 1/2$ , it has the form shown in sketch (ii) of Fig. S.4.3 and  $b = 0$  is best. If  $p = 1/2$ ,  $E[U(X)] = A$  for all values of  $b$ .

14. For any given value of  $b$ ,

$$E[U(X)] = p(A + b)^2 + (1 - p)(A - b)^2.$$

This is a parabola in  $b$ . If  $p \geq 1/2$ , it has the shape shown in sketch (i) of Fig. S.4.4. Therefore,  $E[U(X)]$  is a maximum for  $b = A$ . If  $1/4 < p \leq 1/2$ , it has the shape shown in sketch (ii) of Fig. S.4.4. Therefore,  $E[U(X)]$  is again a maximum for  $b = A$ . If  $0 \leq p < 1/4$ , it has the shape shown in sketch (iii) of Fig. S.4.4. Therefore,  $E[U(X)]$  is a maximum for  $b = 0$ . Finally, if  $p = 1/4$ , then it is symmetric with respect to the point  $b = A/2$ , as shown in sketch (iv) of Fig. S.4.4. Therefore,  $E[U(X)]$  is a maximum for  $b = 0$  and  $b = A$ .

Figure S.4.3: Figure for Exercise 13 of Sec. 4.8.

15. The expected utility for the lottery ticket is

$$E[U(X)] = \int_0^4 x^\alpha \frac{1}{4} dx = \frac{4^\alpha}{\alpha + 1}.$$

The utility of accepting  $x_0$  dollars instead of the lottery ticket is  $U(x_0) = x_0^\alpha$ . Therefore, the person will prefer to sell the lottery ticket for  $x_0$  dollars if

$$x_0^\alpha > \frac{4^\alpha}{\alpha + 1} \quad \text{or if} \quad x_0 > \frac{4}{(\alpha + 1)^{1/\alpha}}.$$

It can be shown that the right-hand side of this last inequality is an increasing function of  $\alpha$ .

16. The expected utility from choosing the prediction  $d$  is

$$E[U(-[Y - d]^2)] = E(|Y - d|).$$

We already saw (in Sec. 4.5) that  $d$  equal to a median of the distribution of  $Y$  minimizes this expectation.

17. The gain is  $10^6$  if  $P > 1/2$  and  $-10^6$  if  $P \leq 1/2$ . The utility of continuing to promote is then  $10^{5.4}$  if  $P > 1/2$  and  $-10^6$  if  $P \leq 1/2$ . To find the expected utility, we need  $\Pr(P \leq 1/2)$ . Using the stated p.d.f. for  $P$ , we get  $\Pr(P \leq 1/2) = \int_0^{1/2} 56p^6(1-p)dp = 0.03516$ . The expected utility is then  $10^{5.4} \times (1 - 0.03516) - 10^6 \times 0.03516 = 207197$ . This is greater than 0, so we would continue to promote the treatment.

## 4.9 Supplementary Exercises

### Solutions to Exercises

1. If  $u \geq 0$ ,

$$\int_u^\infty xf(x)dx \geq u \int_u^\infty f(x)dx = u[1 - F(u)].$$

Since

$$\lim_{u \rightarrow \infty} \int_{-\infty}^u xf(x)dx = E(X) = \int_{-\infty}^\infty xf(x)dx < \infty,$$

it follows that

$$\lim_{u \rightarrow \infty} \left[ E(X) - \int_{-\infty}^u xf(x)dx \right] = \lim_{u \rightarrow \infty} \int_u^\infty xf(x)dx = 0.$$

Figure S.4.4: Figure for Exercise 14 of Sec. 4.8.

2. We use integration by parts. Let  $u = 1 - F(x)$  and  $dv = dx$ . Then  $du = -f(x)dx$  and  $v = x$ , and the integral given in this exercise becomes

$$[uv]_0^\infty - \int_0^\infty v du = \int_0^\infty xf(x)dx = E(X).$$

3. Let  $x_1, x_2, \dots$  denote the possible values of  $X$ . Since  $F(X)$  is a step function, the integral given in Exercise 1 becomes the following sum:

$$\begin{aligned} & (x_1 - 0) + [1 - f(x_1)](x_2 - x_1) + [1 - f(x_1) - f(x_2)](x_3 - x_2) + \dots \\ &= x_1 f(x_1) + x_2 f(x_2) + x_3 f(x_3) + \dots \\ &= E(X). \end{aligned}$$

4. If  $X$ ,  $Y$ , and  $Z$  each had the required uniform distribution, then

$$E(X + Y + Z) = E(X) + E(Y) + E(Z) = \frac{1}{2} + \frac{1}{2} + \frac{1}{2} = \frac{3}{2}.$$

But since  $X + Y + Z \leq 1.3$ , this is impossible.

5. We need  $E(Y) = a\mu + b = 0$  and

$$\text{Var}(Y) = a^2\sigma^2 = 1.$$

Therefore,  $a = \pm \frac{1}{\sigma}$  and  $b = -a\mu$ .

6. The p.d.f.  $h_1(w)$  of the range  $W$  is given at the end of Sec. 3.9. Therefore,

$$E(W) = n(n-1) \int_0^1 w^{n-1} (1-w) dw = \frac{n-1}{n+1}.$$

7. The dealer's expected gain is

$$E(Y - X) = \frac{1}{36} \int_0^6 \int_0^y (y-x)x dx dy = \frac{3}{2}.$$

8. It follows from Sec. 3.9 that the p.d.f. of  $Y_n$  is

$$g_n(y) = n[F(y)]^{n-1} f(y).$$

Here,  $F(y) = \int_0^y 2x dx = y^2$ , so

$$g_n(y) = 2ny^{2n-1} \quad \text{for } 0 < y < 1.$$

$$\text{Hence, } E(Y_n) = \int_0^1 y g_n(y) dy = \frac{2n}{2n+1}.$$

9. Suppose first that  $r(X)$  is nondecreasing. Then

$$\Pr[Y \geq r(m)] = \Pr[r(X) \geq r(m)] \geq \Pr(X \geq m) \geq \frac{1}{2},$$

and

$$\Pr[Y \leq r(m)] = \Pr[r(X) \leq r(m)] \geq \Pr(X \leq m) \geq \frac{1}{2}.$$

Hence,  $r(m)$  is a median of the distribution of  $Y$ . If  $r(X)$  is nonincreasing, then

$$\Pr[Y \geq r(m)] \geq \Pr(X \leq m) \geq \frac{1}{2}$$

and

$$\Pr[Y \leq r(m)] \geq \Pr(X \geq m) \geq \frac{1}{2}.$$

10. Since  $m$  is the median of a continuous distribution,

$$\Pr(X < m) = \Pr(X > m) = \frac{1}{2}. \quad \text{Hence,}$$

$$\begin{aligned} \Pr(Y_n > m) &= 1 - \Pr(\text{All } X'_i < m) \\ &= 1 - \frac{1}{2^n}. \end{aligned}$$

11. Suppose that you order  $s$  liters. If the demand is  $x < s$ , you will make a profit of  $gx$  cents on the  $x$  liters sold and suffer a loss of  $c(s - x)$  cents on the  $s - x$  liters that you do not sell. Therefore, your net profit will be  $gx - c(s - x) = (g + c)x - cs$ . If the demand is  $x \geq s$ , then you will sell all  $s$  liters and make a profit of  $gs$  cents. Hence, your expected net gain is

$$\begin{aligned} E &= \int_0^s [(g + c)x - cs]f(x)dx + gs \int_s^\infty f(x)dx \\ &= \int_0^s (g + c)x f(x)dx - csF(s) + gs[1 - F(s)]. \end{aligned}$$

To find the value of  $s$  that maximizes  $E$ , we find, after some calculations, that

$$\frac{dE}{ds} = g - (g + c) F(s).$$

Thus,  $\frac{dE}{ds} = 0$  and  $E$  is maximized when  $s$  is chosen so that  $F(s) = g/(g + c)$ .

12. Suppose that you return at time  $t$ . If the machine has failed at time  $x \leq t$ , then your cost is  $c(t - x)$ . If the machine has not yet failed ( $x > t$ ), then your cost is  $b$ . Therefore, your expected cost is

$$E = \int_0^t c(t - x)f(x)dx + b \int_t^\infty f(x)dx = ctF(t) - c \int_0^t xf(x)dx + b[1 - F(t)].$$

Hence,

$$\frac{dE}{dt} = cF(t) - bf(t).$$

and  $E$  will be maximized at a time  $t$  such that  $cF(t) = bf(t)$ .

13.  $E(Z) = 5(3) - 1 + 15 = 29$  in all three parts of this exercise. Also,

$$\text{Var}(Z) = 25 \text{Var}(X) + \text{Var}(Y) - 10 \text{Cov}(X, Y) = 109 - 10 \text{Cov}(X, Y).$$

Hence,  $\text{Var}(Z) = 109$  in parts (a) and (b). In part (c),

$$\text{Cov}(X, Y) = \rho\sigma_X\sigma_Y = (.25)(2)(3) = 1.5$$

so  $\text{Var}(Z) = 94$ .

14. In this exercise,  $\sum_{j=1}^n y_j = x_n - x_0$ . Therefore,

$$\text{Var}(\bar{Y}_n) = \frac{1}{n^2} \text{Var}(X_n - X_0).$$

Since  $X_n$  and  $X_0$  are independent,

$$\text{Var}(X_n - X_0) = \text{Var}(X_n) + \text{Var}(X_0).$$

$$\text{Hence, } \text{Var}(\bar{Y}_n) = \frac{2\sigma^2}{n^2}.$$

15. Let  $v^2 = \text{Var}(X_1 + \dots + X_n) = \sum_i \text{Var}(X_i) + 2 \sum_{i < j} \text{Cov}(X_i, X_j)$ . In this problem  $\text{Var}(X_i) = \sigma^2$  for all  $i$  and  $\text{Cov}(X_i, X_j) = \rho\sigma^2$  for all  $i \neq j$ . Therefore,

$$v^2 = n\sigma^2 + n(n-1)\rho\sigma^2.$$

Since  $v^2 \geq 0$ , it follows that  $\rho \geq -1/(n-1)$ .

16. Since the correlation is unaffected by a translation of the distribution of  $X$  and  $Y$  in the  $xy$ -plane, we can assume without loss of generality that the origin is at the center of the rectangle. Hence, by symmetry,  $E(X) = E(Y) = 0$ . But it also follows from symmetry that  $E(XY) = 0$  because, for any positive value of  $XY$  in the first or third quadrant, there is a corresponding negative value in the second or fourth quadrant with the same constant density. Thus,  $\text{Cov}(X, Y) = 0$  and  $\rho(X, Y) = 0$ .

More directly, one can argue that the joint p.d.f. of  $(X, Y)$  factors into constants times the indicator functions of the two intervals that define the sides of the rectangles, hence  $X$  and  $Y$  are independent and uncorrelated.

17. For  $i = 1, \dots, n$ , let  $X_i = 1$  if the  $i$ th letter is placed in the correct envelope and let  $X_i = 0$  otherwise. Then  $E(X_i) = 1/n$  and, for  $i \neq j$ ,

$$E(X_i X_j) = \Pr(X_i X_j = 1) = \Pr(X_i = 1 \text{ and } X_j = 1) = \frac{1}{n(n-1)}.$$

Also,  $E(X_i^2) = E(X_i) = 1/n$ . Hence,

$$\text{Var}(X_i) = \frac{1}{n} - \frac{1}{n^2} = \frac{n-1}{n^2}$$

and  $\text{Cov}(X_i, X_j) = \frac{1}{n(n-1)} - \frac{1}{n^2} = \frac{1}{n^2(n-1)}$ . The total number of correct matches is  $X = \sum_{i=1}^n X_i$ . Therefore,

$$\text{Var}(X) = \sum_{i=1}^n \text{Var}(X_i) + 2 \sum_{i < j} \text{Cov}(X_i, X_j) = n \cdot \frac{n-1}{n^2} + n(n-1) \cdot \frac{1}{n^2(n-1)} = 1.$$

18.

$$\begin{aligned} E[(X - \mu)^3] &= E(X^3) - 3\mu E(X^2) + 3\mu^2 E(X) - \mu^3 \\ &= E(X^3) - 3\mu(\sigma^2 + \mu^2) + 3\mu^3 - \mu^3 \\ &= E(X^3) - 3\mu\sigma^2 - \mu^3. \end{aligned}$$

19.  $c'(t) = \frac{\psi'(t)}{\psi(t)}$  and  $c''(t) = \frac{\psi(t)\psi''(t) - [\psi'(t)]^2}{[\psi(t)]^2}$

Since  $\psi(0) = 1$ ,  $\psi'(0) = \mu$ , and  $\psi''(0) = E(X^2) = \sigma^2 + \mu^2$ , it follows that  $c'(0) = \mu$  and  $c''(0) = \sigma^2$ .

20. It was shown in Exercise 12 of Sec. 4.7 that if  $E(Y | X) = aX + b$ , then

$$a = \frac{\text{Cov}(X, Y)}{\text{Var}(X)} = \frac{\rho\sigma_y}{\sigma_x}$$

and  $b = \mu_Y - a\mu_X$ . The desired result now follows immediately.

21. Since the coefficient of  $X$  in  $E(Y | X)$  is negative, it follows from Exercise 20 that  $\rho < 0$ . Furthermore, it follows from Exercise 20 that the product of the coefficients of  $X$  and  $Y$  in  $E(Y | X)$  and  $E(X | Y)$  must be  $\rho^2$ . Hence,  $\rho^2 = 1/4$  and, since  $\rho < 0$ ,  $\rho = -1/2$ .
22. Let  $X$  and  $Y$  denote the lengths of the longer and shorter pieces, respectively. Since  $Y = 3 - X$  with probability 1, it follows that  $\rho = -1$ .
- 23.

$$\begin{aligned}\text{Cov}(X, X + bY) &= \text{Var}(X) + b \text{Cov}(X, Y) \\ &= 1 + b\rho. \\ \text{Var}(X) &= 1, \text{Var}(X + bY) = 1 + b^2 + 2b\rho.\end{aligned}$$

Hence,

$$\rho(X, X + bY) = \frac{1 + b\rho}{(1 + b^2 + 2b\rho)^{1/2}}.$$

If we set this quantity equal to  $\rho$ , square both sides, and solve for  $b$ , we obtain  $b = -1/(2\rho)$ .

24. The p.f. of the distribution of employees is

$$f(0) = .1, f(1) = .2, f(3) = .3, \text{ and } f(5) = .4.$$

- (a) The unique median of this distribution is 3, so the new office should be located at the point 3.  
 (b) The mean of this distribution is  $(.1)(0) + (.2)(1) + (.3)(3) + (.4)(5) = 3.1$ , so the new office should be located at the point 3.1.
25. (a) The marginal p.d.f. of  $X$  is

$$f_1(x) = \int_0^x 8xy \, dy = 4x^3 \quad \text{for } 0 < x < 1.$$

Therefore, the conditional p.d.f. of  $Y$  given that  $X = .2$  is

$$g_1(y | X = .2) = \frac{f(.2, y)}{f_1(.2)} = 50y \quad \text{for } 0 < y < .2.$$

The mean of this distribution is

$$E(Y | X = .2) = \frac{2}{15} = .1333.$$

- (b) The median of  $g_1(y | X = .2)$  is  $m = \left(\frac{1}{50}\right)^{1/2} = .1414$ .

- 26.

$$\begin{aligned}\text{Cov}(X, Y) &= E[(X - \mu_X)(Y - \mu_Y)] \\ &= E\{[X - E(X | Z) + E(X | Z) - \mu_X] \cdot [Y - E(Y | Z) + E(Y | Z) - \mu_Y]\} \\ &= E\{[X - E(X | Z)][Y - E(Y | Z)]\} + E\{[X - E(X | Z)][E(Y | Z) - \mu_Y]\} \\ &\quad + E\{[E(X | Z) - \mu_X][Y - E(Y | Z)]\} + E\{[E(X | Z) - \mu_X][E(Y | Z) - \mu_Y]\}.\end{aligned}$$

Consider these final four expectations. In the first one, if we first calculate the conditional expectation given  $Z$  and then take the expectation over  $Z$  we obtain  $E[\text{Cov}(X, Y | Z)]$ . In the second and third expectations, we obtain the value 0 when we take the conditional expectation given  $Z$ . The fourth expectation is  $\text{Cov}[E(X | Z), E(Y | Z)]$ .

27. Let  $N$  be the number of balls in the box. Since the proportion of red balls is  $p$ , there are  $Np$  red balls in the box. (Clearly,  $p$  must be an integer multiple of  $1/N$ .) There are  $N(1 - p)$  blue balls in the box. Let  $K = Np$  so that there are  $N - K$  blue balls and  $K$  red balls. If  $n > K$ , then  $\Pr(Y = n) = 0$  since there are not enough red balls. Since  $\Pr(X = n) > 0$  for all  $n$ , the result is true if  $n > K$ . For  $n \leq K$ , let  $X_i = 1$  if the  $i$ th ball is red for  $i = 1, \dots, n$ . For sampling without replacement,

$$\Pr(Y = n) = \Pr(X_1 = 1) \prod_{i=2}^n \Pr(X_i = 1 | X_1 = 1, \dots, X_{i-1} = 1) = \frac{K}{N} \frac{K-1}{N-1} \cdots \frac{K-n+1}{N-n+1}. \quad (\text{S.4.4})$$

For sampling with replacement, the  $X_i$ 's are independent, so

$$\Pr(X = n) = \prod_{i=1}^n \Pr(X_i = 1) = \left(\frac{K}{N}\right)^n. \quad (\text{S.4.5})$$

For  $j = 1, \dots, n-1$ ,  $KN - jN < KN - jK$ , so  $(K-j)/(N-j) < K/N$ . Hence the product in (S.4.4) is smaller than the product in (S.4.5). This argument makes sense only if  $N$  is finite. If  $N$  is infinite, then sampling with and without replacement are equivalent.

28. The expected utility from the gamble  $X$  is  $E[U(X)] = E(X^2)$ . The utility of receiving  $E(X)$  is  $U[E(X)] = [E(X)]^2$ . We know from Theorem 4.3.1 that  $E(X^2) \geq [E(X)]^2$  for any gamble  $X$ , and from Theorem 4.3.3 that there is strict inequality unless  $X$  is actually constant with probability 1.
29. The expected utility from allocating the amounts  $a$  and  $m - a$  is

$$\begin{aligned} E &= p \log(g_1 a) + (1-p) \log[g_2(m-a)] \\ &= p \log a + (1-p) \log(m-a) \\ &\quad + p \log g_1 + (1-p) \log g_2. \end{aligned}$$

The maximum over all values of  $a$  can now be found by elementary differentiation, as in Exercise 7 of Sec.4.8, and we obtain  $a = pm$ .

## Special Distributions

### 5.2 The Bernoulli and Binomial Distributions

#### Commentary

If one is using the statistical software *R*, then the functions `dbinom`, `pbinom`, and `qbinom` give the p.f., the c.d.f., and the quantile function of binomial distributions. The syntax is that the first argument is the argument of the function, and the next two are  $n$  and  $p$  respectively. The function `rbinom` gives a random sample of binomial random variables. The first argument is how many you want, and the next two are  $n$  and  $p$ . All of the solutions that require the calculation of binomial probabilities can be done using these functions instead of tables.

#### Solutions to Exercises

1. Since  $E(X^k)$  has the same value for every positive integer  $k$ , we might try to find a random variable  $X$  such that  $X, X^2, X^3, X^4, \dots$  all have the same distribution. If  $X$  can take only the values 0 and 1, then  $X^k = X$  for every positive integer  $k$  since  $0^k = 0$  and  $1^k = 1$ . If  $\Pr(X = 1) = p = 1 - \Pr(X = 0)$ , then in order for  $E(X^k) = 1/3$ , as required, we must have  $p = 1/3$ . Therefore, a random variable  $X$  such that  $\Pr(X = 1) = 1/3$  and  $\Pr(X = 0) = 2/3$  satisfies the required conditions.
2. We wish to express  $f(x)$  in the form  $p^{\alpha(x)}(1 - p)^{\beta(x)}$ , where  $\alpha(x) = 1$  and  $\beta(x) = 0$  and  $x = a$  and  $\alpha(x) = 0$  and  $\beta(x) = 1$  for  $x = b$ . If we choose  $\alpha(x)$  and  $\beta(x)$  to be linear functions of the form  $\alpha(x) = \alpha_1 + \alpha_2x$  and  $\beta(x) = \beta_1 + \beta_2x$ , then the following two pairs of equations must be satisfied:

$$\begin{aligned}\alpha_1 + \alpha_2a &= 1 \\ \alpha_1 + \alpha_2b &= 0,\end{aligned}$$

and

$$\begin{aligned}\beta_1 + \beta_2a &= 0 \\ \beta_1 + \beta_2b &= 1.\end{aligned}$$

Hence,

$$\begin{aligned}\alpha_1 &= -\frac{b}{a-b}, & \alpha_2 &= \frac{1}{a-b} \\ \beta_1 &= -\frac{a}{b-a}, & \beta_2 &= \frac{1}{b-a}.\end{aligned}$$

3. Let  $X$  be the number of heads obtained. Then strictly more heads than tails are obtained if  $X \in \{6, 7, 8, 9, 10\}$ . The probability of this event is the sum of the numbers in the binomial table corresponding to  $p = 0.5$  and  $n = 10$  for  $k = 6, \dots, 10$ . By the symmetry of this binomial distribution, we can also compute the sum as  $(1 - \Pr(X = 5))/2 = (1 - 0.2461)/2 = 0.37695$ .
4. It is found from a table of the binomial distribution with parameters  $n = 15$  and  $p = 0.4$  that

$$\begin{aligned}\Pr(6 \leq X \leq 9) &= \Pr(X = 6) + \Pr(X = 7) + \Pr(X = 8) + \Pr(X = 9) \\ &= .2066 + .1771 + .1181 + .0612 = .5630.\end{aligned}$$

5. The tables do not include the value  $p = 0.6$ , so we must use the trick described in Exercise 7 of Sec. 3.1. The number of *tails*  $X$  will have the binomial distribution with parameters  $n = 9$  and  $p = 0.4$ . Therefore,

$$\begin{aligned}\Pr(\text{Even number of heads}) &= \Pr(\text{Odd number of tails}) \\ &= \Pr(X = 1) + \Pr(X = 3) + \Pr(X = 5) + \Pr(X = 7) + \Pr(X = 9) \\ &= .0605 + .2508 + .1672 + .0212 + .0003 \\ &= .5000.\end{aligned}$$

6. Let  $N_A, N_B$ , and  $N_C$  denote the number of times each man hits the target. Then

$$\begin{aligned}E(N_A + N_B + N_C) &= E(N_A) + E(N_B) + E(N_C) \\ &= 3 \cdot \frac{1}{8} + 5 \cdot \frac{1}{4} + 2 \cdot \frac{1}{2} = \frac{21}{8}.\end{aligned}$$

7. If we assume that  $N_A, N_B$ , and  $N_C$  are independent, then

$$\begin{aligned}\text{Var}(N_A + N_B + N_C) &= \text{Var}(N_A) + \text{Var}(N_B) + \text{Var}(N_C) \\ &= 3 \cdot \frac{1}{8} \cdot \frac{7}{8} + 5 \cdot \frac{1}{4} \cdot \frac{3}{4} + 2 \cdot \frac{1}{2} \cdot \frac{1}{2} = \frac{113}{64}.\end{aligned}$$

8. The number  $X$  of components that fail will have the binomial distribution with parameters  $n = 10$  and  $p = 0.2$ . Therefore,

$$\begin{aligned}\Pr(X \geq 2 | X \geq 1) &= \frac{\Pr(X \geq 2)}{\Pr(X \geq 1)} = \frac{1 - \Pr(X = 0) - \Pr(X = 1)}{1 - \Pr(X = 0)} \\ &= \frac{1 - .1074 - .2684}{1 - .1074} = \frac{.6242}{.8926} = .6993.\end{aligned}$$

9.  $\Pr\left(X_1 = 1 \mid \sum_{i=1}^n X_i = k\right) = \frac{\Pr\left(X_1 = 1 \text{ and } \sum_{i=1}^n X_i = k\right)}{\Pr\left(\sum_{i=1}^n X_i = k\right)} = \frac{\Pr\left(X_1 = 1 \text{ and } \sum_{i=2}^n X_i = k - 1\right)}{\Pr\left(\sum_{i=1}^n X_i = k\right)}.$

Since the random variables  $X_1, \dots, X_n$  are independent, it follows that  $X_1$  and  $\sum_{i=2}^n X_i$  are independent. Therefore, the final expression can be rewritten as

$$\frac{\Pr(X_1 = 1) \Pr\left(\sum_{i=2}^n X_i = k - 1\right)}{\Pr\left(\sum_{i=1}^n X_i = k\right)}.$$

The sum  $\sum_{i=2}^n X_i$  has the binomial distribution with parameters  $n - 1$  and  $p$ , and the sum  $\sum_{i=1}^n X_i$  has the binomial distribution with parameters  $n$  and  $p$ . Therefore,

$$\Pr\left(\sum_{i=2}^n X_i = k - 1\right) = \binom{n-1}{k-1} p^{k-1} (1-p)^{(n-1)-(k-1)} = \binom{n-1}{k-1} p^{k-1} (1-p)^{n-k},$$

and

$$\Pr\left(\sum_{i=1}^n X_i = k\right) = \binom{n}{k} p^k (1-p)^{n-k}.$$

Also,  $\Pr(X_1 = 1) = p$ . It now follows that

$$\Pr\left(X_1 = 1 \mid \sum_{i=1}^n X_i = k\right) = \frac{\binom{n-1}{k-1} p^k (1-p)^{n-k}}{\binom{n}{k} p^k (1-p)^{n-k}} = \frac{k}{n}.$$

10. The number of children  $X$  in the family who will inherit the disease has the binomial distribution with parameters  $n$  and  $p$ . Let  $f(x|n, p)$  denote the p.f. of this distribution. Then

$$\Pr(X \geq 1) = 1 - \Pr(X = 0) = 1 - f(0|n, p) = 1 - (1-p)^n.$$

For  $x = 1, 2, \dots, n$ ,

$$\Pr(X = x | X \geq 1) = \frac{\Pr(X = x)}{\Pr(X \geq 1)} = \frac{f(x|n, p)}{1 - (1-p)^n}.$$

Therefore, the conditional p.f. of  $X$  given that  $X \geq 1$  is  $f(x|n, p)/(1 - [1-p]^n)$  for  $x = 1, 2, \dots, n$ . The required expectation  $E(X | X \geq 1)$  is the mean of this conditional distribution. Therefore,

$$E(X | X \geq 1) = \sum_{x=1}^n x \frac{f(x|n, p)}{1 - (1-p)^n} = \frac{1}{1 - (1-p)^n} \sum_{x=1}^n x f(x|n, p).$$

However, we know that the mean of the binomial distribution is  $np$ ; i.e.,

$$E(X) = \sum_{x=0}^n x f(x|n, p) = np.$$

Furthermore, we can drop the term corresponding to  $x = 0$  from this summation without affecting the value of the summation, because the value of that term is 0. Hence,  $\sum_{x=1}^n x f(x|n, p) = np$ . It now follows that  $E(X | X \geq 1) = np/(1 - [1-p]^n)$ .

11. Since the value of the term being summed here will be 0 for  $x = 0$  and for  $x = 1$ , we may change the lower limit of the summation from  $x = 2$  to  $x = 0$ , without affecting the value of the sum. The summation can then be rewritten as

$$\sum_{x=0}^n x^2 \binom{n}{x} p^x (1-p)^{n-x} - \sum_{x=0}^n x \binom{n}{x} p^x (1-p)^{n-x}.$$

If  $X$  has the binomial distribution with parameters  $n$  and  $p$ , then the first summation is simply  $E(X^2)$  and the second summation is simply  $E(X)$ . Finally,

$$E(X^2) - E(X) = \text{Var}(X) + [E(X)]^2 - E(X) = np(1-p) + (np)^2 - np = n(n-1)p^2.$$

12. Assuming that  $p$  is not 0 or 1,

$$\frac{f(x+1|n,p)}{f(x|n,p)} = \frac{\binom{n}{x+1} p^{x+1} (1-p)^{n-x-1}}{\binom{n}{x} p^x (1-p)^{n-x}} = \frac{n-x}{x+1} = \frac{p}{1-p}.$$

Therefore,

$$\frac{f(x+1|n,p)}{f(x|n,p)} \geq 1 \quad \text{if and only if } x \leq (n+1)p - 1.$$

It follows from this relation that the values of  $f(x|n,p)$  will increase as  $x$  increases from 0 up to the greatest integer less than  $(n+1)p$ , and will then decrease as  $x$  continues increasing up to  $n$ . Therefore, if  $(n+1)p$  is not an integer, the unique mode will be the greatest integer less than  $(n+1)p$ . If  $(n+1)p$  is an integer, then both  $(n+1)p$  and  $(n+1)p - 1$  are modes. If  $p = 0$ , the mode is 0 and if  $p = 1$ , the mode is  $n$ .

13. Let  $X$  be the number of successes in the group with probability 0.5 of success. Let  $Y$  be the number of successes in the group with probability 0.6 of success. We want  $\Pr(X \geq Y)$ . Both  $X$  and  $Y$  have discrete (binomial) distributions with possible values  $0, \dots, 5$ . There are 36 possible  $(X, Y)$  pairs and we need the sum of the probabilities of the 21 of them for which  $X \geq Y$ . To save time, we shall calculate the probabilities of the 15 other ones and subtract the total from 1. Since  $X$  and  $Y$  are independent, we can write  $\Pr(X = x, Y = y) = \Pr(X = x)\Pr(Y = y)$ , and find each of the factors in the binomial table in the back of the book. For example, for  $x = 1$  and  $y = 2$ , we get  $0.1562 \times 0.2304 = 0.03599$ . Adding up all 15 of these and subtracting from 1 we get 0.4957.
14. Before we prove the three facts, we shall show that they imply the desired result. According to (c), every distribution with the specified moments must take only the values 0 and 1. The mean of such a distribution is  $\Pr(X = 1)$ . This number,  $\Pr(X = 1)$ , uniquely determines every distribution that can only take the two values 0 and 1.

- (a) Suppose that  $\Pr(|X| > 1) > 0$ . Then there exists  $\epsilon > 0$  such that  $\Pr(|X| > 1 + \epsilon) > 0$ . Then

$$E(X^{2k}) \geq (1 + \epsilon)^{2k} \Pr(|X| > 1 + \epsilon).$$

Since the right side of this equation goes to  $\infty$  as  $k \rightarrow \infty$ , it cannot be the case that  $E(X^{2k}) = 1/3$  for all  $k$ . This contradiction means that our assumption that  $\Pr(|X| > 1) > 0$  must be false. That is,  $\Pr(|X| \leq 1) = 1$ .

- (b) Since  $X^4 < X^2$  whenever  $|X| \leq 1$  and  $X^2 \notin \{0, 1\}$ , it follows that  $E(X^4) < E(X^2)$  whenever  $\Pr(|X| \leq 1) = 1$  and  $\Pr(X^2 \notin \{0, 1\}) > 0$ . Since we know that  $E(X^4) = E(X^2)$  and  $\Pr(|X| \leq 1) = 1$ , it must be that  $\Pr(X^2 \notin \{0, 1\}) = 0$ . That is,  $\Pr(X^2 \in \{0, 1\}) = 1$ .
- (c) From (b) we know that  $\Pr(X \in \{-1, 0, 1\}) = 1$ . We also know that

$$\begin{aligned} E(X) &= \Pr(X = 1) - \Pr(X = -1) \\ E(X^2) &= \Pr(X = 1) + \Pr(X = -1). \end{aligned}$$

Since these two are equal, it follows that  $\Pr(X = -1) = 0$ .

15. We need the maximum number of tests if and only if every first-stage and second-stage subgroup has at least one positive result. In that case, we would need  $10 + 100 + 1000 = 1110$  total tests. The probability that we have to run this many tests is the probability that every  $Y_{2,i,k} = 1$ , which in turn is the probability that every  $Z_{2,i,k} > 0$ . The  $Z_{2,i,k}$ 's are independent binomial random variables with parameters 10 and 0.002, and there are 100 of them altogether. The probability that each is positive is 0.0198, as computed in Example 5.2.7. The probability that they are all positive is  $(0.0198)^{100} = 4.64 \times 10^{-171}$ .
16. We use notation like that in Example 5.2.7 with one extra stage. For  $i = 1, \dots, 5$ , let  $Z_{1,i}$  be the number of people in group  $i$  who test positive. Let  $Y_{1,i} = 1$  if  $Z_{1,i} > 0$  and  $Y_{1,i} = 0$  if not. Then  $Z_{1,i}$  has the binomial distribution with parameters 200 and 0.002, while  $Y_{1,i}$  has the Bernoulli distribution with parameter  $1 - 0.998^{200} = 0.3299$ . Let  $Z_{2,i,k}$  be the number of people who test positive in the  $k$ th subgroup of group  $i$  for  $k = 1, \dots, 5$ . Let  $Y_{2,i,k} = 1$  if  $Z_{2,i,k} > 0$  and  $Y_{2,i,k} = 0$  if not. Each  $Z_{2,i,k}$  has the binomial distribution with parameters 40 and 0.002, while  $Y_{2,i,k}$  has the Bernoulli distribution with parameter  $1 - 0.998^{40} = 0.0770$ . Finally, let  $Z_{3,i,k,j}$  be the number of people who test positive in the  $j$ th sub-subgroup of the  $k$ th subgroup of the  $i$ th group. Let  $Y_{3,i,k,j} = 1$  if  $Z_{3,i,k,j} > 0$  and  $Y_{3,i,k,j} = 0$  otherwise. Then  $Z_{3,i,k,j}$  has the binomial distribution with parameters 8 and 0.002, while  $Y_{3,i,k,j}$  has the Bernoulli distribution with parameter  $1 - 0.998^8 = 0.0159$ .

The maximum number of tests is needed if and only if there is at least one positive amongst every one of the 125 sub-subgroups of size 8. In that case, we need to make  $1000 + 125 + 25 + 5 = 1155$  total tests. Let  $Y_1 = \sum_{i=1}^5 Y_{1,i}$ , which is the number of groups that need further attention. Let  $Y_2 = \sum_{i=1}^5 \sum_{k=1}^5 Y_{2,i,k}$ , which is the number of subgroups that need further attention. Let  $Y_3 = \sum_{i=1}^5 \sum_{k=1}^5 \sum_{j=1}^5 Y_{3,i,k,j}$ , which is the number of sub-subgroups that need all 8 members tested. The actual number of tests needed is  $Y = 5 + 5Y_1 + 5Y_2 + 8Y_3$ . The mean of  $Y_1$  is  $5 \times 0.3299 = 1.6497$ . The mean of  $Y_2$  is  $25 \times 0.0770 = 1.9239$ . The mean of  $Y_3$  is  $125 \times 0.0159 = 1.9861$ . The mean of  $Y$  is then

$$E(Y) = 5 + 5 \times 1.6497 + 5 \times 1.9239 + 8 \times 1.9861 = 38.7569.$$

## 5.3 The Hypergeometric Distributions

### Commentary

The hypergeometric distribution arises in finite population sampling and in some theoretical calculations. It actually does not figure in the remainder of this text, and this section could be omitted despite the fact that it is not marked with an asterisk. The section ends with a discussion of how to extend the definition of binomial coefficients in order to make certain formulas easier to write. This discussion is not central to the rest of the text. It does arise again in a theoretical discussion at the end of Sec. 5.5.

If one is using the statistical software  $R$ , then the functions `dhyper`, `phyper`, and `qhyper` give the p.f., the c.d.f., and the quantile function of hypergeometric distributions. The syntax is that the first argument is the argument of the function, and the next three are  $A$ ,  $B$ , and  $n$  in the notation of the text. The function

`rhyper` gives a random sample of hypergeometric random variables. The first argument is how many you want, and the next three are  $A$ ,  $B$ , and  $n$ . All of the solutions that require the calculation of hypergeometric probabilities can be done using these functions.

## Solutions to Exercises

1. Using Eq. (5.3.1) with the parameters  $A = 10$ ,  $B = 24$ , and  $n = 11$ , we obtain the desired probability

$$\Pr(X = 10) = \frac{\binom{10}{10} \binom{24}{1}}{\binom{34}{11}} = 8.389 \times 10^{-8}.$$

2. Let  $X$  denote the number of red balls that are obtained. Then  $X$  has the hypergeometric distribution with parameters  $A = 5$ ,  $B = 10$ , and  $n = 7$ . The maximum value of  $X$  is  $\min\{n, A\} = 5$ , hence,

$$\Pr(X \geq 3) = \sum_{x=3}^5 \frac{\binom{5}{x} \binom{10}{7-x}}{\binom{15}{7}} = \frac{2745}{6435} \approx 0.4266.$$

3. As in Exercise 2, let  $X$  denote the number of red balls in the sample. Then, by Eqs. (5.3.3) and (5.3.4),

$$E(X) = \frac{nA}{A+B} = \frac{7}{3} \quad \text{and} \quad \text{Var}(X) = \frac{nAB}{(A+B)^2} \cdot \frac{A+B-n}{A+B-1} = \frac{8}{9}.$$

Since  $\bar{X} = X/n$ ,

$$E(\bar{X}) = \frac{1}{n} E(X) = \frac{1}{3} \quad \text{and} \quad \text{Var}(\bar{X}) = \frac{1}{n^2} \text{Var}(X) = \frac{8}{441}.$$

4. By Eq. (5.3.4),

$$\text{Var}(X) = \frac{(8)(20)}{(28)^2(27)} n(28-n).$$

The quadratic function  $n(28-n)$  is a maximum when  $n = 14$ .

5. By Eq. (5.3.4),

$$\text{Var}(X) = \frac{A(T-A)}{T^2(T-1)} n(T-n).$$

If  $T$  is an even integer, then the quadratic function  $n(T-n)$  is a maximum when  $n = T/2$ . If  $T$  is an odd integer, then the maximum value of  $n(T-n)$ , for  $n = 0, 1, 2, \dots, T$ , occurs at the two integers  $(T-1)/2$  and  $(T+1)/2$ .

6. For  $x = 0, 1, \dots, k$ ,

$$\Pr(X_1 = x | X_1 + X_2 = k) = \frac{\Pr(X_1 = x \text{ and } X_1 + X_2 = k)}{\Pr(X_1 + X_2 = k)} = \frac{\Pr(X_1 = x \text{ and } X_2 = k - x)}{\Pr(X_1 + X_2 = k)}.$$

Since  $X_1$  and  $X_2$  are independent,

$$\Pr(X_1 = x \text{ and } X_2 = k - x) = \Pr(X_1 = x) \Pr(X_2 = k - x).$$

Furthermore, it follows from a result given in Sec. 5.2 that  $X_1 + X_2$  will have the binomial distribution with parameters  $n_1 + n_2$  and  $p$ . Therefore,

$$\begin{aligned}\Pr(X_1 = x) &= \binom{n_1}{x} p^x (1-p)^{n_1-x}, \\ \Pr(X_2 = k - x) &= \binom{n_2}{k-x} p^{k-x} (1-p)^{n_2-k+x}, \\ \Pr(X_1 + X_2 = k) &= \binom{n_1 + n_2}{k} p^k (1-p)^{n_1+n_2-k}.\end{aligned}$$

By substituting these values into the expression given earlier, we find that for  $x = 0, 1, \dots, k$ ,

$$\Pr(X_1 = x | X_1 + X_2 = k) = \frac{\binom{n_1}{x} \binom{n_2}{k-x}}{\binom{n_1 + n_2}{k}}.$$

It can be seen that this conditional distribution is a hypergeometric distribution with parameters  $n_1, n_2$ , and  $k$ .

7. (a) The probability of obtaining exactly  $x$  defective items is

$$\frac{\binom{0.3T}{x} \binom{0.7T}{10-x}}{\binom{T}{10}}.$$

Therefore, the probability of obtaining not more than one defective item is the sum of these probabilities for  $x = 0$  and  $x = 1$ .

Since

$$\binom{0.3T}{0} = 1 \quad \text{and} \quad \binom{0.3T}{1} = 0.3T,$$

this sum is equal to

$$\frac{\binom{0.7T}{10} + 0.3T \binom{0.7T}{9}}{\binom{T}{10}}.$$

- (b) The probability of obtaining exactly  $x$  defectives according to the binomial distribution, is

$$\binom{10}{x} (0.3)^x (0.7)^{10-x}.$$

The desired probability is the sum of these probabilities for  $x = 0$  and  $x = 1$ , which is

$$(0.7)^{10} + 10(0.3)(0.7)^9.$$

For a large value of  $T$ , the answers in (a) and (b) will be very close to each other, although this fact is not obvious from the different forms of the two answers.

8. If we let  $X_i$  denote the height of the  $i$ th person selected, for  $i = 1, \dots, n$ , then  $X = X_1 + \dots + X_n$ . Furthermore, since  $X_i$  is equally likely to have any one of the  $T$  values  $a_1, \dots, a_T$ , then

$$E(X_i) = \frac{1}{T} \sum_{i=1}^T a_i = \mu$$

and

$$\text{Var}(X_i) = \frac{1}{T} \sum_{i=1}^T (a_i - \mu)^2 = \sigma^2.$$

It follows that  $E(X) = n\mu$ . Furthermore, by Theorem 4.6.7,

$$\text{Var}(X) = \sum_{i=1}^n \text{Var}(X_i) + 2 \sum_{i < j} \text{Cov}(X_i, X_j).$$

Because of the symmetry among the variables  $X_1, \dots, X_n$ , it follows that

$$\text{Var}(X) = n\sigma^2 + n(n-1) \text{Cov}(X_1, X_2).$$

We know that  $\text{Var}(X) = 0$  for  $n = T$ . Therefore,

$$\text{Cov}(X_1, X_2) = -\frac{1}{T-1}\sigma^2.$$

It now follows that

$$\text{Var}(X) = n\sigma^2 - \frac{n(n-1)}{T-1}\sigma^2 = n\sigma^2 \left( \frac{T-n}{T-1} \right).$$

9. By Eq. (5.3.14),

$$\binom{3/2}{4} = \frac{(3/2)(1/2)(-1/2)(-3/2)}{4!} = \frac{3}{128}.$$

10. By Eq. (5.3.14),

$$\binom{-n}{k} = \frac{(-n)(-n-1)\cdots(-n-k+1)}{k!} = \frac{(-1)^k(n)(n+1)\cdots(n+k-1)}{k!}.$$

If we reverse the order of the factors in the numerator, we can rewrite this relation as follows:

$$\binom{-n}{k} = \frac{(-1)^k(n+k-1)(n+k-2)\cdots(n)}{k!} = (-1)^k \binom{n+k-1}{k}.$$

11. Write  $(1 + a_n)^{c_n} e^{-a_n c_n} = \exp[c_n \log(1 + a_n) - a_n c_n]$ . The result is proven if we can show that

$$\lim_{n \rightarrow \infty} [c_n \log(1 + a_n) - a_n c_n] = 0. \quad (\text{S.5.1})$$

Use Taylor's theorem with remainder to write

$$\log(1 + a_n) = a_n - \frac{a_n^2}{2(1 + y_n)^2},$$

where  $y_n$  is between 0 and  $a_n$ . It follows that

$$c_n \log(1 + a_n) - a_n c_n = c_n a_n - \frac{c_n a_n^2}{2(1 + y_n)^2} - a_n c_n = -\frac{c_n a_n^2}{2(1 + y_n)^2}.$$

We have assumed that  $c_n a_n^2$  goes to 0. Since  $y_n$  is between 0 and  $a_n$ , and  $a_n$  goes to 0, we have  $1/[2(1 + y_n)^2]$  goes to 0. This establishes (S.5.1).

## 5.4 The Poisson Distributions

### Commentary

This section ends with a more theoretical look at the assumptions underlying the Poisson process. This material is designed for the more mathematically inclined students who might wish to see a derivation of the Poisson distribution from those assumptions. Such a derivation is outlined in Exercise 16 in this section.

If one is using the statistical software *R*, then the functions `dpois`, `ppois`, and `qpois` give the p.f., the c.d.f., and the quantile function of Poisson distributions. The syntax is that the first argument is the argument of the function, and the second is the mean. The function `rpois` gives a random sample of Poisson random variables. The first argument is how many you want, and the second is the mean. All of the solutions that require the calculation of Poisson probabilities can be done using these functions instead of tables.

### Solutions to Exercises

1. The number of oocysts  $X$  in  $t = 100$  liters of water has the Poisson distribution with mean  $0.2 \times 0.1 \times 100 = 2$ . Using the Poisson distribution table in the back of the book, we find

$$\Pr(X \geq 2) = 1 - \Pr(X \leq 1) = 1 - 0.1353 - 0.2707 = 0.594.$$

2. From the table of the Poisson distribution in the back of the book it is found that

$$\Pr(X \geq 3) = .0284 + .0050 + .0007 + .0001 + .0000 = .0342.$$

3. Since the number of defects on each bolt has the Poisson distribution with mean 0.4, and the observations for the five bolts are independent, the sum for the numbers of defects on five bolts will have the Poisson distribution with mean  $5(0.4) = 2$ . It is found from the table of the Poisson distribution that

$$\Pr(X \geq 6) = .0120 + .0034 + .0009 + .0002 + .0000 = .0165.$$

There is some rounding error in this, and 0.0166 is closer.

4. If  $f(x | \lambda)$  is the p.f. of the Poisson distribution with mean  $\lambda$ , then

$$\Pr(X = 0) = f(0 | \lambda) = \exp(-\lambda).$$

5. Let  $Y$  denote the number of misprints on a given page. Then the probability  $p$  that a given page will contain more than  $k$  misprints is

$$p = \Pr(Y > k) = \sum_{i=k+1}^{\infty} f(i | \lambda) = \sum_{i=k+1}^{\infty} \frac{\exp(-\lambda)\lambda^i}{i!}.$$

Therefore,

$$1 - p = \sum_{i=0}^k f(i | \lambda) = \sum_{i=0}^k \frac{\exp(-\lambda)\lambda^i}{i!}.$$

Now let  $X$  denote the number of pages, among the  $n$  pages in the book, on which there are more than  $k$  misprints. Then for  $x = 0, 1, \dots, n$ ,

$$\Pr(X = x) = \binom{n}{x} p^x (1-p)^{n-x}$$

and

$$\Pr(X \geq m) = \sum_{x=m}^n \binom{n}{x} p^x (1-p)^{n-x}.$$

6. We shall assume that defects occur in accordance with a Poisson process. Then the number of defects in 1200 feet of tape will have the Poisson distribution with mean  $\mu = 3(1.2) = 3.6$ . Therefore, the probability that there will be no defects is  $\exp(-\mu) = \exp(-3.6)$ .
7. We shall assume that customers are served in accordance with a Poisson process. Then the number of customers served in a two-hour period will have the Poisson distribution with mean  $\mu = 2(15) = 30$ . Therefore, the probability that more than 20 customers will be served is

$$\Pr(X > 20) = \sum_{x=21}^{\infty} \frac{\exp(-30)(30)^x}{x!}.$$

8. For  $x = 0, 1, \dots, k$ ,

$$\Pr(X_1 = x | X_1 + X_2 = k) = \frac{\Pr(X_1 = x \text{ and } X_1 + X_2 = k)}{\Pr(X_1 + X_2 = k)} = \frac{\Pr(X_1 = x \text{ and } X_2 = k - x)}{\Pr(X_1 + X_2 = k)}.$$

Since  $X_1$  and  $X_2$  are independent,

$$\Pr(X_1 = x \text{ and } X_2 = k - x) = \Pr(X_1 = x) \Pr(X_2 = k - x).$$

Also, by Theorem 5.4.4 the sum  $X_1 + X_2$  will have the Poisson distribution with mean  $\lambda_1 + \lambda_2$ . Hence,

$$\begin{aligned} \Pr(X_1 = x) &= \frac{\exp(-\lambda_1)\lambda_1^x}{x!} \\ \Pr(X_2 = k - x) &= \frac{\exp(-\lambda_2)\lambda_2^{k-x}}{(k-x)!} \\ \Pr(X_1 + X_2 = k) &= \frac{\exp(-(\lambda_1 + \lambda_2))(\lambda_1 + \lambda_2)^k}{k!} \end{aligned}$$

It now follows that

$$\Pr(X_1 = x | X_1 + X_2 = k) = \frac{k!}{x!(k-x)!} \left( \frac{\lambda_1}{\lambda_1 + \lambda_2} \right)^x \left( \frac{\lambda_2}{\lambda_1 + \lambda_2} \right)^{k-x} = \binom{k}{x} p^x (1-p)^{k-x},$$

where  $p = \lambda_1/(\lambda_1 + \lambda_2)$ . It can now be seen that this conditional distribution is a binomial distribution with parameters  $k$  and  $p = \lambda_1/(\lambda_1 + \lambda_2)$ .

9. Let  $N$  denote the total number of items produced by the machine and let  $X$  denote the number of defective items produced by the machine. Then, for  $x = 0, 1, \dots$ ,

$$\Pr(X = x) = \sum_{n=0}^{\infty} \Pr(X = x | N = n) \Pr(N = n).$$

Clearly, it must be true that  $X \leq N$ . Therefore, the terms in this summation for  $n < x$  will be 0, and we may write

$$\Pr(X = x) = \sum_{n=x}^{\infty} \Pr(X = x | N = n) \Pr(N = n).$$

Clearly,  $\Pr(X = 0 | N = 0) = 1$ . Also, given that  $N = n > 0$ , the conditional distribution of  $X$  will be a binomial distribution with parameters  $n$  and  $p$ . Therefore,

$$\Pr(X = x | N = n) = \frac{n!}{x!(n-x)!} p^x (1-p)^{n-x}.$$

Also, since  $N$  has the Poisson distribution with mean  $\lambda$ ,

$$\Pr(N = n) = \frac{\exp(-\lambda)\lambda^n}{n!}.$$

Hence,

$$\Pr(X = x) = \sum_{n=x}^{\infty} \frac{n!}{x!(n-x)!} p^x (1-p)^{n-x} \frac{\exp(-\lambda)\lambda^n}{n!} = \frac{1}{x!} p^x \exp(-\lambda) \sum_{n=x}^{\infty} \frac{1}{(n-x)!} (1-p)^{n-x} \lambda^n.$$

If we let  $t = n - x$ , then

$$\begin{aligned} \Pr(X = x) &= \frac{1}{x!} p^x \exp(-\lambda) \sum_{t=0}^{\infty} \frac{1}{t!} (1-p)^t \lambda^{t+x} \\ &= \frac{1}{x!} (\lambda p)^x \exp(-\lambda) \sum_{t=0}^{\infty} \frac{[\lambda(1-p)]^t}{t!} \\ &= \frac{1}{x!} (\lambda p)^x \exp(-\lambda) \exp(\lambda(1-p)) = \frac{\exp(-\lambda p)(\lambda p)^x}{x!}. \end{aligned}$$

It can be seen that this final term is the value of the p.f. of the Poisson distribution with mean  $\lambda p$ .

10. It must be true that  $X + Y = N$ . Therefore, for any nonnegative integers  $x$  and  $y$ ,

$$\begin{aligned}\Pr(X = x \text{ and } Y = y) &= \Pr(X = x \text{ and } N = x + y) \\ &= \Pr(X = x | N = x + y) \Pr(N = x + y) \\ &= \frac{(x+y)!}{x!y!} p^x (1-p)^y \frac{\exp(-\lambda)\lambda^{x+y}}{(x+y)!} \\ &= \exp(-\lambda) \frac{(\lambda p)^x}{x!} \cdot \frac{[\lambda(1-p)]^y}{y!}.\end{aligned}$$

The fact that we have factored  $\Pr(X = x \text{ and } Y = y)$  into the product of a function of  $x$  and a function of  $y$  is sufficient for us to be able to conclude that  $X$  and  $Y$  are independent. However, if we continue further and write

$$\exp(-\lambda) = \exp(-\lambda p) \exp(-\lambda(1-p))$$

then we can obtain the factorization

$$\Pr(X = x \text{ and } Y = y) = \frac{\exp(-\lambda)p(\lambda p)^x}{x!} \cdot \frac{\exp(-\lambda(1-p))[\lambda(1-p)]^y}{y!} = \Pr(X = x) \Pr(Y = y).$$

11. If  $f(x | \lambda)$  denotes the p.f. of the Poisson distribution with mean  $\lambda$ , then

$$\frac{f(x+1 | \lambda)}{f(x | \lambda)} = \frac{\lambda}{x+1}.$$

Therefore,  $f(x | \lambda) < f(x+1 | \lambda)$  if and only if  $x+1 < \lambda$ . It follows that if  $\lambda$  is not an integer, then the mode of this distribution will be the largest integer  $x$  that is less than  $\lambda$  or, equivalently, the smallest integer  $x$  such that  $x+1 > \lambda$ . If  $\lambda$  is an integer, then both the values  $\lambda - 1$  and  $\lambda$  will be modes.

12. It can be assumed that the exact distribution of the number of colorblind people in the group is a binomial distribution with parameters  $n = 600$  and  $p = 0.005$ . Therefore, this distribution can be approximated by a Poisson distribution with mean  $600(0.005) = 3$ . It is found from the table of the Poisson distribution that

$$\Pr(X \leq 1) = .0498 + .1494 = .1992.$$

13. It can be assumed that the exact number of sets of triplets in this hospital is a binomial distribution with parameters  $n = 700$  and  $p = 0.001$ . Therefore, this distribution can be approximated by a Poisson distribution with mean  $700(0.001) = 0.7$ . It is found from the table of the Poisson distribution that

$$\Pr(X = 1) = 0.3476.$$

14. Let  $X$  denote the number of people who do not appear for the flight. Then everyone who does appear will have a seat if and only if  $X \geq 2$ . It can be assumed that the exact distribution of  $X$  is a binomial distribution with parameters  $n = 200$  and  $p = 0.01$ . Therefore, this distribution can be approximated by a Poisson distribution with mean  $200(0.01) = 2$ . It is found from the table of the Poisson distribution that

$$\Pr(X \geq 2) = 1 - \Pr(X \leq 1) = 1 - .1353 - .2707 = .5940.$$

15. The joint p.f./p.d.f. of  $X$  and  $\lambda$  is the Poisson p.f. with parameter  $\lambda$  times  $f(\lambda)$  which equals

$$\exp(-\lambda) \frac{\lambda^x}{x!} 2 \exp(-2\lambda) = 2 \exp(-3\lambda) \frac{\lambda^x}{x!}. \quad (\text{S.5.2})$$

We need to compute the marginal p.f. of  $X$  at  $x = 1$  and divide that into (S.5.2) to get the conditional p.d.f. of  $\lambda$  given  $X = 1$ . The marginal p.f. of  $X$  at  $x = 1$  is the integral of (S.5.2) over  $\lambda$  when  $x = 1$  is plugged in.

$$f_1(1) = \int_0^\infty 2\lambda \exp(-3\lambda) d\lambda = \frac{2}{9}.$$

This makes the conditional p.d.f. of  $\lambda$  equal to  $9\lambda \exp(-3\lambda)$  for  $\lambda > 0$ .

16. (a) Let  $A = \cup_{i=1}^n A_i$ . Then

$$\{X = k\} = (\{X = k\} \cap A) \cup (\{X = k\} \cap A^c).$$

The second event on the right side of this equation is  $\{W_n = k\}$ . Call the first event on the right side of this equation  $B$ . Then  $B \subset A$ . Since  $B$  and  $\{W_n = k\}$  are disjoint,  $\Pr(X = k) = \Pr(W_n = k) + \Pr(B)$ .

- (b) Since the subintervals are disjoint, the events  $A_1, \dots, A_n$  are independent. Since the subintervals all have the same length  $t/n$ , each  $A_i$  has the same probability. It follows that

$$\Pr(\cap_{i=1}^n A_i^c) = [1 - \Pr(A_1)]^n.$$

By assumption,  $\Pr(A_i) = o(1/n)$ , so

$$\Pr(A) = 1 - \Pr(\cap_{i=1}^n A_i^c) = 1 - [1 - o(1/n)]^n.$$

So,

$$\lim_{n \rightarrow \infty} \Pr(A) = 1 - \lim_{n \rightarrow \infty} [1 - o(1/n)]^n = 1,$$

according to Eq. (5.4.9).

- (c) Since the  $Y_i$  are i.i.d. Bernoulli random variables with parameter  $p_n = \lambda t/n + o(1/n)$ , we know that  $W_n$  has the binomial distribution with parameters  $n$  and  $p_n$ . Hence

$$\Pr(W_n = k) = \binom{n}{k} p_n^k (1 - p_n)^{n-k} = \frac{n!}{(n-k)! k!} \left[ \frac{\lambda t}{n} + o(1/n) \right]^k \left[ 1 - \frac{\lambda t}{n} - o(1/n) \right]^{n-k}.$$

For fixed  $k$ ,

$$\lim_{n \rightarrow \infty} n^k \left[ \frac{\lambda t}{n} + o(1/n) \right]^k = (\lambda t)^k.$$

Also, using the formula stated in the exercise,

$$\lim_{n \rightarrow \infty} n^k \left[ 1 - \frac{\lambda t}{n} - o(1/n) \right]^{n-k} = \exp(-\lambda t).$$

It follows that

$$\lim_{n \rightarrow \infty} \Pr(W_n = k) = \exp(-\lambda t) \frac{(\lambda t)^k}{k!} \lim_{n \rightarrow \infty} \frac{n!}{n^k (n-k)!}.$$

We can write

$$\frac{n!}{n^k (n-k)!} = \frac{n(n-1) \cdots (n-k+1)}{n \cdot n \cdots n}.$$

For fixed  $k$ , the limit of this ratio is 1 as  $n \rightarrow \infty$ .

(d) We have established that

$$\Pr(X = k) = \Pr(W_n = k) + \Pr(B).$$

Since the left side of this equation does not depend on  $n$ , we can write

$$\Pr(X = k) = \lim_{n \rightarrow \infty} \Pr(W_n = k) + \lim_{n \rightarrow \infty} \Pr(B).$$

In earlier parts of this exercise we showed that the two limits on the right are  $\exp(-\lambda t)(\lambda t)^k/k!$  and 0 respectively. So,  $X$  has the Poisson distribution with mean  $\lambda t$ .

17. Because  $n_T A_T / (A_T + B_T)$  converges to  $\lambda$ ,  $n_T / (A_T + B_T)$  goes to 0. Hence,  $B_T$  eventually gets larger than  $n_T$ . Once  $B_T$  is larger than  $n_T + x$  and  $A_T$  is larger than  $x$ , we have

$$\Pr(X_T = x) = \frac{\binom{A_T}{x} \binom{B_T}{n_T - x}}{\binom{A_T + B_T}{n_T}} = \frac{A_T! B_T! n_T! (A_T + B_T - n_T)!}{x! (A_T - x)! (n_T - x)! (B_T - n_T + x)! (A_T + B_T)!}.$$

Apply Stirling's formula to each of the factorials in the above expression except  $x!$ . A little manipulation gives that

$$\begin{aligned} & \lim_{T \rightarrow \infty} \frac{A_T^{A_T+1/2} B_T^{B_T+1/2} n_T^{n_T+1/2} (A_T + B_T - n_T)^{A_T+B_T-n_T+1/2} e^x}{\Pr(X_T = x) x! (A_T - x)^{A_T-x+1/2} (n_T - x)^{n_T-x+1/2} (B_T - n + x)^{B_T-n+x+1/2} (A_T + B_T)^{A_T+B_T+1/2}} \\ &= 1. \end{aligned} \quad (\text{S.5.3})$$

Each of the following limits follows from Theorem 5.3.3:

$$\begin{aligned} & \lim_{T \rightarrow \infty} \left( \frac{A_T}{A_T - x} \right)^{A_T - x + 1/2} = e^x, \\ & \lim_{T \rightarrow \infty} \left( \frac{B_T}{B_T - n_T + x} \right)^{B_T - n_T + x + 1/2} e^{-n_T} = e^{-x}, \\ & \lim_{T \rightarrow \infty} \left( \frac{A_T + B_T - n_T}{A_T + B_T} \right)^{A_T + B_T - n + 1/2} e^{n_T} = 1, \\ & \lim_{T \rightarrow \infty} \left( \frac{n_T}{n_T - x} \right)^{n_T - x + 1/2} = e^{-x}, \\ & \lim_{T \rightarrow \infty} \left( \frac{B_T}{A_T + B_T} \right)^{n_T - x} = e^{-\lambda}, \end{aligned}$$

Inserting these limits in (S.5.3) yields

$$\lim_{T \rightarrow \infty} \frac{A_T^x e^{-\lambda} n_T^x}{\Pr(X_T = x) x! (A_T + B_T)^x} = 1. \quad (\text{S.5.4})$$

Since  $n_T A_T / (A_T + B_T)$  converges to  $\lambda$ , we have

$$\lim_{T \rightarrow \infty} \frac{A_T^x n_T^x}{(A_T + B_T)^x} = \lambda^x. \quad (\text{S.5.5})$$

Together (S.5.4) and (S.5.5) imply that

$$\lim_{T \rightarrow \infty} \frac{\lambda^x e^{-\lambda} / x!}{\Pr(X_T = x)} = 1.$$

The numerator of this last expression is  $\Pr(Y = x)$ , which completes the proof.

18. First write

$$\frac{n_T A_T}{B_T} - \frac{n_T A_T}{A_T + B_T} = \frac{n_T A_T^2}{B_T(A_T + B_T)} = n_T \frac{A_T}{B_T} \frac{A_T}{A_T + B_T}. \quad (\text{S.5.6})$$

For the “if” part, assume that  $n_T A_T / B_T$  converges to  $\lambda$ . Since  $n_T$  goes to  $\infty$ , then  $A_T / B_T$  goes to 0, which implies that  $A_T / (A_T + B_T)$  (which is smaller) goes to 0. In the final expression in (S.5.6), the product of the first two factors goes to  $\lambda$  by assumption, and the third factor goes to 0, so  $n_T A_T / (A_T + B_T)$  converges to the same thing as  $n_T A_T / B_T$ , namely  $\lambda$ . For the “only if” part, assume that  $n_T A_T / (A_T + B_T)$  converges to  $\lambda$ . It follows that  $A_T / (A_T + B_T) = 1/(1 + B_T/A_T)$  goes to 0, hence  $A_T / B_T$  goes to 0. In the last expression in (S.5.6), the product of the first and third factors goes to  $\lambda$  by assumption, and the second factor goes to 0, hence  $n_T A_T / B_T$  converges to the same thing as  $n_T A_T / (A_T + B_T)$ , namely  $\lambda$ .

## 5.5 The Negative Binomial Distributions

### Commentary

This section ends with a discussion of how to extend the definition of negative binomial distribution by making use of the extended definition of binomial coefficients from Sec. 5.3.

If one is using the statistical software *R*, then the functions `dnbino`, `pnbino`, and `qnbinom` give the p.f., the c.d.f., and the quantile function of negative binomial distributions. The syntax is that the first argument is the argument of the function, and the next two are  $r$  and  $p$  in the notation of the text. The function `rnbino` gives a random sample of binomial random variables. The first argument is how many you want, and the next two are  $r$  and  $p$ . All of the solutions that require the calculation of negative binomial probabilities can be done using these functions. There are also functions `dgeom`, `pgeom`, `qgeom`, and `rgeom` that compute similar features of geometric distributions. Just remove the “ $r$ ” argument.

### Solutions to Exercises

1. (a) Two particular days in a row have independent draws, and each draw has probability 0.01 of producing triples. So, the probability that two particular days in a row will both have triples is  $10^{-4}$ .  
(b) Since a particular day and the next day are independent, the conditional probability of triples on the next day is 0.01 conditional on whatever happens on the first day.
2. (a) The number of tails will have the negative binomial distribution with parameters  $r = 5$  and  $p = 1/30$ . By Eq. (5.5.7),

$$E(X) = \frac{r(1-p)}{p} = 5(29) = 145.$$

- (b) By Eq. (5.5.7),  $\text{Var}(X) = \frac{r(1-p)}{p^2} = 4350$ .
3. (a) Let  $X$  denote the number of tails that are obtained before five heads are obtained, and let  $Y$  denote the total number of tosses that are required. Then  $Y = X + 5$ . Therefore,  $E(Y) = E(X) + 5$ . It follows from Exercise 2(a) that  $E(Y) = 150$ .  
(b) Suppose  $Y = X + 5$ , then  $\text{Var}(Y) = \text{Var}(X)$ . Therefore, it follows from Exercise 2(b) that  $\text{Var}(Y) = 4350$ .

4. (a) The number of failures  $X_A$  obtained by player  $A$  before he obtains  $r$  successes will have the negative binomial distribution with parameters  $r$  and  $p$ . The total number of throws required by player  $A$  will be  $Y_A = X_A + r$ . Therefore,

$$E(Y_A) = E(X_A) + r = r \frac{1-p}{p} + r = \frac{r}{p}.$$

The number of failures  $X_B$  obtained by player  $B$  before he obtains  $mr$  successes will have the negative binomial distribution with parameters  $mr$  and  $mp$ . The total number of throws required by player  $B$  will be  $Y_B = X_B + mr$ . Therefore,

$$E(Y_B) = E(X_B) + mr = (mr) \frac{(1-mp)}{mp} + mr = \frac{r}{p}.$$

(b)

$$\text{Var}(Y_A) = \text{Var}(X_A) = \frac{r(1-p)}{p^2} = \frac{r}{p^2}(1-p) \text{ and}$$

$$\text{Var}(Y_B) = \text{Var}(X_B) = \frac{(mr)(1-mp)}{(mp)^2} = \frac{r}{p^2} \left( \frac{1}{m} - p \right).$$

Therefore,  $\text{Var}(Y_B) < \text{Var}(Y_A)$ .

5. By Eq. (5.5.6), the m.g.f. of  $X_i$  is

$$\psi_i(t) = \left( \frac{p}{1 - (1-p)\exp(t)} \right)^{r_i} \quad \text{for } t < \log\left(\frac{1}{1-p}\right).$$

Therefore, the m.g.f. of  $X_1 + \dots + X_k$  is

$$\psi(t) = \prod_{i=1}^k \psi_i(t) = \left( \frac{p}{1 - (1-p)\exp(t)} \right)^{r_1+\dots+r_k} \quad \text{for } t < \log\left(\frac{1}{1-p}\right).$$

Since  $\psi(t)$  is the m.g.f. of the negative binomial distribution with parameters  $r_1 + \dots + r_k$  and  $p$ , that must be the distribution of  $X_1 + \dots + X_k$ .

6. For  $x = 0, 1, 2, \dots$ ,

$$\Pr(X = x) = p(1-p)^x.$$

If we let  $x = 2i$ , then as  $i$  runs through all the integers  $0, 1, 2, \dots$ , the value of  $2i$  will run through all the even integers  $0, 2, 4, \dots$ . Therefore,

$$\Pr(X \text{ is an even integer}) = \sum_{i=0}^{\infty} p(1-p)^{2i} = p \sum_{i=0}^{\infty} ([1-p]^2)^i = p \frac{1}{1 - (1-p)^2}.$$

7.  $\Pr(X \geq k) = \sum_{x=j}^{\infty} p(1-p)^x = p(1-p)^k \sum_{x=j}^{\infty} (1-p)^{x-k}$ . If we let  $i = x - k$ , then

$$\Pr(X \geq k) = p(1-p)^k \sum_{x=j}^{\infty} (1-p)^i = p(1-p)^k \frac{1}{1 - [1-p]} = (1-p)^k.$$

$$8. \Pr(X = k + t | X \geq k) = \frac{\Pr(X = k + t \text{ and } X \geq k)}{\Pr(X \geq k)} = \frac{\Pr(X = k + t)}{\Pr(X \geq k)}.$$

By Eq. (5.5.3),  $\Pr(X = k + t) = p(1 - p)^{k+t}$ . By Exercise 7,  $\Pr(X \geq k) = (1 - p)^k$ . Therefore,  $\Pr(X = k + t | X \geq k) = p(1 - p)^t = \Pr(X = t)$ .

9. Since the components are connected in series, the system will function properly only as long as every component functions properly. Let  $X_i$  denote the number of periods that component  $i$  functions properly, for  $i = 1, \dots, n$ , and let  $X$  denote the number of periods that system functions properly. Then for any nonnegative integer  $x$ ,

$$\Pr(X \geq x) = \Pr(X_1 \geq x, \dots, X_n \geq x) = \Pr(X_1 \geq x) \dots \Pr(X_n \geq x),$$

because the  $n$  components are independent. By Exercise 7,

$$\Pr(X_i \geq x) = (1 - p_i)^x = (1 - p_i)^x.$$

Therefore,  $\Pr(X \geq x) = \prod_{i=1}^n (1 - p_i)^x$ . It follows that

$$\begin{aligned}\Pr(X = x) &= \Pr(X \geq x) - \Pr(X \geq x + 1) = \prod_{i=1}^n (1 - p_i)^x - \prod_{i=1}^n (1 - p_i)^{x+1} \\ &= \left(1 - \prod_{i=1}^n (1 - p_i)\right) \left(\prod_{i=1}^n (1 - p_i)\right)^x.\end{aligned}$$

It can be seen that this is the p.f. of the geometric distribution with  $p = 1 - \prod_{i=1}^n (1 - p_i)$ .

10. By the assumptions of the problem we have  $p = 1 - \lambda/r$  and  $r \rightarrow \infty$ . To simplify some of the formulas, let  $q = 1 - p$  so that  $q = \lambda/r$ . It now follows from Eq. (5.5.1) that

$$\begin{aligned}f(x | r, p) &= \frac{(r + x - 1)(r + x - 2) \dots r}{x!} \left(1 - \frac{\lambda}{r}\right)^r q^x \\ &= \frac{[q(r + x - 1)][q(r + x - 2)] \dots (qr)}{x!} \left(1 - \frac{\lambda}{r}\right)^r \\ &= \frac{[\lambda + q(x - 1)][\lambda + q(x - 2)] \dots (\lambda)}{x!} \left(1 - \frac{\lambda}{r}\right)^r.\end{aligned}$$

As  $r \rightarrow \infty$ ,  $q \rightarrow 0$  and

$$\begin{aligned}[\lambda + q(x - 1)][\lambda + q(x - 2)] \dots (\lambda) &\rightarrow \lambda^x, \text{ and} \\ \left(1 - \frac{\lambda}{r}\right)^r &\rightarrow \exp(-\lambda).\end{aligned}$$

Hence,  $f(x | r, p) \rightarrow \frac{\lambda^x}{x!} \exp(-\lambda) = f(x | \lambda)$ .

11. According to Exercise 10 in Sec. 5.3,

$$\binom{-r}{x} = (-1)^x \binom{r + x - 1}{x}.$$

This makes

$$\binom{-r}{x} p^r (-[1-p])^x = \binom{r+x-1}{x} p^r (1-p)^x,$$

which is the proper form of the negative binomial p.f. for  $x = 0, 1, 2, \dots$ .

12. The joint p.f./p.d.f. of  $X$  and  $P$  is  $f(p)$  times the geometric p.f. with parameter  $p$ , that is

$$p(1-p)^x 10(1-p)^9 = p(1-p)^{x+9}, \text{ for } x = 0, 1, \dots \text{ and } 0 < p < 1. \quad (\text{S.5.7})$$

The marginal p.f. of  $X$  at  $x = 12$  is the integral of (S.5.7) over  $p$  with  $x = 12$  substituted:

$$\int_0^1 p(1-p)^{21} dp = \int_0^1 p^{21}(1-p) dp = \frac{1}{22} - \frac{1}{23} = \frac{1}{506}.$$

The conditional p.d.f. of  $P$  given  $X = 12$  is (S.5.7) divided by this last value

$$g(p|12) = 506p(1-p)^{21}, \text{ for } 0 < p < 1.$$

13. (a) The memoryless property says that, for all  $k, t \geq 0$ ,

$$\frac{\Pr(X = k+t)}{1 - F(t-1)} = \Pr(X = k).$$

(The above version switches the use of  $k$  and  $t$  from Theorem 5.5.5.) If we sum both sides of this over  $k = h, h+1, \dots$ , we get

$$\frac{1 - F(t+h-1)}{1 - F(t-1)} = 1 - F(h-1).$$

- (b)  $\ell(t+h) = \log[1 - F(t+h-1)]$ . From part (a), we have

$$1 - F(t+h-1) = [1 - F(t-1)][1 - F(h-1)],$$

Hence

$$\ell(t+h) = \log([1 - F(t-1)] + \log[1 - F(h-1)]) = \ell(t) + \ell(h).$$

- (c) We prove this by induction. Clearly  $\ell(1) = 1 \times \ell(1)$ , so the result holds for  $t = 1$ . Assume that the result holds for all  $t \leq t_0$ . Then  $\ell(t_0+1) = \ell(t_0) + \ell(1)$  by part (b). By the induction hypothesis,  $\ell(t_0) = t_0\ell(1)$ , hence  $\ell(t_0+1) = (t_0+1)\ell(1)$ , and the result holds for  $t = t_0+1$ .
- (d) Since  $\ell(1) = \log[1 - F(0)]$ , we have  $\ell(1) < 0$ . Let  $p = 1 - \exp[\ell(1)]$ , which between 0 and 1. For every integer  $x \geq 1$ , we have, from part (c) and the definition of  $\ell$ , that

$$F(x-1) = 1 - \exp[\ell(x)] = 1 - \exp[x\ell(1)] = 1 - (1-p)^x.$$

Setting  $t = x-1$  for  $x \geq 1$ , we get

$$F(t) = 1 - (1-p)^{t+1}, \text{ for } t = 0, 1, \dots \quad (\text{S.5.8})$$

It is easy to verify that (S.5.8) is the c.d.f. of the geometric distribution with parameter  $p$ .

## 5.6 The Normal Distributions

### Commentary

In addition to introducing the family of normal distributions, we also describe the family of lognormal distributions. These distributions arise frequently in engineering and financial applications. (Examples 5.6.9 and 5.6.10 give two such cases.) It is true that lognormal distributions are nothing more than simple transformations of normal distributions. However, at this point in their study, many students will not yet be sufficiently comfortable with transformations to be able to derive these distributions and their properties without a little help.

If one is using the statistical software *R*, then the functions `dnorm`, `pnorm`, and `qnorm` give the p.d.f., the c.d.f., and the quantile function of normal distributions. The syntax is that the first argument is the argument of the function, and the next two are the mean and standard deviation. The function `rnorm` gives a random sample of normal random variables. The first argument is how many you want, and the next two are the mean and standard deviation. All of the solutions that require the calculation of normal probabilities and quantiles can be done using these functions instead of tables. There are also functions `dlnorm`, `plnorm`, `qlnorm`, and `rlnorm` that compute similar features for lognormal distributions.

### Solutions to Exercises

1. By the symmetry of the standard normal distribution around 0, the 0.5 quantile must be 0. The 0.75 quantile is found by locating 0.75 in the  $\Phi(x)$  column of the standard normal table and interpolating in the  $x$  column. We find  $\Phi(0.67) = 0.7486$  and  $\Phi(0.68) = 0.7517$ . Interpolating gives the 0.75 quantile as 0.6745. By symmetry, the 0.25 quantile is  $-0.6745$ . Similarly we find the 0.9 quantile by interpolation using  $\Phi(1.28) = 0.8997$  and  $\Phi(1.29) = 0.9015$ . The 0.9 quantile is then 1.282 and the 0.1 quantile is  $-1.282$ .
2. Let  $Z = (X - 1)/2$ . Then  $Z$  has the standard normal distribution.
  - (a)  $\Pr(X \leq 3) = \Pr(Z \leq 1) = \Phi(1) = 0.8413$
  - (b)  $\Pr(X > 1.5) = \Pr(Z > 0.25) = 1 - \Phi(0.25) = 0.4013$ .
  - (c)  $\Pr(X = 1) = 0$ , because  $X$  has a continuous distribution.
  - (d)  $\Pr(2 < X < 5) = \Pr(0.5 < Z < 2) = \Phi(2) - \Phi(0.5) = 0.2858$ .
  - (e)  $\Pr(X \geq 0) = \Pr(Z \geq -0.5) = \Pr(Z \leq 0.5) = \Phi(0.5) = 0.6915$ .
  - (f)  $\Pr(-1 < X < 0.5) = \Pr(-1 < Z < -0.25) = \Pr(0.25 < Z < 1) = \Phi(1) - \Phi(0.25) = 0.2426$ .
  - (g)

$$\begin{aligned}\Pr(|X| \leq 2) &= \Pr(-2 \leq X \leq 2) = \Pr(-1.5 \leq Z \leq 0.5) \\ &= \Pr(Z \leq 0.5) - \Pr(Z \leq -1.5) = \Pr(Z \leq 0.5) \\ &\quad - \Pr(Z \geq 1.5) = \Phi(0.5) - [1 - \Phi(1.5)] = 0.6247.\end{aligned}$$

(h)

$$\begin{aligned}\Pr(1 \leq -2X + 3 \leq 8) &= \Pr(-2 \leq -2X \leq 5) = \Pr(-2.5 \leq X \leq 1) \\ &= \Pr(-1.75 \leq Z \leq 0) = \Pr(0 \leq Z \leq 1.75) \\ &= \Phi(1.75) - \Phi(0) = 0.4599.\end{aligned}$$

3. If  $X$  denotes the temperature in degrees Fahrenheit and  $Y$  denotes the temperature in degrees Celsius, then  $Y = 5(X - 32)/9$ . Since  $Y$  is a linear function of  $X$ , then  $Y$  will also have a normal distribution. Also,

$$E(Y) = \frac{5}{9}(68 - 32) = 20 \quad \text{and} \quad \text{Var}(Y) = \left(\frac{5}{9}\right)^2 (16) = \frac{400}{81}.$$

4. The  $q$  quantile of the temperature in degrees Fahrenheit is  $68 + 4\Phi^{-1}(q)$ . Using Exercise 1, we have  $\Phi^{-1}(0.75) = 0.6745$  and  $\Phi^{-1}(0.25) = -0.6745$ . So, the 0.25 quantile is 65.302, and the 0.75 quantile is 70.698.
5. Let  $A_i$  be the event that chip  $i$  lasts at most 290 hours. We want the probability of  $\cup_{i=1}^3 A_i^c$ , whose probability is

$$1 - \Pr\left(\cap_{i=1}^3 A_i\right) = 1 - \prod_{i=1}^3 \Pr(A_i).$$

Since the lifetime of each chip has the normal distribution with mean 300 and standard deviation 10, each  $A_i$  has probability

$$\Phi([290 - 300]/10) = \Phi(-1) = 1 - 0.8413 = 0.1587.$$

So the probability we want is  $1 - 0.1587^3 = 0.9960$ .

6. By comparing the given m.g.f. with the m.g.f. of a normal distribution presented in Eq. (5.6.5), we can see that, for the given m.g.f.,  $\mu = 0$  and  $\sigma^2 = 2$ .
7. If  $X$  is a measurement having the specified normal distribution, and if  $Z = (X - 120)/2$ , then  $Z$  will have the standard normal distribution. Therefore, the probability that a particular measurement will lie in the given interval is

$$p = \Pr(116 < X < 118) = \Pr(-2 < Z < -1) = \Pr(1 < Z < 2) = \Phi(2) - \Phi(1) = 0.1360.$$

The probability that all three measurements will lie in the interval is  $p^3$ .

8. Except for a constant factor, this integrand has the form of the p.d.f. of a normal distribution for which  $\mu = 0$  and  $\sigma^2 = 1/6$ . Therefore, if we multiply the integrand by

$$\frac{1}{(2\pi)^{1/2}\sigma} = \left(\frac{3}{\pi}\right)^{1/2},$$

we obtain the p.d.f. of a normal distribution and we know that the integral of this p.d.f. over the entire real line must be equal to 1. Therefore,

$$\int_{-\infty}^{\infty} \exp(-3x^2) dx = \left(\frac{\pi}{3}\right)^{1/2}.$$

Finally, since the integrand is symmetric with respect to  $x = 0$ , the integral over the positive half of the real line must be equal to the integral over the negative half of the real line. Hence,

$$\int_0^{\infty} \exp(-3x^2) dx = \frac{1}{2} \left(\frac{\pi}{3}\right)^{1/2}.$$

9. The total length of the rod is  $X = A + B + C - 4$ . Since  $X$  is a linear combination of  $A$ ,  $B$ , and  $C$ , it will also have the normal distribution with

$$E(X) = 20 + 14 + 26 - 4 = 56$$

and  $\text{Var}(X) = 0.04 + 0.01 + 0.04 = 0.09$ . If we let  $Z = (X - 56)/0.3$ , then  $Z$  will have the standard normal distribution. Hence,

$$\Pr(55.7 < X < 56.3) = \Pr(-1 \leq Z \leq 1) = 2\Phi(1) - 1 = 0.6827.$$

10. We know that  $E(\bar{X}_n) = \mu$  and  $\text{Var}(\bar{X}_n) = \sigma^2/n = 4/25$ . Hence, if we let  $Z = (\bar{X}_n - \mu)/(2/5) = (5/2)(\bar{X}_n - \mu)$ , then  $Z$  will have the standard normal distribution. Hence,

$$\Pr(|\bar{X}_n - \mu| \leq 1) = \Pr(|Z| \leq 2.5) = 2\Phi(2.5) - 1 = 0.9876.$$

11. If we let  $Z = \sqrt{n}(\bar{X}_n - \mu)/2$ , then  $Z$  will have the standard normal distribution. Therefore,

$$\Pr(|\bar{X}_n - \mu| < 0.1) = \Pr(|Z| < 0.05\sqrt{n}) = 2\Phi(0.05\sqrt{n}) - 1.$$

This value will be at least 0.9 if  $2\Phi(0.05\sqrt{n}) - 1 \geq 0.9$  or  $\Phi(0.05\sqrt{n}) \geq 0.95$ . It is found from a table of the values of  $\Phi$  that we must therefore have  $0.05\sqrt{n} \geq 1.645$ . The smallest integer  $n$  which satisfies this inequality is  $n = 1083$ .

12. (a) The general shape is as shown in Fig. S.5.1.

Figure S.5.1: Figure for Exercise 12 of Sec. 5.6.

- (b) The sketch remains the same with the scale changed on the  $x$ -axis so that the points  $-1$  and  $0$  become  $-5$  and  $-2$ , respectively. It turns out that the point  $x = 1$  remains fixed in this transformation.
13. Let  $X$  denote the diameter of the bolt and let  $Y$  denote the diameter of the nut. The  $Y - X$  will have the normal distribution for which

$$E(Y - X) = 2.02 - 2 = 0.02$$

and

$$\text{Var}(Y - X) = 0.0016 + 0.0009 = 0.0025.$$

If we let  $Z = (Y - X - 0.02)/0.05$ , then  $Z$  will have the standard normal distribution. Therefore,

$$\Pr(0 < Y - X \leq 0.05) = \Pr(-0.4 < Z \leq 0.6) = \Phi(0.6) - [1 - \Phi(0.4)] = 0.3812.$$

14. Let  $\bar{X}$  denote the average of the two scores from university  $A$  and let  $\bar{Y}$  denote the average of the three scores from university  $B$ . Then  $\bar{X}$  has the normal distribution for which

$$E(\bar{X}) = 625 \quad \text{and} \quad \text{Var}(\bar{X}) = \frac{100}{2} = 50.$$

Also,  $\bar{Y}$  has the normal distribution for which

$$E(\bar{Y}) = 600 \quad \text{and} \quad \text{Var}(\bar{Y}) = \frac{150}{3} = 50.$$

Therefore  $\bar{X} - \bar{Y}$  has the normal distribution for which

$$E(\bar{X} - \bar{Y}) = 625 - 600 = 25 \quad \text{and} \quad \text{Var}(\bar{X} - \bar{Y}) = 50 + 50 = 100.$$

It follows that if we let  $Z = (\bar{X} - \bar{Y} - 25)/10$ , then  $Z$  will have the standard normal distribution. Hence,

$$\Pr(\bar{X} - \bar{Y} > 0) = \Pr(Z > -2.5) = \Pr(Z < 2.5) = \Phi(2.5) = 0.9938.$$

15. Let  $f_1(x)$  denote the p.d.f. of  $X$  if the person has glaucoma and let  $f_2(x)$  denote the p.d.f. of  $X$  if the person does not have glaucoma. Furthermore, let  $A_1$  denote the event that the person has glaucoma and let  $A_2 = A_1^C$  denote the event that the person does not have glaucoma. Then

$$\begin{aligned} \Pr(A_1) &= 0.1, \quad \Pr(A_2) = 0.9, \\ f_1(x) &= \frac{1}{(2\pi)^{1/2}} \exp\left\{-\frac{1}{2}(x-25)^2\right\} \quad \text{for } -\infty < x < \infty, \\ f_2(x) &= \frac{1}{(2\pi)^{1/2}} \exp\left\{-\frac{1}{2}(x-20)^2\right\} \quad \text{for } -\infty < x < \infty. \end{aligned}$$

$$(a) \quad \Pr(A_1 | X = x) = \frac{\Pr(A_1)f_1(x)}{\Pr(A_1)f_1(x) + \Pr(A_2)f_2(x)}$$

(b) The value found in part (a) will be greater than  $1/2$  if and only if

$$\Pr(A_1)f_1(x) > \Pr(A_2)f_2(x).$$

All of the following inequalities are equivalent to this one:

- (i)  $\exp\{-(x-25)^2/2\} > 9 \exp\{-(x-20)^2/2\}$
- (ii)  $-(x-25)^2/2 > \log 9 - (x-20)^2/2$
- (iii)  $(x-20)^2 - (x-25)^2 > 2 \log 9$
- (iv)  $10x - 225 > 2 \log 9$
- (v)  $x > 22.5 + \log(9)/5.$

16. The given joint p.d.f. is the joint p.d.f. of two random variables that are independent and each of which has the standard normal distribution. Therefore,  $X + Y$  has the normal distribution for which

$$E(X + Y) = 0 + 0 = 0 \quad \text{and} \quad \text{Var}(X + Y) = 1 + 1 = 2.$$

If we let  $Z = (X + Y)/\sqrt{2}$ , then  $Z$  will have the standard normal distribution. Hence,

$$\begin{aligned} \Pr(-\sqrt{2} < X + Y < 2\sqrt{2}) &= \Pr(-1 < Z < 2) \\ &= \Pr(Z < 2) - \Pr(Z < -1) \\ &= \Phi(2) - [1 - \Phi(1)] = 0.8186. \end{aligned}$$

17. If  $Y = \log X$ , then the p.d.f. of  $Y$  is

$$g(y) = \frac{1}{(2\pi)^{1/2}\sigma} \exp\left\{-\frac{1}{2\sigma^2}(y-\mu)^2\right\} \quad \text{for } -\infty < y < \infty.$$

Since  $\frac{dy}{dx} = \frac{1}{x}$ , it now follows that the p.d.f. of  $X$ , for  $x > 0$ , is  $f(x) = g(\log x)/x$ .

18. Let  $U = X/Y$  and, as a convenient device, let  $V = Y$ . If we exclude the possibility that  $Y = 0$ , the transformation from  $X$  and  $Y$  to  $U$  and  $V$  is then one-to-one. (Since  $\Pr(Y = 0) = 0$ , we can exclude this possibility.) The inverse transformation is

$$X = UV \quad \text{and} \quad Y = V.$$

Hence, the Jacobian is

$$J = \det \begin{bmatrix} \frac{\partial x}{\partial u} & \frac{\partial x}{\partial v} \\ \frac{\partial y}{\partial u} & \frac{\partial y}{\partial v} \end{bmatrix} = \det \begin{bmatrix} v & u \\ 0 & 1 \end{bmatrix} = v.$$

Since  $X$  and  $Y$  are independent and each has the standard normal distribution, their joint p.d.f.  $f(x, y)$  is as given in Exercise 16. Therefore, the joint p.d.f.  $g(u, v)$  of  $U$  and  $V$  will be

$$g(u, v) = f(uv, v) |v| = \frac{|v|}{2\pi} \exp\left\{-\frac{1}{2}(u^2 + 1)v^2\right\}.$$

To find the marginal p.d.f.  $g_1(u)$  of  $U$ , we can now integrate  $g(u, v)$  over all values of  $v$ . (The fact that the single point  $v = 0$  was excluded does not affect the value of the integral over the entire real line.) We have

$$\begin{aligned} g_1(u) &= \int_{-\infty}^{\infty} \frac{|v|}{2\pi} \exp\left\{-\frac{1}{2}(u^2 + 1)v^2\right\} dv \\ &= \int_0^{\infty} \frac{1}{\pi} \exp\left\{-\frac{1}{2}(u^2 + 1)v^2\right\} v dv \\ &= \frac{1}{\pi(u^2 + 1)} \quad \text{for } -\infty < u < \infty. \end{aligned}$$

It can now be seen that  $g_1(u)$  is the p.d.f. of a Cauchy distribution as defined in Eq. (4.1.7).

19. The conditional p.d.f. of  $X$  given  $\mu$  is

$$g_1(x|\mu) = \frac{1}{(2\pi)^{1/2}} \exp(-(x-\mu)^2/2),$$

while the marginal p.d.f. of  $\mu$  is  $f_2(\mu) = 0.1$  for  $5 \leq \mu \leq 15$ . We need the marginal p.d.f. of  $X$ , which we get by integrating  $\mu$  out of the joint p.d.f.

$$g_1(x|\mu)f_2(\mu) = \frac{0.1}{(2\pi)^{1/2}} \exp(-(x-\mu)^2/2), \quad \text{for } 5 \leq \mu \leq 15.$$

The integral is

$$f_1(x) = \int_5^{15} \frac{0.1}{(2\pi)^{1/2}} \exp(-(x-\mu)^2/2) d\mu = 0.1[\Phi(15-x) - \Phi(5-x)].$$

With  $x = 8$ , the value is  $0.1[\Phi(7) - \Phi(-3)] = 0.0999$ . This makes the conditional p.d.f. of  $\mu$  given  $X = 8$

$$g_2(\mu|8) = \frac{1.0013}{(2\pi)^{1/2}} \exp(-(8-\mu)^2/2), \text{ for } 5 \leq \mu \leq 15.$$

20. This probability is the probability that  $\log(X) \leq \log(6.05) = 1.80$ , which equals

$$\Phi([1.80 - 3]/1.44^{1/2}) = \Phi(-1) = 0.1587.$$

21. Note that  $\log(XY) = \log(X) + \log(Y)$ . Since  $X$  and  $Y$  are independent with normal distributions, we have that  $\log(XY)$  has the normal distribution with the sum of the means (4.6) and sum of the variances (10.5). This means that  $XY$  has the lognormal distribution with parameters 4.6 and 10.5.
22. Since  $\log(1/X) = -\log(X)$ , we know that  $-\log(X)$  has the normal distribution with mean  $-\mu$  and variance  $\sigma^2$ . This mean that  $1/X$  has the lognormal distribution with parameters  $-\mu$  and  $\sigma^2$ .
23. Since  $\log(3X^{1/2}) = \log(3) + \log(X)/2$ , we know that  $\log(3X^{1/2})$  has the normal distribution with mean  $\log(3) + 4.1/2 = 3.149$  and variance  $8/4 = 2$ . This means that  $3X^{1/2}$  has the lognormal distribution with parameters 3.149 and 2.
24. First expand the left side of the equation to get

$$\sum_{i=1}^n a_i(x - b_i)^2 + cx = cx + \sum_{i=1}^n [a_i x^2 - 2a_i b_i x + b_i^2]. \quad (\text{S.5.9})$$

Now collect all the squared and linear terms in  $x$ . The coefficient of  $x^2$  is  $\sum_{i=1}^n a_i$ . The coefficient of  $x$  is  $c - 2 \sum_{i=1}^n a_i b_i$ . The constant term is  $\sum_{i=1}^n a_i b_i^2$ . This makes (S.5.9) equal to

$$x^2 \sum_{i=1}^n a_i + x \left[ c - 2 \sum_{i=1}^n a_i b_i \right] + \sum_{i=1}^n a_i b_i^2. \quad (\text{S.5.10})$$

Next, expand each term on the right side of the original equation to produce

$$\begin{aligned} & \left( \sum_{i=1}^n a_i \right) \left[ x^2 - 2x \frac{\sum_{i=1}^n a_i b_i - c/2}{\sum_{i=1}^n a_i} \right] + \frac{\left( \sum_{i=1}^n a_i b_i \right)^2 - c \sum_{i=1}^n a_i b_i + c^2/4}{\sum_{i=1}^n a_i} \\ & + \sum_{i=1}^n a_i b_i^2 - \frac{\left( \sum_{i=1}^n a_i b_i \right)^2}{\sum_{i=1}^n a_i} + \frac{c \sum_{i=1}^n a_i b_i - c^2/4}{\sum_{i=1}^n a_i}. \end{aligned}$$

Combining like terms in this expression produces the same terms that are in (S.5.10).

25. Divide the time interval of  $u$  years into  $n$  intervals of length  $u/n$  each. At the end of  $n$  such intervals, the principal gets multiplied by  $(1 + ru/n)^n$ . The limit of this as  $n \rightarrow \infty$  is  $\exp(ru)$ .
26. The integral that defines the mean is

$$E(X) = \int_{-\infty}^{\infty} \frac{x}{(2\pi)^{1/2}} \exp\left[-\frac{x^2}{2}\right] dx.$$

The integrand is a function  $f$  with the property that  $f(-x) = -f(x)$ . Since the range of integration is symmetric around 0, the integral is 0. The integral that defines the variance is then

$$\text{Var}(X) = E(X^2) = \int_{-\infty}^{\infty} \frac{x^2}{(2\pi)^{1/2}} \exp\left[-\frac{x^2}{2}\right] dx.$$

In this integral, let  $u = x$  and

$$dv = \frac{x}{(2\pi)^{1/2}} \exp\left[-\frac{x^2}{2}\right] dx.$$

It is easy to see that  $du = dx$  and

$$v = -\frac{1}{(2\pi)^{1/2}} \exp\left[-\frac{x^2}{2}\right].$$

Integration by parts yields

$$\text{Var}(X) = -\frac{x}{(2\pi)^{1/2}} \exp\left[-\frac{x^2}{2}\right] \Big|_{x=-\infty}^{\infty} + \int \frac{1}{(2\pi)^{1/2}} \exp\left[-\frac{x^2}{2}\right] dx.$$

The term on the right above equals 0 at both  $\infty$  and  $-\infty$ . The remaining integral is 1 because it is the integral of the standard normal p.d.f. So  $\text{Var}(X) = 1$ .

## 5.7 The Gamma Distributions

### Commentary

Gamma distributions are used in the derivation of the chi-square distribution in Sec. 8.2 and as conjugate prior distributions for various parameters. The gamma function arises in several integrals later in the text and is interesting in its own right as a generalization of the factorial function to noninteger arguments.

If one is using the statistical software *R*, then the function `gamma` computes the gamma function, and `lgamma` computes the logarithm of the gamma function. They take only one argument. The functions `dgamma`, `pgamma`, and `qgamma` give the p.d.f., the c.d.f., and the quantile function of gamma distributions. The syntax is that the first argument is the argument of the function, and the next two are  $\alpha$  and  $\beta$  in the notation of the text. The function `rgamma` gives a random sample of gamma random variables. The first argument is how many you want, and the next two are  $\alpha$  and  $\beta$ . All of the solutions that require the calculation of gamma probabilities and quantiles can be done using these functions. There are also functions `dexp`, `pexp`, `qexp`, and `rexp` that compute similar features for exponential distributions. Just remove the “ $\alpha$ ” parameter.

### Solutions to Exercises

1. Let  $f(x)$  denote the p.d.f. of  $X$  and let  $Y = cX$ . Then  $X = Y/c$ . Since  $dx = dy/c$ , then for  $x > 0$ ,

$$g(y) = \frac{1}{c} f\left(\frac{y}{c}\right) = \frac{1}{c} \frac{\beta^\alpha}{\Gamma(\alpha)} \left(\frac{y}{c}\right)^{\alpha-1} \exp(-\beta(y/c)) = \frac{(\beta/c)^\alpha}{\Gamma(\alpha)} y^{\alpha-1} \exp(-(\beta/c)y).$$

2. The c.d.f. of the exponential distribution with parameter  $\beta$  is  $F(x) = 1 - \exp(-\beta x)$  for  $x > 0$ . The inverse of this is the quantile function  $F^{-1}(p) = -\log(1-p)/\beta$ .
3. The three p.d.f.'s are in Fig. S.5.2.

Figure S.5.2: Figure for Exercise 3 of Sec. 5.7.

4.

$$\begin{aligned} f(x) &= \frac{\beta^\alpha}{\Gamma(\alpha)} x^{\alpha-1} \exp(-\beta x) && \text{for } x > 0. \\ f'(x) &= \frac{\beta^\alpha}{\Gamma(\alpha)} (\alpha - 1 - \beta x) x^{\alpha-2} \exp(-\beta x) && \text{for } x > 0. \end{aligned}$$

If  $\alpha \leq 1$ , then  $f'(x) < 0$  for  $x > 0$ . Therefore, the maximum value of  $f(x)$  occurs at  $x = 0$ . If  $\alpha > 1$ , then  $f'(x) = 0$  for  $x = (\alpha - 1)/\beta$  and it can be verified that  $f(x)$  is actually a maximum at this value of  $x$ .

5. All three p.d.f.'s are in Fig. S.5.3.
6. Each  $X_i$  has the gamma distribution with parameters 1 and  $\beta$ . Therefore, by Theorem 5.7.7, the sum  $\sum_{i=1}^n X_i$  has the gamma distribution with parameters  $n$  and  $\beta$ . Finally, by Exercise 1,  $\bar{X}_n = \sum_{i=1}^n X_i/n$  has the gamma distribution with parameters  $n$  and  $n\beta$ .
7. Let  $A_i = \{X_i > t\}$  for  $i = 1, 2, 3$ . The event that at least one  $X_i$  is greater than  $t$  is  $\bigcup_{i=1}^3 A_i$ . We could use the formula in Theorem 1.10.1, or we could use that  $\Pr(\bigcup_{i=1}^3 A_i) = 1 - \Pr(\bigcap_{i=1}^3 A_i^c)$ . The latter is easier because the  $X_i$  are mutually independent and identically distributed.

$$\Pr\left(\bigcap_{i=1}^3 A_i^c\right) = \Pr(A_1^c)^3 = [1 - \exp(-\beta t)]^3.$$

So, the probability we want is  $1 - [1 - \exp(-\beta t)]^3$ .

Figure S.5.3: Figure for Exercise 5 of Sec. 5.7.

8. For any number  $y > 0$ ,

$$\begin{aligned}\Pr(Y > y) &= \Pr(X_1 > y, \dots, X_k > y) = \Pr(X_1 > y) \dots \Pr(X_k > y) \\ &= \exp(-\beta_1 y) \dots \exp(-\beta_k y) = \exp(-(\beta_1 + \dots + \beta_k)y),\end{aligned}$$

which is the probability that an exponential random variable with parameter  $\beta_1 + \dots + \beta_k$  is greater than  $y$ . Hence,  $Y$  has that exponential distribution.

9. Let  $Y$  denote the length of life of the system. Then by Exercise 8,  $Y$  has the exponential distribution with parameter  $0.001 + 0.003 + 0.006 = 0.01$ . Therefore,

$$\Pr(Y > 100) = \exp(-100(0.01)) = \frac{1}{e}$$

10. Since the mean of the exponential distribution is  $\mu$ , the parameter is  $\beta = 1/\mu$ . Therefore, the distribution of the time until the system fails is an exponential distribution with parameter  $n\beta = n/\mu$ . The mean of this distribution is  $1/(n\beta) = \mu/n$  and the variance is  $1/(n\beta)^2 = (\mu/n)^2$ .
11. The length of time  $Y_1$  until one component fails has the exponential distribution with parameter  $n\beta$ . Therefore,  $E(Y_1) = 1/(n\beta)$ . The additional length of time  $Y_2$  until a second component fails has the exponential distribution with parameter  $(n-1)\beta$ . Therefore,  $E(Y_2) = 1/[(n-1)\beta]$ . Similarly,  $E(Y_3) = 1/[(n-2)\beta]$ . The total time until three components fail is  $Y_1 + Y_2 + Y_3$  and  $E(Y_1 + Y_2 + Y_3) = \left(\frac{1}{n} + \frac{1}{n-1} + \frac{1}{n-2}\right) \frac{1}{\beta}$ .
12. The length of time until the system fails will be  $Y_1 + Y_2$ , where these variables were defined in Exercise 11. Therefore,  $E(Y_1 + Y_2) = \frac{1}{n\beta} + \frac{1}{(n-1)\beta} = \left(\frac{1}{n} + \frac{1}{n-1}\right) \mu$ . Also, the variables  $Y_1$  and  $Y_2$  are independent, because the distribution of  $Y_2$  is always the same exponential distribution regardless of the value of  $Y_1$ . Therefore,

$$\text{Var}(Y_1 + Y_2) = \text{Var}(Y_1) + \text{Var}(Y_2) = \frac{1}{(n\beta)^2} + \frac{1}{[(n-1)\beta]^2} = \left[\frac{1}{n^2} + \frac{1}{(n-1)^2}\right] \mu^2.$$

13. The time  $Y_1$  until one of the students completes the examination has the exponential distribution with parameter  $5\beta = 5/80 = 1/16$ . Therefore,

$$\Pr(Y_1 < 40) = 1 - \exp(-40/16) = 1 - \exp(-5/2) = 0.9179.$$

14. The time  $Y_2$  after one student completes the examination until a second student completes it has the exponential distribution with parameter  $4\beta = 4/80 = 1/20$ . Therefore,

$$\Pr(Y_2 < 35) = 1 - \exp(-35/20) = 1 - \exp(-7/4) = 0.8262.$$

15. No matter when the first student completes the examination, the second student to complete the examination will do so at least 10 minutes later than the first student if  $Y_2 > 10$ . Similarly, the third student to complete the examination will do so at least 10 minutes later than the second student if  $Y_3 > 10$ . Furthermore, the variables  $Y_1, Y_2, Y_3, Y_4$ , and  $Y_5$  are independent. Therefore, the probability that no two students will complete the examination within 10 minutes of each other is

$$\begin{aligned}\Pr(Y_2 > 10, \dots, Y_5 > 10) &= \Pr(Y_2 > 10) \dots \Pr(Y_5 > 10) \\ &= \exp(-(10)4\beta) \exp(-(10)3\beta) \exp(-(10)2\beta) \exp(-10\beta) \\ &= \exp(-40/80) \exp(-30/80) \exp(-20/80) \exp(-10/80) \\ &= \exp(-5/4) = 0.2865.\end{aligned}$$

16. If  $Y = \log(X/x_0)$ , then  $X = x_0 \exp(Y)$ . Also,  $dx = x_0 \exp(y)dy$  and  $x > x_0$  if and only if  $y > 0$ . Therefore, for  $y > 0$ ,

$$g(y) = f(x_0 \exp(y)|x_0, \alpha)x_0 \exp(y) = \alpha y^{-\alpha}.$$

17.

$$\begin{aligned}E[(X - \mu)^{2n}] &= \int_{-\infty}^{\infty} (x - \mu)^{2n} \frac{1}{(2\pi)^{1/2}\sigma} \exp\left\{-\frac{(x - \mu)^2}{2\sigma^2}\right\} dx \\ &= \frac{2}{(2\pi)^{1/2}\sigma} \int_{\mu}^{\infty} (x - \mu)^{2n} \exp\left\{-\frac{(x - \mu)^2}{2\sigma^2}\right\} dx.\end{aligned}$$

Let  $y = (x - \mu)^2$ . Then  $dx = dy/(2y^{1/2})$  and the above integral can be rewritten as

$$\frac{2}{(2\pi)^{1/2}\sigma} \int_0^{\infty} y^n \exp\left\{-\frac{y}{2\sigma^2}\right\} \frac{1}{2y^{1/2}} dy = \frac{1}{(2\pi)^{1/2}\sigma} \int_0^{\infty} y^{n-1/2} \exp\left\{-\frac{y}{2\sigma^2}\right\} dy.$$

The integrand in this integral is the p.d.f. of a gamma distribution with parameters  $\alpha = n + 1/2$  and  $\beta = 1/(2\sigma^2)$ , except for the constant factor

$$\frac{\beta^\alpha}{\Gamma(\alpha)} = \frac{1}{(2\sigma^2)^{n+1/2}\Gamma(n+1/2)}.$$

Since the integral of the p.d.f. of the gamma distribution must be equal to 1, it follows that

$$\int_0^{\infty} y^{n-1/2} \exp\left\{-\frac{y}{2\sigma^2}\right\} dy = (2\sigma^2)^{n+1/2}\Gamma(n+1/2).$$

From Eqs. (5.7.6) and (5.7.9),  $\Gamma\left(n + \frac{1}{2}\right) = \left(n - \frac{1}{2}\right)\left(n - \frac{3}{2}\right) \cdots \left(\frac{1}{2}\right)\pi^{1/2}$ . Therefore,

$$\begin{aligned} E[(X - \mu)^{2n}] &= \frac{1}{(2\pi)^{1/2}\sigma}(2\sigma^2)^{n+1/2}\left(n - \frac{1}{2}\right)\left(n - \frac{3}{2}\right) \cdots \left(\frac{1}{2}\right)\pi^{1/2} \\ &= 2^n\left(n - \frac{1}{2}\right)\left(n - \frac{3}{2}\right) \cdots \left(\frac{1}{2}\right)\sigma^{2n} \\ &= (2n - 1)(2n - 3) \cdots (1)\sigma^{2n}. \end{aligned}$$

18. For the exponential distribution with parameter  $\beta$ ,

$$f(x) = \beta \exp(-\beta x)$$

and

$$1 - F(x) = \Pr(X > x) = \exp(-\beta x).$$

Therefore,  $h(x) = \beta$  for  $x > 0$ .

19. Let  $Y = X^b$ . Then  $X = Y^{1/b}$  and  $dx = \frac{1}{b}y^{(1-b)/b}dy$ . Therefore, for  $y > 0$ ,

$$g(y) = f(y^{1/b}|a, b)\frac{1}{b}y^{(1-b)/b} = \frac{1}{a^b} \exp(-y/a^b).$$

20. If  $X$  has the Weibull distribution with parameters  $a$  and  $b$ , then the c.d.f. of  $X$  is

$$F(x) = \int_0^x \frac{b}{a^b}t^{b-1} \exp(-(t/a)^b)dt = [-\exp(-(t/a)^b)]_0^x = 1 - \exp(-(x/a)^b).$$

Therefore,

$$h(x) = \frac{b}{a^b}x^{b-1}.$$

If  $b > 1$ , then  $h(x)$  is an increasing function of  $x$  for  $x > 0$ , and if  $b < 1$ , then  $h(x)$  is an decreasing function of  $x$  for  $x > 0$ .

21. (a) The mean of  $1/X$  is

$$\int_0^\infty \frac{1}{x}\frac{\beta^\alpha}{\Gamma(\alpha)}x^{\alpha-1} \exp(-\beta x)dx = \frac{\beta^\alpha}{\Gamma(\alpha)} \int_0^\infty x^{\alpha-2} \exp(-\beta x)dx = \frac{\beta^\alpha}{\Gamma(\alpha)} \frac{\Gamma(\alpha-1)}{\beta^{\alpha-1}} = \frac{\beta}{\alpha-1}.$$

- (b) The mean of  $1/X^2$  is

$$\begin{aligned} \int_0^\infty \frac{1}{x^2}\frac{\beta^\alpha}{\Gamma(\alpha)}x^{\alpha-1} \exp(-\beta x)dx &= \frac{\beta^\alpha}{\Gamma(\alpha)} \int_0^\infty x^{\alpha-3} \exp(-\beta x)dx = \frac{\beta^\alpha}{\Gamma(\alpha)} \frac{\Gamma(\alpha-2)}{\beta^{\alpha-2}} \\ &= \frac{\beta^2}{(\alpha-1)(\alpha-2)}. \end{aligned}$$

This makes the variance of  $1/X$  equal to

$$\frac{\beta^2}{(\alpha-1)(\alpha-2)} - \left(\frac{\beta}{\alpha-1}\right) = \frac{\beta^2}{(\alpha-1)^2(\alpha-2)}.$$

22. The conditional p.d.f. of  $\lambda$  given  $X = x$  can be obtained from Bayes' theorem for random variables (Theorem 3.6.4). We know

$$\begin{aligned} g_1(x|\lambda) &= \exp(-\lambda t) \frac{(\lambda t)^x}{x!}, \text{ for } x = 0, 1, \dots, \\ f_2(\lambda) &= \frac{\beta^\alpha}{\Gamma(\alpha)} \lambda^{\alpha-1} \exp(-\lambda\beta), \text{ for } \lambda > 0. \end{aligned}$$

The marginal p.f. of  $X$  is

$$\begin{aligned} f_1(x) &= \frac{t^x \beta^\alpha}{x! \Gamma(\alpha)} \int_0^\infty \lambda^{\alpha+x-1} \exp(-\lambda[\beta+t]) d\lambda \\ &= \frac{t^x \beta^\alpha \Gamma(\alpha+x)}{x! \Gamma(\alpha) (\beta+t)^{\alpha+x}}. \end{aligned}$$

So, the conditional p.d.f. of  $\lambda$  given  $X = x$  is

$$g_2(\lambda|x) = \frac{(\beta+t)^{\alpha+x}}{\Gamma(\alpha+x)} \lambda^{\alpha+x-1} \exp(-\lambda[\beta+t]), \text{ for } \lambda > 0,$$

which is easily recognized as the p.d.f. of a gamma distribution with parameters  $\alpha + x$  and  $\beta + t$ .

23. The memoryless property means that  $\Pr(X > t+h|X > t) = \Pr(X > h)$ .

- (a) In terms of the c.d.f. the memoryless property means

$$\frac{1 - F(t+h)}{1 - F(t)} = 1 - F(h).$$

- (b) From (a) we obtain  $[1 - F(h)][1 - F(t)] = [1 - F(t+h)]$ . Taking logarithms of both sides yields  $\ell(h) + \ell(t) = \ell(t+h)$ .

- (c) Apply the result in part (b) with  $h$  and  $t$  both replaced by  $t/m$ . We obtain  $\ell(2t/m) = 2\ell(t/m)$ . Repeat with  $t$  replaced by  $2t/m$  and  $h = t/m$ . The result is  $\ell(3t/m) = 3\ell(t/m)$ . After  $k-1$  such applications, we obtain

$$\ell(kt/m) = k\ell(t/m). \quad (\text{S.5.11})$$

In particular, when  $k = m$ , we get  $\ell(t) = m\ell(t/m)$  or  $\ell(t/m) = \ell(t)/m$ . Substituting this into (S.5.11) we obtain  $\ell(kt/m) = (k/m)\ell(t)$ .

- (d) Let  $c > 0$  and let  $c_1, c_2, \dots$  be a sequence of rational numbers that converges to  $c$ . Since  $\ell$  is a continuous function,  $\ell(c_n t) \rightarrow \ell(ct)$ . But  $\ell(c_n t) = c_n \ell(t)$  by part (c) since  $c_n$  is rational. It follows that  $c_n \ell(t) \rightarrow \ell(ct)$ . But, we know that  $c_n \ell(t) \rightarrow c\ell(t)$ . So,  $c\ell(t) = \ell(ct)$ .
- (e) Apply part (d) with  $c = 1/t$  to obtain  $\ell(t)/t = \ell(1)$ , a constant.
- (f) Let  $\beta = \ell(1)$ . According to part (e),  $\ell(t) = \beta t$  for all  $t > 0$ . Then  $\log[1 - F(x)] = \beta x$  for  $x > 0$ . Solving for  $F(x)$  gives  $F(x) = 1 - \exp(-\beta x)$ , which is the c.d.f. the exponential distribution with parameter  $\beta = \ell(1)$ .

24. Let  $\psi$  be the m.g.f. of  $W_u$ . The mean of  $S_u$  is

$$E(S_u) = S_0 E(\exp(\mu u + W_u)) = S_0 \exp(\mu u) \psi(1).$$

- (a) Since  $W_u$  has the gamma distribution with parameters  $\alpha u$  and  $\beta > 1$ , the m.g.f. is  $\psi(t) = (\beta/[\beta - t])^{\alpha u}$ . This makes the mean

$$E(S_u) = S_0 \exp(\mu u) \left( \frac{\beta}{\beta - 1} \right)^{\alpha u}.$$

So  $\exp(-ru)E(S_u) = S_0$  if and only if

$$\exp((\mu - r)u) \left( \frac{\beta}{\beta - 1} \right)^{\alpha u} = 1.$$

Solving this equation for  $\mu$  yields

$$\mu = r - \alpha \log \left( \frac{\beta}{\beta - 1} \right).$$

- (b) Once again, we use the function

$$h(x) = \begin{cases} x - q & \text{if } x \geq q, \\ 0 & \text{if } x < q. \end{cases}$$

The value of the option at time  $u$  is  $h(S_u)$ . Notice that  $S_u \geq q$  if and only if  $W_u \geq \log(q/S_0) - \mu u = c$ , as defined in the exercise. Then the present value of the option is

$$\begin{aligned} \exp(-ru)E[h(S_u)] &= \exp(-ru) \int_c^\infty [S_0 \exp(\mu u + w) - q] \frac{\beta^{\alpha u}}{\Gamma(\alpha u)} w^{\alpha u - 1} \exp(-\beta w) dw \\ &= S_0 \exp([\mu - r]u) \frac{\beta^{\alpha u}}{\Gamma(\alpha u)} \int_c^\infty w^{\alpha u - 1} \exp(-w[\beta - 1]) dw \\ &\quad - q \exp(-ru) \frac{\beta^{\alpha u}}{\Gamma(\alpha u)} \int_c^\infty w^{\alpha u - 1} \exp(-\beta w) dw \\ &= S_0 \frac{(\beta - 1)^{\alpha u}}{\Gamma(\alpha u)} \int_c^\infty w^{\alpha u - 1} \exp(-(\beta - 1)w) dw - q \exp(-ru) R(c\beta) \\ &= S_0 R(c[\beta - 1]) - q \exp(-ru) R(c\beta). \end{aligned}$$

- (c) We plug the values  $u = 1$ ,  $q = S_0$ ,  $r = 0.06$ ,  $\alpha = 1$ , and  $\beta = 10$  into the previous formula to get

$$\begin{aligned} c &= \log(10/9) - 0.06 = 0.0454 \\ S_0 [R(0.0454 \times 9) - e^{-0.06} R(0.0454 \times 10)] &= 0.0665 S_0. \end{aligned}$$

## 5.8 The Beta Distributions

### Commentary

Beta distributions arise as conjugate priors for the parameters of the Bernoulli, binomial, geometric, and negative binomial distributions. They also appear in several exercises later in the text, either because of their relationship to the  $t$  and  $F$  distributions (Exercise 1 in Sec. 8.4 and Exercise 6 in Sec. 9.7) or as examples of numerical calculation of M.L.E.'s (Exercise 10 in Sec. 7.6) or calculation of sufficient statistics (Exercises 24(h), 24(i) in Sec. 7.3, Exercise 7 in Sec. 7.7, and Exercises 2 and 7(c) in Sec. 7.8). The derivation of the p.d.f. of the beta distribution relies on material from Sec. 3.9 (particularly Jacobians) which the instructor might have skipped earlier in the course.

If one is using the statistical software  $R$ , then the function `beta` computes the beta function, and `lbeta` computes the logarithm of the beta function. They take only the two necessary arguments. The functions `dbeta`, `pbeta`, and `qbeta` give the p.d.f., the c.d.f., and the quantile function of beta distributions. The syntax is that the first argument is the argument of the function, and the next two are  $\alpha$  and  $\beta$  in the notation of the

text. The function `rbeta` gives a random sample of beta random variables. The first argument is how many you want, and the next two are  $\alpha$  and  $\beta$ . All of the solutions that require the calculation of beta probabilities and quantiles can be done using these functions.

### Solutions to Exercises

1. The c.d.f. of the beta distribution with parameters  $\alpha > 0$  and  $\beta = 1$  is

$$F(x) = \begin{cases} 0 & \text{for } x \leq 0, \\ x^\alpha & \text{for } 0 < x < 1, \\ 1 & \text{for } x \geq 1. \end{cases}$$

Setting this equal to  $p$  and solving for  $x$  yields  $F^{-1}(p) = p^{1/\alpha}$ .

2.  $f'(x|\alpha, \beta) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)}[(\alpha - 1)(1 - x) - (\beta - 1)x]x^{\alpha-2}(1 - x)^{\beta-2}$ . Therefore,  $f'(x|\alpha, \beta) = 0$  and  $x = (\alpha - 1)/(\alpha + \beta - 2)$ . It can be verified that if  $\alpha > 1$  and  $\beta > 1$ , then  $f(x|\alpha, \beta)$  is actually a maximum for this value of  $x$ .
3. The vertical scale is to be chosen in each part of Fig. S.5.4 so that the area under the curve is 1. The figure in (h) is the mirror image of the figure in (g) with respect to  $x = 1/2$ .
4. Let  $Y = 1 - X$ . Then  $X = 1 - Y$ . Therefore,  $|dx/dy| = 1$  and,  $0 < y < 1$ ,

$$g(y) = f(1 - y) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)}(1 - y)^{\alpha-1}y^{\beta-1}.$$

This is the p.d.f. of the beta distribution with the values  $\alpha$  and  $\beta$  interchanged.

5.

$$\begin{aligned} E[X^r(1 - X)^s] &= \int_0^1 x^r(1 - x)^s \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1}(1 - x)^{\beta-1} dx \\ &= \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} \int_0^1 x^{\alpha+r-1}(1 - x)^{\beta+s-1} dx \\ &= \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} \cdot \frac{\Gamma(\alpha + r)\Gamma(\beta + s)}{\Gamma(\alpha + \beta + r + s)} \\ &= \frac{\Gamma(\alpha + r)}{\Gamma(\alpha)} \cdot \frac{\Gamma(\beta + s)}{\Gamma(\beta)} \cdot \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha + \beta + r + s)} \\ &= \frac{[\alpha(\alpha + 1) \cdots (\alpha + r - 1)][\beta(\beta + 1) \cdots (\beta + s - 1)]}{(\alpha + \beta)(\alpha + \beta + 1) \cdots (\alpha + \beta + r + s - 1)}. \end{aligned}$$

6. The joint p.d.f. of  $X$  and  $Y$  will be the product of their marginal p.d.f.'s Therefore, for  $x > 0$  and  $y > 0$ ,

$$\begin{aligned} f(x, y) &= \frac{\beta^{\alpha_1}}{\Gamma(\alpha_1)} x^{\alpha_1-1} \exp(-\beta x) \frac{\beta^{\alpha_2}}{\Gamma(\alpha_2)} y^{\alpha_2-1} \exp(-\beta y) \\ &= \frac{\beta^{\alpha_1+\alpha_2}}{\Gamma(\alpha_1)\Gamma(\alpha_2)} x^{\alpha_1-1} y^{\alpha_2-1} \exp(-\beta(x + y)). \end{aligned}$$

Figure S.5.4: Figure for Exercise 3 of Sec. 5.8.

Also,  $X = UV$  and  $Y = (1 - U)V$ . Therefore, the Jacobian is

$$J = \det \begin{bmatrix} \frac{\partial x}{\partial u} & \frac{\partial x}{\partial v} \\ \frac{\partial y}{\partial u} & \frac{\partial y}{\partial v} \end{bmatrix} = \det \begin{bmatrix} v & u \\ -v & 1-u \end{bmatrix} = v.$$

As  $x$  and  $y$  vary over all positive values,  $u$  will vary over the interval  $(0, 1)$  and  $v$  will vary over all possible values. Hence, for  $0 < u < 1$  and  $v > 0$ , the joint p.d.f. of  $U$  and  $V$  will be

$$g(u, v) = f[uv, (1 - u)v]v = \frac{\Gamma(\alpha_1 + \alpha_2)}{\Gamma(\alpha_1)\Gamma(\alpha_2)} u^{\alpha_1-1} (1-u)^{\alpha_2-1} \frac{\beta^{\alpha_1+\alpha_2}}{\Gamma(\alpha_1 + \alpha_2)} v^{\alpha_1+\alpha_2-1} \exp(-\beta v).$$

It can be seen that this joint p.d.f. has been factored into the product of the p.d.f. of a beta distribution with parameters  $\alpha_1$  and  $\alpha_2$  and the p.d.f. of a gamma distribution with parameters  $\alpha_1 + \alpha_2$  and  $\beta$ . Therefore,  $U$  and  $V$  are independent, the distribution of  $U$  is the specified beta distribution, and the distribution of  $V$  is the specified gamma distribution.

7. Since  $X_1$  and  $X_2$  each have the gamma distribution with parameters  $\alpha = 1$  and  $\beta$ , it follows from Exercise 6 that the distribution of  $X_1/(X_1 + X_2)$  will be a beta distribution with parameters  $\alpha = 1$  and  $\beta = 1$ . This beta distribution is the uniform distribution on the interval  $(0, 1)$ .

8. (a) Let  $A$  denote the event that the item will be defective. Then

$$\Pr(A) = \int_0^1 \Pr(A|x)f(x)dx = \int_0^1 xf(x)dx = E(X) = \frac{\alpha}{\alpha+\beta}.$$

- (b) Let  $B$  denote the event that both items will be defective. Then

$$\Pr(B) = \int_0^1 \Pr(B|x)f(x)dx = \int_0^1 x^2f(x)dx = E(X^2) = \frac{\alpha(\alpha+1)}{(\alpha+\beta)(\alpha+\beta+1)}.$$

9. Prior to observing the sample, the mean of  $P$  is  $\alpha/(\alpha+\beta) = 0.05$ , which means that  $\alpha = \beta/19$ . If we use the result in the note that follows Example 5.8.3, the distribution of  $P$  after finding 10 defectives in a sample of size 10 would be beta with parameters  $\alpha+10$  and  $\beta$ , whose mean is  $(\alpha+10)/(\alpha+\beta+10) = 0.9$ . This means that  $\alpha = 9\beta - 10$ . So  $9\beta - 10 = \beta/19$  and  $\beta = 19/17$  so  $\alpha = 1/17$ . The distribution of  $P$  is then a beta distribution with parameters  $1/17$  and  $19/17$ .
10. The distribution of  $P$  is a beta distribution with parameters 1 and 1. Applying the note after Example 5.8.3 with  $n = 25$  and  $x = 6$ , the conditional distribution of  $P$  after observing the data is a beta distribution with parameters 7 and 20.

## 5.9 The Multinomial Distributions

### Commentary

The family of multinomial distributions is the only named family of discrete multivariate distributions in the text. It arises in finite population sampling problems, but does not figure in the remainder of the text.

If one is using the statistical software *R*, then the function `dmultinom` gives the joint p.f. of a multinomial vector. The syntax is that the first argument is the argument of the function and must be a vector of the appropriate length with nonnegative integer coordinates. The next argument must be specified as `prob`= followed by the vector of probabilities, which must be a vector of the same length as the first argument. The function `rmultinom` gives a random sample of multinomial random vectors. The first argument is how many you want, the next argument specifies what the sum of the coordinates of every vector must be ( $n$  in the notation of the text), and the third argument is `prob` as above. All of the solutions that require the calculation of multinomial probabilities can be done using these functions.

### Solutions to Exercises

1. Let  $Y = X_1 + \dots + X_\ell$ . We shall show that  $Y$  has the binomial distribution with parameters  $n$  and  $p_1 + \dots + p_\ell$ . Let  $Z_1, \dots, Z_n$  be i.i.d. random variables with the p.f.

$$f(z) = \begin{cases} p_i & \text{for } z = i, i = 1, \dots, k, \\ 0 & \text{otherwise.} \end{cases}$$

For each  $i = 1, \dots, k$  and each  $j = 1, \dots, n$ , define

$$\begin{aligned} A_{ij} &= \{Z_j = i\}, \\ W_{ij} &= \begin{cases} 1 & \text{if } A_{ij} \text{ occurs,} \\ 0 & \text{if not.} \end{cases} \end{aligned}$$

Finally, define  $V_i = \sum_{j=1}^n W_{ij}$  for  $i = 1, \dots, k$ . It follows from the discussion in the text that  $(X_1, \dots, X_k)$  has the same distribution as  $(V_1, \dots, V_k)$ . Hence  $Y$  has the same distribution as  $U = V_1 + \dots + V_\ell$ . But

$$U = V_1 + \dots + V_\ell = \sum_{i=1}^\ell \sum_{j=1}^n W_{ij} = \sum_{j=1}^n \sum_{i=1}^\ell W_{ij}.$$

Define  $U_j = \sum_{i=1}^\ell W_{ij}$ . It is easy to see that  $U_j = 1$  if  $\cup_{i=1}^\ell A_{ij}$  occurs and  $U_j = 0$  if not. Also  $\Pr(\cup_{i=1}^\ell A_{ij}) = p_1 + \dots + p_\ell$ . Hence,  $U_1, \dots, U_n$  are i.i.d. random variables each having a Bernoulli distribution with parameter  $p_1 + \dots + p_\ell$ . Since  $U = \sum_{i=1}^n U_i$ , we know that  $U$  has the binomial distribution with parameters  $n$  and  $p_1 + \dots + p_\ell$ .

2. The probability that a given observed value will be less than  $\alpha_1$  is  $p_1 = F(\alpha_1) = 0.3$ , the probability that it will be between  $\alpha_1$  and  $\alpha_2$  is  $p_2 = F(\alpha_2) - F(\alpha_1) = 0.5$ , and the probability that it will be greater than  $\alpha_2$  is  $p_3 = 1 - F(\alpha_2) = 0.2$ . Therefore, the numbers of the 25 observations in each of these three intervals will have the multinomial distribution with parameters  $n = 25$  and  $\mathbf{p} = (p_1, p_2, p_3)$ . Therefore, the required probability is

$$\frac{25!}{6!10!9!}(0.3)^6(0.5)^{10}(0.2)^9.$$

3. Let  $X_1$  denote the number of times that the number 1 appears, let  $X_2$  denote the number of times that the number 4 appears, and let  $X_3$  denote the number of times that a number other than 1 or 4 appears. Then the vector  $(X_1, X_2, X_3)$  has the multinomial distribution with parameters  $n = 5$  and  $\mathbf{p} = (1/6, 1/6, 4/6)$ . Therefore,

$$\begin{aligned} \Pr(X_1 = X_2) &= \Pr(X_1 = 0, X_2 = 0, X_3 = 5) + \Pr(X_1 = 1, X_2 = 1, X_3 = 3) \\ &\quad + \Pr(X_1 = 2, X_2 = 2, X_3 = 1) \\ &= \left(\frac{4}{6}\right)^5 + \frac{5!}{1!1!3!} \left(\frac{1}{6}\right) \left(\frac{1}{6}\right) \left(\frac{4}{6}\right)^3 + \frac{5!}{2!2!1!} \left(\frac{1}{6}\right)^2 \left(\frac{1}{6}\right)^2 \left(\frac{4}{6}\right) \\ &= \frac{1024}{6^5} + \frac{1280}{6^5} + \frac{120}{6^5} = \frac{2424}{6^5}. \end{aligned}$$

4. Let  $X_3$  denote the number of rolls for which the number 5 appears. If  $X_1 = 20$  and  $X_2 = 15$ , then it must also be true that  $X_3 = 5$ . The vector  $(X_1, X_2, X_3)$  has the multinomial distribution with parameters

$$\begin{aligned} n &= 40, \\ q_1 &= p_2 + p_4 + p_6 = 0.30 + 0.05 + 0.07 = 0.42, \\ q_2 &= p_1 + p_3 = 0.11 + 0.22 = 0.33, \\ q_3 &= p_5 = 0.25. \end{aligned}$$

Therefore,

$$\Pr(X_1 = 20 \text{ and } X_2 = 15) = \Pr(X_1 = 20, X_2 = 15, X_3 = 5) = \frac{40!}{20!15!5!}(0.42)^{20}(0.33)^{15}(0.25)^5.$$

5. The number  $X$  of freshman or sophomores selected will have the binomial distribution with parameters  $n = 15$  and  $p = 0.16 + 0.14 = 0.30$ . Therefore, it is found from the table in the back of the book that

$$\Pr(X \geq 8) = .0348 + .0116 + .0030 + .0006 + .0001 = .0501.$$

6. By Eq. (5.9.3)

$$\begin{aligned} E(X_3) &= 15(0.38) = 5.7, \\ E(X_4) &= 15(0.32) = 4.8, \\ \text{Var}(X_3) &= 15(0.38)(0.62) = 3.534, \\ \text{Var}(X_4) &= 15(0.32)(0.68) = 3.264. \end{aligned}$$

By Eq. (5.9.3),

$$\text{Cov}(X_3, X_4) = -15(0.38)(0.32) = -1.824.$$

Hence,

$$E(X_3 - X_4) = 5.7 - 4.8 = 0.9$$

and

$$\text{Var}(X_3 - X_4) = 3.534 + 3.264 - 2(-1.824) = 10.446.$$

7. For any nonnegative integers  $x_1, \dots, x_k$  such that  $\sum_{i=1}^k x_i = n$ ,

$$\Pr\left(X_1 = x_1, \dots, X_k = x_k \middle| \sum_{i=1}^k X_i = n\right) = \frac{\Pr(X_1 = x_1, \dots, X_k = x_k)}{\Pr\left(\sum_{i=1}^k X_i = n\right)}$$

Since  $X_1, \dots, X_k$  are independent,

$$\Pr(X_1 = x_1, \dots, X_k = x_k) = \Pr(X_1 = x_1) \dots \Pr(X_k = x_k).$$

Since  $X_i$  has the Poisson distribution with mean  $\lambda_i$ ,

$$\Pr(X_i = x_i) = \frac{\exp(-\lambda_i)\lambda_i^{x_i}}{x_i!}.$$

Also, by Theorem 5.4.4, the distribution of  $\sum_{i=1}^k X_i$  will be a Poisson distribution with mean  $\lambda = \sum_{i=1}^k \lambda_i$ . Therefore,

$$\Pr\left(\sum_{i=1}^k X_i = n\right) = \frac{\exp(-\lambda)\lambda^n}{n!}.$$

It follows that

$$\Pr\left(X_1 = x_1, \dots, X_k = x_k \middle| \sum_{i=1}^k X_i = n\right) = \frac{n!}{x_1! \dots x_k!} \prod_{i=1}^k \left(\frac{\lambda_i}{\lambda}\right)^{x_i}$$

8. Let the data be called  $\mathbf{X} = (X_1, X_2, X_3)$ , with  $X_1$  being the number of working parts,  $X_2$  being the number of impaired parts, and  $X_3$  being the number of defective parts. The conditional distribution of  $\mathbf{X}$  given  $\mathbf{p}$  is a multinomial distribution with parameters 10 and  $\mathbf{p}$ . So, the conditional p.f. of the observed data is

$$g(8, 2, 0 | \mathbf{p}) = \binom{10}{8, 2, 0} p_1^8 p_2^2.$$

The joint p.f./p.d.f. of  $\mathbf{X}$  and  $\mathbf{p}$  is the product of this with the p.d.f. of  $\mathbf{p}$ :

$$12 \binom{10}{8, 2, 0} p_1^{10} p_2^2 = 540 p_1^{10} p_2^2.$$

To find the conditional p.d.f. of  $\mathbf{p}$  given  $\mathbf{X} = (10, 2, 0)$ , we need to divide this expression by the marginal p.f. of  $\mathbf{X}$ , which is the integral of this last expression over all  $(p_1, p_2)$  such that  $p_i > 0$  and  $p_1 + p_2 < 1$ . This integral can be written as

$$\int_0^1 \int_0^{1-p_1} 540 p_1^{10} p_2^2 dp_2 dp_1 = \int_0^1 180 p_1^{10} (1 - p_1)^3 = 180 \frac{\Gamma(11)\Gamma(4)}{\Gamma(15)} = 0.0450.$$

For the second equality, we use Theorem 5.8.1. So, the conditional p.d.f. of  $\mathbf{p}$  given  $\mathbf{X} = (10, 2, 0)$  is

$$\begin{cases} 12012 p_1^{10} p_2^2 & \text{if } 0 < p_1, p_2 < 1 \text{ and } p_1 + p_2 < 1, \\ 0 & \text{otherwise.} \end{cases}$$

## 5.10 The Bivariate Normal Distributions

### Commentary

The joint distribution of the least squares estimators in a simple linear regression model (Sec. 11.3) is a bivariate normal distribution, as is the posterior distribution of the regression parameters in a Bayesian analysis of simple linear regression (Sec. 11.4). It also arises in the regression fallacy (Exercise 19 in Sec. 11.2 and Exercise 8 in Sec. 11.9) and as another theoretical avenue for introducing regression concepts (Exercises 2 and 3 in Sec. 11.9). The derivation of the bivariate normal p.d.f. relies on Jacobians from Sec. 3.9 which the instructor might have skipped earlier in the course.

### Solutions to Exercises

1. The conditional distribution of the height of the wife given that the height of the husband is 72 inches is a normal distribution with mean  $66.8 + 0.68 \times 2(72 - 70)/2 = 68.16$  and variance  $(1 - 0.68^2)2^2 = 2.1504$ . The 0.95 quantile of this distribution is

$$68.16 + 2.1504^{1/2} \Phi^{-1}(0.95) = 68.16 + 1.4664 \times 1.645 = 70.57.$$

2. Let  $X_1$  denote the student's score on test A and let  $X_2$  denote his score on test B. The conditional distribution of  $X_2$  given that  $X_1 = 80$  is a normal distribution with mean  $90 + (0.8)(16) \left( \frac{80 - 85}{10} \right) = 83.6$  and variance  $(1 - 0.64)(256) = 92.16$ . Therefore, given that  $X_1 = 80$ , the random variable  $Z = (X_2 - 83.6)/9.6$  will have the standard normal distribution. It follows that

$$\Pr(X_2 > 90 | X_1 = 80) = \Pr\left(Z > \frac{2}{3}\right) = 1 - \Phi\left(\frac{2}{3}\right) = 0.2524.$$

3. The sum  $X_1 + X_2$  will have the normal distribution with mean  $85 + 90 = 175$  and variance  $(10)^2 + (16)^2 + 2(0.8)(10)(16) = 612$ . Therefore,  $Z = (X_1 + X_2 - 175)/\sqrt{612}$  will have the standard normal distribution. It follows that

$$\Pr(X_1 + X_2 > 200) = \Pr(Z > 1.0106) = 1 - \Phi(1.0106) = 0.1562.$$

4. The difference  $X_1 - X_2$  will have the normal distribution with mean  $85 - 90 = -5$  and variance  $(10)^2 + (16)^2 - 2(0.8)(10)(16) = 100$ . Therefore,  $Z = (X_1 - X_2 + 5)/\sqrt{100}$  will have the standard normal distribution. It follows that

$$\Pr(X_1 > X_2) = \Pr(X_1 - X_2 > 0) = \Pr(Z > 0.5) = 1 - \Phi(0.5) = 0.3085.$$

5. The predicted value should be the mean of the conditional distribution of  $X_1$  given that  $X_2 = 100$ . This value is  $85 + (0.8)(10)\left(\frac{100 - 90}{16}\right) = 90$ . The M.S.E. for this prediction is the variance of the conditional distribution, which is  $(1 - 0.64)100 = 36$ .

6.  $\text{Var}(X_1 + bX_2) = \sigma_1^2 + b^2\sigma_2^2 + 2b\rho\sigma_1\sigma_2$ . This is a quadratic function of  $b$ . By differentiating with respect to  $b$  and setting the derivative equal to 0, we obtain the value  $b = -\rho\sigma_1/\sigma_2$ .

7. Since  $E(X_1|X_2) = 3.7 - 0.15X_2$ , it follows from Eq. (5.10.8) that

$$(i) \mu_1 - \rho\frac{\sigma_1}{\sigma_2}\mu_2 = 3.7,$$

$$(ii) \rho\frac{\sigma_1}{\sigma_2} = -0.15. \text{ Since } E(X_2|X_1) = 0.4 - 0.6X_1, \text{ it follows from Eq. (5.10.6) that}$$

$$(iii) \mu_2 - \rho\frac{\sigma_2}{\sigma_1}\mu_1 = 0.4,$$

$$(iv) \rho\frac{\sigma_2}{\sigma_1} = -0.6.$$

Finally, since  $\text{Var}(X_2|X_1) = 3.64$ , it follows that

$$(v) (1 - \rho^2)\sigma_2^2 = 3.64.$$

By multiplying (ii) and (iv) we find that  $\rho^2 = 0.09$ . Therefore,  $\rho = \pm 0.3$ . Since the right side of (ii) is negative,  $\rho$  must be negative also. Hence,  $\rho = -0.3$ . It now follows from (v) that  $\sigma_2^2 = 4$ . Hence,  $\sigma_2 = 2$  and it is found from (ii) that  $\sigma_1 = 1$ . By using the values we have obtained, we can rewrite (i) and (iii) as follows:

$$(i) \mu_1 + 0.15\mu_2 = 3.7,$$

$$(iii) 0.6\mu_1 + \mu_2 = 0.4.$$

By solving these two simultaneous linear equations, we find that  $\mu_1 = 4$  and  $\mu_2 = -2$ .

8. The value of  $f(x_1, x_2)$  will be a maximum when the exponent inside the curly braces is a maximum. In turn, this exponent will be a maximum when the expression inside the square brackets is a minimum. If we let

$$a_1 = \frac{x_1 - \mu_1}{\sigma_1} \quad \text{and} \quad a_2 = \frac{x_2 - \mu_2}{\sigma_2},$$

then this expression is

$$a_1^2 - 2\rho a_1 a_2 + a_2^2.$$

We shall now show that this expression must be nonnegative. We have

$$0 \leq (|a_1| - |a_2|)^2 = a_1^2 + a_2^2 - 2|a_1 a_2| \leq a_1^2 + a_2^2 - 2|\rho a_1 a_2|,$$

since  $|\rho| < 1$ . Furthermore,  $|\rho a_1 a_2| \geq \rho a_1 a_2$ . Hence,

$$0 \leq a_1^2 + a_2^2 - 2\rho a_1 a_2.$$

The minimum possible value of  $a_1^2 - 2\rho a_1 a_2 + a_2^2$  is therefore 0, and this value is attained when  $a_1 = 0$  and  $a_2 = 0$  or, equivalently, when  $x_1 = \mu_1$  and  $x_2 = \mu_2$ .

9. Let  $a_1$  and  $a_2$  be as defined in Exercise 8. If  $f(x_1, x_2) = k$ , then  $a_1^2 - 2\rho a_1 a_2 + a_2^2 = b^2$ , where  $b$  is a particular positive constant. Suppose first that  $\rho = 0$  and  $\sigma_1 = \sigma_2 = \sigma$ . Then this equation has the form

$$(x_1 - \mu_1)^2 + (x_2 - \mu_2)^2 = b^2 \sigma^2.$$

This is the equation of a circle with center at  $(\mu_1, \mu_2)$  and radius  $b\sigma$ . Suppose next that  $\rho = 0$  and  $\sigma_1 \neq \sigma_2$ . Then the equation has the form

$$\frac{(x_1 - \mu_1)^2}{\sigma_1^2} + \frac{(x_2 - \mu_2)^2}{\sigma_2^2} = b^2.$$

This is the equation of an ellipse for which the center is  $(\mu_1, \mu_2)$  and the major and minor axes are parallel to the  $x_1$  and  $x_2$  axes. Suppose finally that  $\rho \neq 0$ . It was shown in Exercise 8 that  $a_1^2 - 2\rho a_1 a_2 + a_2^2 \geq 0$  for all values of  $a_1$  and  $a_2$ . It therefore follows from the methods of analytic geometry and elementary calculus that the set of points which satisfy the equation

$$\frac{(x_1 - \mu_1)^2}{\sigma_1^2} - 2\rho \frac{(x_1 - \mu_1)}{\sigma_1} \cdot \frac{(x_2 - \mu_2)}{\sigma_2} + \frac{(x_2 - \mu_2)^2}{\sigma_2^2} = b^2.$$

will be an ellipse for which the center is  $(\mu_1, \mu_2)$  and for which the major and minor axes are rotated so that they are not parallel to the  $x_1$  and  $x_2$  axes.

10. Let  $\Delta = \det \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$ . Since  $\Delta \neq 0$ , the transformation from  $X_1$  and  $X_2$  to  $Y_1$  and  $Y_2$  is a one-to-one transformation, for which the inverse transformation is:

$$\begin{aligned} X_1 &= \frac{1}{\Delta} [a_{22}(y_1 - b_1) - a_{12}(Y_2 - b_2)], \\ X_2 &= \frac{1}{\Delta} [-a_{21}(y_1 - b_1) + a_{11}(Y_2 - b_2)]. \end{aligned}$$

The joint p.d.f. of  $Y_1$  and  $Y_2$  can therefore be obtained by replacing  $x_1$  and  $x_2$  in  $f(x_1, x_2)$  by their expressions in terms of  $y_1$  and  $y_2$ , and then multiplying the result by the constant  $1/|\Delta|$ . After a great deal of algebra the exponent in this joint p.d.f. can be put into the following form:

$$-\frac{1}{2(1-r^2)} \left[ \left( \frac{y_1 - m_1}{s_1} \right)^2 - 2r \left( \frac{y_1 - m_1}{s_1} \right) \left( \frac{y_2 - m_2}{s_2} \right) + \left( \frac{y_2 - m_2}{s_2} \right)^2 \right],$$

where

$$\begin{aligned} m_1 &= E(Y_1) = a_{11}\mu_1 + a_{12}\mu_2 + b_1, \\ m_2 &= E(Y_2) = a_{21}\mu_1 + a_{22}\mu_2 + b_2, \\ s_1^2 &= \text{Var}(Y_1) = a_{11}^2\sigma_1^2 + a_{12}^2\sigma_2^2 + 2a_{11}a_{12}\rho\sigma_1\sigma_2, \\ s_2^2 &= \text{Var}(Y_2) = a_{21}^2\sigma_1^2 + a_{22}^2\sigma_2^2 + 2a_{21}a_{22}\rho\sigma_1\sigma_2, \\ r &= \frac{\text{Cov}(Y_1, Y_2)}{s_1 s_2} = \frac{1}{s_1 s_2} [a_{11}a_{21}\sigma_1^2 + (a_{11}a_{22} + a_{12}a_{21})\rho\sigma_1\sigma_2 + a_{12}^2a_{22}\sigma_2^2]. \end{aligned}$$

It can then be concluded that this joint p.d.f. is the p.d.f. of a bivariate normal distribution for which the means are  $m_1$  and  $m_2$ , the variances are  $s_1^2$  and  $s_2^2$ , and the correlation is  $r$ .

11. By Exercise 10, the joint distribution of  $X_1 + X_2$  and  $X_1 - X_2$  is a bivariate normal distribution. By Exercise 9 of Sec. 4.6, these two variables are uncorrelated. Therefore, they are also independent.
12. (a) For the first species, the mean of  $a_1X_1 + a_2X_2$  is  $201a_1 + 118a_2$ , while the variance is

$$15.2^2a_1^2 + 6.6^2a_2^2 + 2 \times 15.2 \times 6.6 \times 0.64a_1a_2.$$

The square-root of this is the standard deviation,  $(231.04a_1^2 + 43.56a_2^2 + 128.41a_1a_2)^{1/2}$ . For the second species, the mean is  $187a_1 + 131a_2$ . The standard deviation will be the same as for the first species because the values of  $\sigma_1$ ,  $\sigma_2$  and  $\rho$  are the same for both species.

- (b) At first, it looks like we need a two-dimensional maximization. However, it is clear that the ratio in question, namely,

$$\frac{-14a_1 + 13a_2}{(231.04a_1^2 + 43.56a_2^2 + 128.41a_1a_2)^{1/2}} \quad (\text{S.5.12})$$

will have the same value if we multiply both  $a_1$  and  $a_2$  by the same positive constant. We could then assume that the pair  $(a_1, a_2)$  lies on a circle and hence reduce the maximization to a one-dimensional problem. Alternatively, we could assume that  $a_1 + a_2 = 1$  and then find the maximum of the square of (S.5.12). (We would also have to check the one extra case in which  $a_1 = -a_2$  to see if that produced a larger value.) We shall use this second approach. If we replace  $a_2$  by  $1 - a_1$ , we need to find the maximum of

$$\frac{(13 - 27a_1)^2}{231.04a_1^2 + 43.56(1 - a_1)^2 + 128.41a_1(1 - a_1)}.$$

The derivative of this is the ratio of two polynomials, the denominator of which is always positive. So, the derivative is 0 when the numerator is 0. The numerator of the derivative is  $13 - 27a_1$  times a linear function of  $a_1$ . The two roots of the numerator are 0.4815 and  $-0.5878$ . The first root produces the value 0 for (S.5.12), while the second produces the value 3.456. All pairs with  $a_1 = -a_2$  lead to the values  $\pm 2.233$ . So  $a_1 = -0.5878$  and  $a_2 = 1.5878$  provide the maximum of (S.5.12).

13. The exponent of a bivariate normal p.d.f. can be expressed as  $-(ax^2 + by^2 + cxy + ex + gy + h)$ , where

$$\begin{aligned} a &= \frac{1}{2\sigma_1^2(1 - \rho^2)}, \\ b &= \frac{1}{2\sigma_2^2(1 - \rho^2)}, \\ c &= -\frac{\rho}{\sigma_1\sigma_2(1 - \rho^2)}, \end{aligned}$$

$$\begin{aligned} e &= -\frac{\mu_1}{\sigma_1^2(1-\rho^2)} + \frac{\mu_2\rho}{\sigma_1\sigma_2(1-\rho^2)}, \\ g &= -\frac{\mu_2}{\sigma_2^2(1-\rho^2)} + \frac{\mu_1\rho}{\sigma_1\sigma_2(1-\rho^2)}, \end{aligned}$$

and  $h$  is irrelevant because  $\exp(-h)$  just provides an additional constant factor that we are ignoring anyway. The only restrictions that the bivariate normal p.d.f. puts on the numbers  $a, b, c, e$ , and  $g$  are that  $a, b > 0$  and whatever is equivalent to  $|\rho| < 1$ . It is easy to see that, so long as  $a, b > 0$ , we will have  $|\rho| < 1$  if and only if  $ab > (c/2)^2$ . Hence, every set of numbers that satisfies these inequalities corresponds to a bivariate normal p.d.f. Assuming that these inequalities are satisfied, we can solve the above equations to find the parameters of the bivariate normal distribution.

$$\begin{aligned} \rho &= -\frac{c/2}{(ab)^{1/2}}, \\ \sigma_1^2 &= \frac{1}{2a - c^2/[2b]}, \\ \sigma_2^2 &= \frac{1}{2b - c^2/[2a]}, \\ \mu_1 &= \frac{cg - 2be}{4ab - c^2}, \\ \mu_2 &= \frac{ce - 2ag}{4ab - c^2}. \end{aligned}$$

14. The marginal p.d.f. of  $X$  is

$$f_1(x) = \frac{1}{(2\pi\sigma^2)^{1/2}} \exp\left(-\frac{1}{2\sigma^2}[x - \mu]^2\right),$$

where  $\mu$  and  $\sigma^2$  are the mean and variance of  $X$ . The conditional p.d.f. of  $Y$  given  $X = x$  is

$$g_2(y|x) = \frac{1}{(2\pi\tau^2)^{1/2}} \exp\left(-\frac{1}{2\tau^2}[y - ax - b]^2\right).$$

The joint p.d.f. of  $(X, Y)$  is the product of these two

$$f(x, y) = \frac{1}{2\pi\sigma\tau} \exp\left(-[a'x^2 + b'y^2 + cxy + ex + gy + h]\right),$$

where

$$\begin{aligned} a' &= \frac{1}{2\sigma^2} + \frac{a^2}{2\tau^2}, \\ b' &= \frac{1}{2\tau^2}, \\ c &= -\frac{a}{\tau^2}, \\ e &= -\frac{\mu}{\sigma^2} + \frac{ab}{\tau^2}, \\ g &= -\frac{b}{\tau^2}, \end{aligned}$$

and  $h$  is irrelevant since we are going to apply the result from Exercise 13. Clearly  $a'$  and  $b'$  are positive. We only need to check that  $a'b' > (c/2)^2$ . Notice that

$$a'b' = \frac{1}{4\sigma^2\tau^2} + \frac{a^2}{4\tau^2} = (c/2)^2 + \frac{1}{4\sigma^2\tau^2},$$

so the conditions of Exercise 13 are met.

15. (a) Let  $Y = \sum_{j \neq i} X_j$ . Since  $X_1, \dots, X_n$  are independent, we know that  $Y$  is independent of  $X_i$ . Since  $Y$  is the sum of independent normal random variables it has a normal distribution. The mean and variance of  $Y$  are easily seen to be  $(n-1)\mu$  and  $(n-1)\sigma^2$  respectively. Since  $Y$  and  $X_i$  are independent, all pairs of linear combinations of them have a bivariate normal distribution. Now write

$$\begin{aligned} X_i &= 1X_i + 0Y, \\ \bar{X}_n &= \frac{1}{n}X_i + \frac{1}{n}Y. \end{aligned}$$

Clearly, both  $X_i$  and  $Y$  have mean  $\mu$ , and we already know that  $X_i$  has variance  $\sigma^2$  while  $Y$  has variance  $\sigma^2/n$ . The correlation can be computed from the covariance of the two linear combinations.

$$\text{Cov}\left(1X_i + 0Y, \frac{1}{n}X_i + \frac{1}{n}Y\right) = \frac{1}{n}\sigma^2.$$

The correlation is then  $(\sigma^2/n)/[\sigma^2\sigma^2/n]^{1/2} = 1/n^{1/2}$ .

- (b) The conditional distribution of  $X_i$  given  $\bar{X}_n = \bar{x}_n$  is a normal distribution with mean equal to

$$\mu + \frac{1}{n^{1/2}} \frac{\sigma}{\sigma/\sqrt{n}} (\bar{x}_n - \mu) = \bar{x}_n.$$

The conditional variance is

$$\sigma^2 - \left(1 - \frac{1}{n}\right).$$

## 5.11 Supplementary Exercises

### Solutions to Exercises

1. Let  $g_1(x|p)$  be the conditional p.f. of  $X$  given  $P = p$ , which is the binomial p.f. with parameters  $n$  and  $p$ . Let  $f_2(p)$  be the marginal p.d.f. of  $P$ , which is beta p.d.f. with parameters 1 and 1, also known as the uniform p.d.f. on the interval  $[0, 1]$ . According to the law of total probability for random variables, the marginal p.f. of  $X$  is

$$f_1(x) = \int g_1(x|p)f_2(p)dp = \int_0^1 \binom{n}{x} p^x (1-p)^{n-x} dp = \binom{n}{x} \frac{x!(n-x)!}{(n+1)!} = \frac{1}{n+1},$$

for  $x = 0, \dots, n$ . In the above, we used Theorem 5.8.1 and the fact that  $\Gamma(k+1) = k!$  for each integer  $k$ .

2. The random variable  $U = 3X + 2Y - 6Z$  has the normal distribution with mean 0 and variance  $3^2 + 2^2 + 6^2 = 49$ . Therefore,  $Z = U/7$  has the standard normal distribution. The required probability is

$$\Pr(U < -7) = \Pr(Z < -1) = 1 - \Phi(1) = .1587.$$

3. Since  $\text{Var}(X) = E(X) = \lambda_1$  and  $\text{Var}(Y) = E(Y) = \lambda_2$ , it follows that  $\lambda_1 + \lambda_2 = 5$ . Hence,  $X + Y$  has the Poisson distribution with mean 5 and

$$\Pr(X + Y < 2) = \Pr(X + Y = 0) + \Pr(X + Y = 1) = \exp(-5) + 5 \exp(-5) = .0067 + .0337 = .0404.$$

4. It can be found from the table of the standard normal distribution that 116 must be .84 standard deviations to the left of the mean and 328 must be 1.28 standard deviations to the right of the mean. Hence,

$$\begin{aligned}\mu - .84\sigma &= 116, \\ \mu + 1.28\sigma &= 328.\end{aligned}$$

Solving these equations, we obtain  $\mu = 200$  and  $\sigma = 100$ ,  $\sigma^2 = 10,000$ .

5. The event  $\{\bar{X} < 1/2\}$  can occur only if all four observations are 0, which has probability  $(\exp(-\lambda))^4$ , or three of the observations are 0 and the other is 1, which has probability  $4(\lambda \exp(-\lambda))(\exp(-\lambda))^3$ . Hence, the total probability is as given in this exercise.
6. If  $X$  has the exponential distribution with parameter  $\beta$ , then

$$.25 = \Pr(X > 1000) = \exp(-(1000)\beta).$$

$$\text{Hence, } \beta = \frac{1}{1000} \log 4 \text{ and } E(X) = \frac{1}{\beta} = \frac{1000}{\log 4}.$$

7. It follows from Exercise 18 of Sec. 4.9 that

$$E[(X - \mu)^3] = E(X^3) - 3\mu\sigma^2 - \mu^3.$$

Because of the symmetry of the normal distribution with respect to  $\mu$ , the left side of this relation is 0. Hence,

$$E(X^3) = 3\mu\sigma^2 + \mu^3.$$

8.  $\bar{X}$  and  $\bar{Y}$  have independent normal distributions with the same mean  $\mu$ , and  $\text{Var}(\bar{X}) = 144/16 = 9$ ,  $\text{Var}(\bar{Y}) = 400/25 = 16$ . Hence,  $\bar{X} - \bar{Y}$  has the normal distribution with mean 0 and variance  $9 + 16 = 25$ . Thus,  $Z = (\bar{X} - \bar{Y})/5$  has the standard normal distribution. It follows that the required probability is  $\Pr(|Z| < 1) = .6826$ .
9. The number of men that arrive during the one-minute period has the Poisson distribution with mean 2. The number of women is independent of the number of men and has the Poisson distribution with mean 1. Therefore, the total number of people  $X$  that arrive has the Poisson distribution with mean 3. From the table in the back of the book it is found that

$$\Pr(X \leq 4) = .0498 + .1494 + .2240 + .2240 + .1680 = .8152.$$

10.

$$\begin{aligned}
\dot{\psi}_Y(t) &= E(\exp(tY)) = E[\exp(tX_1 + \dots + tX_N)] \\
&= E\{E[\exp(tX_1 + \dots + tX_N)|N]\} \\
&= E\{[\psi(t)]^N\} \\
&= \sum_{x=0}^{\infty} [\psi(t)]^x \frac{\exp(-\lambda)\lambda^x}{x!} \\
&= \exp(-\lambda) \sum_{x=0}^{\infty} \frac{[\lambda\psi(t)]^x}{x!} \\
&= \exp(-\lambda) \exp(\lambda\psi(t)) = \exp\{\lambda[\psi(t) - 1]\}.
\end{aligned}$$

11. The probability that at least one of the two children will be successful on a given Sunday is  $(1/3) + (1/5) - (1/3)(1/5) = 7/15$ . Therefore, from the geometric distribution, the expected number of Sundays until a successful launch is achieved is  $15/7$ .
12. For any positive integer  $n$ , the event  $X > n$  will occur if and only if the first  $n$  tosses are either all heads or all tails. Therefore,

$$\Pr(X > n) = \left(\frac{1}{2}\right)^n + \left(\frac{1}{2}\right)^n = \left(\frac{1}{2}\right)^{n-1},$$

and, for  $n = 2, 3, \dots$

$$\Pr(X = n) = \Pr(X > n - 1) - \Pr(X > n) = \left(\frac{1}{2}\right)^{n-2} - \left(\frac{1}{2}\right)^{n-1} = \left(\frac{1}{2}\right)^{n-1}.$$

Hence,

$$f(x) = \begin{cases} \left(\frac{1}{2}\right)^{x-1} & \text{for } x = 2, 3, 4, \dots \\ 0 & \text{otherwise.} \end{cases}$$

13. By the Poisson approximation, the distribution of  $X$  is approximately Poisson with mean  $120(1/36) = 10/3$ . The probability that such a Poisson random variable equals 3 is  $\exp(-10/3)(10/3)^3/3! = 0.2202$ . (The actual binomial probability is 0.2229.)
14. It was shown in Sec. 3.9 that the p.d.f.'s of  $Y_1$ ,  $Y_n$ , and  $W$ , respectively, are as follows:

$$\begin{aligned}
g_1(y) &= n(1-y)^{n-1} && \text{for } 0 < y < 1, \\
g_n(y) &= ny^{n-1} && \text{for } 0 < y < 1, \\
h_1(w) &= n(n-1)w^{n-2}(1-w) && \text{for } 0 < w < 1.
\end{aligned}$$

Each of these is the p.d.f. of a beta distribution. For  $g_1$ ,  $\alpha = 1$  and  $\beta = n$ . For  $g_n$ ,  $\alpha = n$  and  $\beta = 1$ . For  $h_1$ ,  $\alpha = n - 1$  and  $\beta = 2$ .

15. (a)  $\Pr(T_1 > t) = \Pr(X = 0)$ , where  $X$  is the number of occurrences between time 0 and time  $t$ . Since  $X$  has the Poisson distribution with mean  $5t$ , it follows that  $\Pr(T_1 > t) = \exp(-5t)$ . Hence,  $T_1$  has the exponential distribution with parameter  $\beta = 5$ .

- (b)  $T_k$  is the sum of  $k$  i.i.d. random variables, each of which has the exponential distribution given in part (a). Therefore, the distribution of  $T_k$  is a gamma distribution with parameters  $\alpha = k$  and  $\beta = 5$ .
- (c) Let  $X_i$  denote the time following the  $i$ th occurrence until the  $(i+1)$ st occurrence. Then the random variable  $X_1, \dots, X_{k-1}$  are i.i.d., each of which has the exponential distribution given in part (a). Since  $t$  is measured in hours in that distribution, the required probability is

$$\Pr\left(X_i > \frac{1}{3}, i = 1, \dots, k-1\right) = (\exp(-5/3))^{k-1}.$$

16. We can express  $T_5$  as  $T_1 + V$ , where  $V$  is the time required after one of the components has failed until the other four have failed. By the memoryless property of the exponential distribution, we know that  $T_1$  and  $V$  are independent. Therefore,

$$\text{Cov}(T_1, T_5) = \text{Cov}(T_1, T_1 + V) = \text{Cov}(T_1, T_1) + \text{Cov}(T_1, V) = \text{Var}(T_1) + 0 = \frac{1}{25\beta^2},$$

since  $T_1$  has the exponential distribution with parameter  $5\beta$ .

17.  $\Pr(X_1 > kX_2) = \int_0^\infty \Pr(X_1 > kX_2 | X_2 = x)(f_{2x})dx = \int_0^\infty \exp(-\beta_1 kx)\beta_2 \exp(-\beta_2 x)dx = \frac{\beta_2}{k\beta_1 + \beta_2}.$
18. Since the sample size is small relative to the size of the population, the distribution of the number  $X$  of people in the sample who are watching will have essentially the binomial distribution with  $n = 200$  and  $p = 15000/500000 = .03$ , even if sampling is done without replacement. This binomial distribution is closely approximated by Poisson distribution with mean  $\lambda = np = 6$ . Hence, from the table in the back of the text,

$$\Pr(X < 4) = .0025 + .0149 + .0446 + .0892 = .1512.$$

19. It follows from Eq. (5.3.8) that

$$\text{Var}(\bar{X}) = \frac{1}{n^2} \text{Var}(X) = \frac{p(1-p)}{n} \cdot \frac{T-n}{T-1},$$

where  $T$  is the population size,  $p$  is the proportion of persons in the population who have the characteristic, and  $n = 100$ . Since  $p(1-p) \leq 1/4$  for  $0 \leq p \leq 1$  and  $(T-n)(T-1) \leq 1$  for all values of  $T$ , it follows that

$$\text{Var}(\bar{X}_n) \leq \frac{1}{400}.$$

Hence, the standard deviation is  $\leq 1/20 = .05$ .

20. Consider the event that less than  $r$  successes are obtained in the first  $n$  Bernoulli trials. The left side represents the probability of this event in terms of the binomial distribution. But the event also means that more than  $n$  trials are going to be required in order to obtain  $r$  successes, which means that more than  $n - r$  failures are going to be obtained before  $r$  successes are obtained. The right side expresses this probability in terms of the negative binomial distribution.
21. Consider the event that there are at least  $k$  occurrences between time 0 and time  $t$ . The number  $X$  of occurrences in this interval has the specified Poisson distribution, so the left side represents the probability of this event. But the event also means that the total waiting time  $Y$  until the  $k$ th event occurs is  $\leq t$ . It follows from part (b) of Exercise 15 that  $Y$  has the specified gamma distribution. Hence, the right side also expresses the probability of this same event.

22. It follows from the definition of  $h(x)$  that

$$\int_0^x h(t)dt = \int_0^x \frac{f(t)}{1 - F(t)}dt = -\log [1 - F(x)].$$

Therefore,

$$\exp \left[ - \int_0^x h(t) dt \right] = 1 - F(x).$$

23. (a) It follows from Theorem 5.9.2 that

$$\rho(X_i, X_j) = \frac{\text{Cov}(X_i, X_j)}{[\text{Var}(X_i)\text{Var}(X_j)]^{1/2}} = \frac{-10p_i p_j}{10[p_i(1-p_i)p_j(1-p_j)]^{1/2}} = -\left(\frac{p_i}{1-p_i} \cdot \frac{p_j}{1-p_j}\right)^{1/2}$$

- (b)  $\rho(X_i, X_j)$  is most negative when  $p_i$  and  $p_j$  have their largest values; i.e., for  $i = 1$  ( $p_i = .4$ ) and  $j = 2$  ( $p_2 = .3$ ).
  - (c)  $\rho(X_i, X_j)$  is closest to 0 when  $p_i$  and  $p_j$  have their smallest values; i.e., for  $i = 3$  ( $p_3 = .2$ ) and  $j = 4$  ( $p_4 = .1$ ).
24. It follows from Theorem 5.10.5 that  $X_1 - 3X_2$  will have the normal distribution with mean  $\mu_1 - 3\mu_2$  and variance  $\sigma_1^2 + 9\sigma_2^2 - 6\rho\sigma_1\sigma_2$ .
25. Since  $X$  has a normal distribution and the conditional distribution of  $Y$  given  $X$  is also normal with a mean that is a linear function of  $X$  and constant variance, it follows that  $X$  and  $Y$  jointly have a bivariate normal distribution. Hence,  $Y$  has a normal distribution. From Eq. (5.10.6),  $2X - 3 = \mu_2 + \rho\sigma_2 X$ . Hence,  $\mu_2 = -3$  and  $\rho\sigma_2 = 2$ . Also,  $(1 - \rho^2)\sigma_2^2 = 12$ . Therefore  $\sigma_2^2 = 16$  and  $\rho = 1/2$ . Thus,  $Y$  has the normal distribution with mean  $-3$  and variance  $16$ , and  $\rho(X, Y) = 1/2$ .

26. We shall use the relation

$$E(X_1^2 X_2) = E[E(X_1^2 X_2 | X_2)] = E[X_2 E(X_1^2 | X_2)].$$

But

$$E(X_1^2 | X_2) = \text{Var}(X_1 | X_2) + [E(X_1 | X_2)]^2 = (1 - \rho^2)\sigma_1^2 + \left(\mu_1 + \rho \frac{\sigma_1}{\sigma_2} X_2\right)^2.$$

Hence,

$$X_2 E(X_1^2 | X_2) = (1 - \rho^2)\sigma_1^2 X_2 + \mu_1^2 X_2 + 2\rho\mu_1 \frac{\sigma_1}{\sigma_2} X_2^2 + \left(\rho \frac{\sigma_1}{\sigma_2}\right)^2 X_2^3.$$

The required value  $E(X_1^2 X_2)$  is the expectation of this quantity. But since  $X_2$  has the normal distribution with  $E(X_2) = 0$ , it follows that  $E(X_2^2) = \sigma_2^2$  and  $E(X_2^3) = 0$ .

Hence,

$$E(X_1^2 X_2) = 2\rho\mu_1\sigma_1\sigma_2.$$

# Chapter 6

## Large Random Samples

### 6.1 Introduction

#### Solutions to Exercises

1. The p.d.f. of  $Y = X_1 + X_2$  is

$$g(y) = \begin{cases} y & \text{if } 0 < y \leq 1, \\ 2 - y & \text{if } 1 < y < 2, \\ 0 & \text{otherwise.} \end{cases}$$

It follows easily from the fact that  $\bar{X}_2 = Y/2$  that the p.d.f. of  $\bar{X}_2$  is

$$h(x) = \begin{cases} 4x & \text{if } 0 < x \leq 1/2, \\ 4 - 4x & \text{if } 1/2 < x < 1, \\ 0 & \text{otherwise.} \end{cases}$$

We easily compute

$$\begin{aligned} \Pr(|X_1 - 0.5| < 0.1) &= 0.6 - 0.4 = 0.2, \\ \Pr(|\bar{X}_2 - 0.5| < 0.1) &= \int_{0.4}^{0.5} 4x dx + \int_{0.5}^{0.6} (4 - 4x) dx \\ &= 2(0.5^2 - 0.4^2) + 4(0.6 - 0.5) - 2(0.6^2 - 0.5^2) = 0.36. \end{aligned}$$

The reason that  $\bar{X}_2$  has higher probability of being close to 0.5 is that its p.d.f. is much higher near 0.5 than is the uniform p.d.f. of  $X_1$  (twice as high right at 0.5).

2. The distribution of  $\bar{X}_n$  is (by Corollary 5.6.2) the normal distribution with mean  $\mu$  and variance  $\sigma^2/n$ . By Theorem 5.6.6,

$$\begin{aligned} \Pr(|\bar{X}_n - \mu| \leq c) &= \Pr(\bar{X}_n \leq c) - \Pr(\bar{X}_n \leq -c) \\ &= \Phi\left(\frac{c}{\sigma/n^{1/2}}\right) - \Phi\left(\frac{-c}{\sigma/n^{1/2}}\right). \end{aligned} \tag{S.6.1}$$

As  $n \rightarrow \infty$ ,  $c/(\sigma/n^{1/2}) \rightarrow \infty$  and  $-c/(\sigma/n^{1/2}) \rightarrow -\infty$ . It follows from Property 3.3.2 of all c.d.f.'s that (S.6.1) goes to 1 as  $n \rightarrow \infty$ .

3. To do this by hand we would have to add all of the binomial probabilities corresponding to  $W = 80, \dots, 120$ . Most statistical software will do this calculation automatically. The result is 0.9964. It looks like the probability is increasing to 1.

## 6.2 The Law of Large Numbers

### Commentary

The discussion of the strong law of large numbers at the end of the section might be suitable only for the more mathematically inclined students.

### Solutions to Exercises

- Let  $\epsilon > 0$ . We need to show that

$$\lim_{n \rightarrow \infty} \Pr(|X_n - 0| \geq \epsilon) = 0. \quad (\text{S.6.2})$$

Since  $X_n \geq 0$ , we have  $|X_n - 0| \geq \epsilon$  if and only if  $X_n \geq \epsilon$ . By the Markov inequality  $\Pr(X_n \geq \epsilon) \leq \mu_n/\epsilon$ . Since  $\lim_{n \rightarrow \infty} \mu_n = 0$ , Eq. (S.6.2) holds.

- By the Markov inequality,

$$E(X) \geq 10 \Pr(X \geq 10) = 2.$$

- By the Chebyshev inequality,

$$\text{Var}(X) \geq 9 \Pr(|X - \mu| \geq 3) = 9 \Pr(X \leq 7 \text{ or } X \geq 13) = 9(0.2 + 0.3) = \frac{9}{2}.$$

- Consider a distribution which is concentrated on the three points  $\mu$ ,  $\mu + 3\sigma$ , and  $\mu - 3\sigma$ . Let  $\Pr(X = \mu) = p_1$ ,  $\Pr(X = \mu + 3\sigma) = p_2$ , and  $\Pr(X = \mu - 3\sigma) = p_3$ . If we are to have  $E(X) = \mu$ , then we must have  $p_2 = p_3$ . Let  $p$  denote the common value of  $p_2$  and  $p_3$ . Then  $p_1 = 1 - 2p$ , because  $p_1 + p_2 + p_3 = 1$ . Now

$$\text{Var}(X) = E[(X - \mu)^2] = 9\sigma^2(p) + 9\sigma^2(p) + 0(1 - 2p) = 18\sigma^2p.$$

Since we must have  $\text{Var}(X) = \sigma^2$ , then we must choose  $p = 1/18$ . Therefore, the only distribution which is concentrated on the three points  $\mu$ ,  $\mu + 3\sigma$ , and  $\mu - 3\sigma$ , and for which  $E(X) = \mu$  and  $\text{Var}(X) = \sigma^2$ , is the one with  $p_1 = 8/9$  and  $p_2 = p_3 = 1/18$ . It can now be verified that for this distribution we have

$$\Pr(|X - \mu| \geq 3\sigma) = \Pr(X = \mu + 3\sigma) + \Pr(X = \mu - 3\sigma) = \frac{1}{18} + \frac{1}{18} = \frac{1}{9}.$$

- By the Chebyshev inequality,

$$\Pr(|X_n - \mu| \leq 2\sigma) \geq 1 - \frac{1}{4n}.$$

Therefore, we must have  $1 - \frac{1}{4n} \geq 0.99$ . or  $n \geq 25$ .

- By the Chebyshev inequality,

$$\Pr(6 \leq \bar{X}_n \leq 7) = \Pr\left(|\bar{X}_n - \mu| \leq \frac{1}{2}\right) \geq 1 - \frac{16}{n}.$$

Therefore, we must have  $1 - \frac{16}{n} \geq 0.8$  or  $n \geq 80$ .

7. By the Markov inequality,

$$\Pr(|X - \mu| \geq t) = \Pr(|X - \mu|^4 \geq t^4) \leq \frac{E(|X - \mu|^4)}{t^4} = \frac{\beta_4}{t^4}.$$

8. (a) In this example  $E(Q_n) = 0.3$  and  $\text{Var}(Q_n) = (0.3)(0.7)/n = 0.21/n$ . Therefore,

$$\Pr(0.2 \leq Q_n \leq 0.4) = \Pr(|Q_n - E(Q_n)| \leq 0.1) \geq 1 - \frac{0.21}{n(0.01)} = 1 - \frac{21}{n}.$$

Therefore, we must have  $1 - \frac{21}{n} \geq 0.75$  or  $n \geq 84$ .

(b) Let  $X_n$  denote the total number of items in the sample that are of poor quality. Then  $X_n = nQ_n$  and

$$\Pr(0.2 \leq Q_n \leq 0.4) = \Pr(0.2n \leq X_n \leq 0.4n).$$

Since  $X_n$  has a binomial distribution with parameters  $n$  and  $p = 0.3$ , the value of this probability can be determined for various values of  $n$  from the table of the binomial distribution given in the back of the book. For  $n = 15$ , it is found that

$$\Pr(0.2n \leq X_n \leq 0.4n) = \Pr(3 \leq X_n \leq 6) = 0.7419.$$

For  $n = 20$ , it is found that

$$\Pr(0.2n \leq X_n \leq 0.4n) = \Pr(4 \leq X_n \leq 8) = 0.7796.$$

Since this probability must be at least 0.75, we must have  $n = 20$ , although it is possible that some value between  $n = 15$  and  $n = 20$  will also satisfy the required condition.

9.  $E(Z_n) = n^2 \cdot \frac{1}{n} + 0 \left(1 - \frac{1}{n}\right) = n$ . Hence,  $\lim_{n \rightarrow \infty} E(Z_n) = \infty$ . Also, for any given  $\epsilon > 0$ ,

$$\Pr(|Z_n| < \epsilon) = \Pr(Z_n = 0) = 1 - \frac{1}{n}.$$

Hence,  $\lim_{n \rightarrow \infty} \Pr(|Z_n| < \epsilon) = 1$ , which means that  $Z_n \xrightarrow{P} 0$ .

10. By Exercise 5 of Sec. 4.3,

$$E[(Z_n - b)^2] = [E(Z_n) - b]^2 + \text{Var}(Z_n).$$

Therefore, the limit of the left side will be 0 if and only if the limit of each of the two terms on the right side is 0. Moreover,  $\lim_{n \rightarrow \infty} [E(Z_n) - b]^2 = 0$  if and only if  $\lim_{n \rightarrow \infty} E(Z_n) = b$ .

11. Suppose that the sequence  $Z_1, Z_2, \dots$  converges to  $b$  in the quadratic mean. Since

$$|Z_n - b| \leq |Z_n - E(Z_n)| + |E(Z_n) - b| ,$$

then for any value of  $\epsilon > 0$ ,

$$\begin{aligned} \Pr(|Z_n - b| < \epsilon) &\geq \Pr(|Z_n - E(Z_n)| + |E(Z_n) - b| < \epsilon) \\ &= \Pr(|Z_n - E(Z_n)| < \epsilon - |E(Z_n) - b|). \end{aligned}$$

By Exercise 10, we know that  $\lim_{n \rightarrow \infty} E(Z_n) = b$ . Therefore, for sufficiently large values of  $n$ , it will be true that  $\epsilon - |E(Z_n) - b| > 0$ . Hence, by the Chebyshev inequality, the final probability will be at least as large as

$$1 - \frac{\text{Var}(Z_n)}{[\epsilon - |E(Z_n) - b|]^2}.$$

Again, by Exercise 10,

$$\lim_{n \rightarrow \infty} \text{Var}(Z_n) = 0 \text{ and } \lim_{n \rightarrow \infty} [\epsilon - |E(Z_n) - b|]^2 = \epsilon^2.$$

Therefore,

$$\lim_{n \rightarrow \infty} \Pr(|Z_n - b| < \epsilon) \geq \lim_{n \rightarrow \infty} \left\{ 1 - \frac{\text{Var}(Z_n)}{[\epsilon - |E(Z_n) - b|]^2} \right\} = 1,$$

which means that  $Z_n \xrightarrow{p} b$ .

12. We know that  $E(\bar{X}_n) = \mu$  and  $\text{Var}(\bar{X}_n) = \sigma^2/n$ . Therefore,  $\lim_{n \rightarrow \infty} E(\bar{X}_n) = \mu$  and  $\lim_{n \rightarrow \infty} \text{Var}(\bar{X}_n) = 0$ . The desired result now follows from Exercise 10.
13. (a) For any value of  $n$  large enough so that  $1/n < \epsilon$ , we have

$$\Pr(|Z_n| < \epsilon) = \Pr\left(Z_n = \frac{1}{n}\right) = 1 - \frac{1}{n^2}.$$

Therefore,  $\lim_{n \rightarrow \infty} \Pr(|Z_n| < \epsilon) = 1$ , which means that  $Z_n \xrightarrow{p} 0$ .

- (b)  $E(Z_n) = \frac{1}{n} \left(1 - \frac{1}{n^2}\right) + n \left(\frac{1}{n^2}\right) = \frac{2}{n} - \frac{1}{n^3}$ . Therefore,  $\lim_{n \rightarrow \infty} E(Z_n) = 0$ . It follows from Exercise 10 that the only possible value for the constant  $c$  is  $c = 0$ , and there will be convergence to this value if and only if  $\lim_{n \rightarrow \infty} \text{Var}(Z_n) = 0$ . But

$$E(Z_n^2) = \frac{1}{n^2} \left(1 - \frac{1}{n^2}\right) + n^2 \cdot \frac{1}{n^2} = 1 + \frac{1}{n^2} - \frac{1}{n^4}.$$

$$\text{Hence, } \text{Var}(Z_n) = 1 + \frac{1}{n^2} - \frac{1}{n^4} - \left(\frac{2}{n} - \frac{1}{n^3}\right)^2 \text{ and } \lim_{n \rightarrow \infty} \text{Var}(Z_n) = 1.$$

14. Let  $X$  have p.f. equal to  $f$ . Assume that  $\text{Var}(X) > 0$  (otherwise it is surely less than  $1/4$ ). First, suppose that  $X$  has only two possible values, 0 and 1. Let  $p = \Pr(X = 1)$ . Then  $E(X) = E(X^2) = p$  and  $\text{Var}(X) = p - p^2$ . The largest possible value of  $p - p^2$  occurs when  $p = 1/2$ , and the value is  $1/4$ . So  $\text{Var}(X) \leq 1/4$  if  $X$  only has the two possible values 0 and 1. For the remainder of the proof, we shall show that if  $X$  has any possible values strictly between 0 and 1, then there is another random variable  $Y$  taking only the values 0 and 1 and with  $\text{Var}(Y) \geq \text{Var}(X)$ . So, assume that  $X$  takes at least one value strictly between 0 and 1. Without loss of generality, assume that one of those possible values is between 0 and  $\mu$ . (Otherwise replace  $X$  by  $1 - X$  which has the same variance.) Let  $\mu = E(X)$ , and let  $x_1, x_2, \dots$  be the values such that  $x_i \leq \mu$  and  $f(x_i) > 0$ . Define a new random variable

$$X^* = \begin{cases} 0 & \text{if } X \leq \mu, \\ X & \text{if } X > \mu. \end{cases}$$

The p.f. of  $X^*$  is

$$f^*(x) = \begin{cases} f(x) & \text{for all } x > \mu, \\ \sum_i f(x_i) & \text{for } x = 0, \\ 0 & \text{otherwise.} \end{cases}$$

The mean of  $X^*$  is  $\mu^* = \mu - \sum_i x_i f(x_i)$ . The mean of  $X^{*2}$  is  $E(X^2) - \sum_i x_i^2 f(x_i)$ . So, the variance of  $X^*$  is

$$\begin{aligned} \text{Var}(X^*) &= E(X^2) - \sum_i x_i^2 f(x_i) - \left[ \mu - \sum_i x_i f(x_i) \right]^2 \\ &= \text{Var}(X) - \sum_i x_i^2 f(x_i) + 2\mu \sum_i x_i f(x_i) - \left[ \sum_i x_i f(x_i) \right]^2. \end{aligned} \quad (\text{S.6.3})$$

since  $x_i \leq \mu$  for each  $i$ , we have

$$-\sum_i x_i^2 f(x_i) + 2\mu \sum_i x_i f(x_i) \geq \sum_i x_i^2 f(x_i). \quad (\text{S.6.4})$$

Let  $t = \sum_i f(x_i) > 0$ . Then

$$g(x) = \begin{cases} f(x)/t & \text{for } x \in \{x_1, x_2, \dots\}, \\ 0 & \text{otherwise,} \end{cases}$$

is a p.f. Let  $Z$  be a random variable whose p.f. is  $g$ . Then

$$\begin{aligned} E(Z) &= \frac{1}{t} \sum_i x_i f(x_i), \\ \text{Var}(Z) &= \frac{1}{t} \sum_i x_i^2 f(x_i). \end{aligned}$$

Since  $\text{Var}(Z) \geq 0$  and  $t \leq 1$ , we have

$$\sum_i x_i^2 f(x_i) \geq \frac{1}{t} \left[ \sum_i x_i f(x_i) \right]^2 \geq \left[ \sum_i x_i f(x_i) \right]^2.$$

Combine this with (S.6.3) and (S.6.4) to see that  $\text{Var}(X^*) \geq \text{Var}(X)$ . If  $f^*(x) > 0$  for some  $x$  strictly between 0 and 1, replace  $X^*$  by  $1 - X^*$  and repeat the above process to produce the desired random variable  $Y$ .

15. We need to prove that, for every  $\epsilon > 0$ ,

$$\lim_{n \rightarrow \infty} \Pr(|g(Z_n) - g(b)| < \epsilon) = 1.$$

Let  $\epsilon > 0$ . Since  $g$  is continuous at  $b$ , there exists  $\delta$  such that  $|z - b| < \delta$  implies that  $|g(z) - g(b)| < \epsilon$ . Also, since  $Z_n \xrightarrow{P} b$ , we know that

$$\lim_{n \rightarrow \infty} \Pr(|Z_n - b| < \delta) = 1.$$

But  $\{|Z_n - b| < \delta\} \subset \{|g(Z_n) - g(b)| < \epsilon\}$ . So

$$\Pr(|g(Z_n) - g(b)| < \epsilon) \geq \Pr(|Z_n - b| < \delta) \quad (\text{S.6.5})$$

Since the right side of (S.6.5) goes to 1 as  $n \rightarrow \infty$  so does the left side.

16. The argument here is similar to that given in Exercise 15. Let  $\epsilon > 0$ . Since  $g$  is continuous at  $(b, c)$ , there exists  $\delta$  such that  $\sqrt{(z-b)^2 + (y-c)^2} < \delta$  implies  $|g(z, y) - g(b, c)| < \epsilon$ . Also,  $|z - b| < \delta/\sqrt{2}$  and  $|y - c| < \delta/\sqrt{2}$  together imply  $\sqrt{(z-b)^2 + (y-c)^2} < \delta$ . Let  $B_n = \{|Z_n - b| < \delta/\sqrt{2}\}$  and  $C_n = \{|Y_n - c| < \delta/\sqrt{2}\}$ . It follows that

$$B_n \cap C_n \subset \{|g(Z_n, Y_n) - g(b, c)| < \delta\}. \quad (\text{S.6.6})$$

We can write

$$\begin{aligned} \Pr(B_n \cap C_n) &= 1 - \Pr([B_n \cap C_n]^c) = 1 - \Pr(B_n^c \cup C_n^c) \geq 1 - \Pr(B_n^c) - \Pr(C_n^c) \\ &= \Pr(B_n) + \Pr(C_n) - 1. \end{aligned}$$

Combining this with (S.6.6), we get

$$\Pr(|g(Z_n, Y_n) - g(b, c)| < \delta) \geq \Pr(B_n) + \Pr(C_n) - 1.$$

Since  $Z_n \xrightarrow{P} b$  and  $Y_n \xrightarrow{P} c$ , we know that both  $\Pr(B_n)$  and  $\Pr(C_n)$  go to 1 as  $n \rightarrow \infty$ . Hence  $\Pr(|g(Z_n, Y_n) - g(b, c)| < \delta)$  goes to 1 as well.

17. (a) The mean of  $X$  is  $np$ , and the mean of  $Y$  is  $np/k$ . Since  $Z = kY$ , the mean of  $Z$  is  $knp/k = np$ .  
 (b) The variance of  $X$  is  $np(1-p)$ , and the variance of  $Y$  is  $n(p/k)(1-p/k)$ . So, the variance  $Z = kY$  is  $k^2$  times the variance of  $Y$ , i.e.,

$$\text{Var}(Z) = k^2 n(p/k)(1-p/k) = knp(1-p/k).$$

If  $p$  is small, then both  $1-p$  and  $1-p/k$  will be close to 1, and  $\text{Var}(Z)$  is approximately  $knp$  while the variance of  $X$  is approximately  $np$ .

- (c) In Fig. 6.1, each bar has height equal to 0.01 times a binomial random variable with parameters 100 and the probability that  $X_1$  is in the interval under the bar. In Fig. 6.2, each bar has height equal to 0.02 times a binomial random variable with parameters 100 and probability that  $X_1$  is in the interval under the bar. The bars in Fig. 6.2 have approximately one-half of the probability of the bars in Fig. 6.1, but their heights have been multiplied by 2. By part (b), we expect the heights in Fig. 6.2 to have approximately twice the variance of the heights in Fig. 6.1.
18. The result is trivial if the m.g.f. is infinite for all  $s > 0$ . So, assume that the m.g.f. is finite for at least some  $s > 0$ . For every  $t$  and every  $s > 0$  such that the m.g.f. is finite, we can write

$$\Pr(X > t) = \Pr(\exp(sX) > \exp(st)) \leq \frac{E(\exp(sX))}{\exp(st)} = \psi(s) \exp(-st),$$

where the second equality follows from the Markov inequality. Since  $\Pr(X > t) \leq \psi(s) \exp(-st)$  for every  $s$   $\Pr(Y > t) \leq \min_s \psi(s) \exp(-st)$ .

19. (a) First, insert  $s$  from (6.2.15) into the expression in (6.2.14). We get

$$n \left[ \log(p) + \left( \frac{1-p}{p} + u \right) \log \left\{ \frac{(1+u)p+1-p}{up+1-p}(1-p) \right\} - \log \left\{ 1 - \frac{1-p}{\frac{(1+u)p+1-p}{up+1-p}(1-p)} \right\} \right].$$

The last term can be rewritten as

$$-\log \left\{ 1 - \frac{up+1-p}{(1+u)p+1-p} \right\} = -\log(p) + \log \{(1+u)p+1-p\}.$$

The result is then

$$n \left[ \left( \frac{1-p}{p} + u \right) \log \left\{ \frac{(1+u)p+1-p}{up+1-p}(1-p) \right\} + \log \{(1+u)p+1-p\} \right].$$

This is easily recognized as  $n$  times the logarithm of (6.2.16).

- (b) For all  $u, q$  is given by (6.2.16). For  $u = 0, q = (1-p)^{(1-p)/p}$ . Since  $0 < 1-p < 1$  and  $(1-p)/p > 0$ , we have  $0 < q < 1$  when  $u = 0$ . For general  $u$ , let  $x = p(1+u) + 1-p$  and rewrite

$$\log(q) = \log(p+x) + \frac{p+x}{p} \log \frac{(1-p)(p+x)}{x}.$$

Since  $x$  is a linear increasing function of  $u$ , if we show that  $\log(q)$  is decreasing in  $x$ , then  $q$  is decreasing in  $u$ . The derivative of  $\log(q)$  with respect to  $x$  is

$$-\frac{p}{x(p+x)} + \frac{1}{p} \log \frac{(1-p)(p+x)}{x}.$$

The first term is negative, and the second term is negative at  $u = 0$  ( $x = 1$ ). To be sure that the sum is always negative, examine the second term more closely. The derivative of the second term is

$$\frac{1}{p} \left( \frac{1}{p+x} - \frac{1}{x} \right) = \frac{-1}{x(p+x)} < 0.$$

Hence, the derivative is always negative, and  $q$  is less than 1 for all  $u$ .

20. We already have the m.g.f. of  $Y$  in (6.2.9). We can multiply it by  $e^{-sn/10}$  and minimize over  $s > 0$ . Before minimizing, take the logarithm:

$$\log[\psi(s)e^{-sn/10}] = n \left[ \log(1/2) + \log[\exp(s) + 1] - \frac{3s}{5} \right]. \quad (\text{S.6.7})$$

The derivative of this logarithm is

$$n \left[ \frac{\exp(s)}{\exp(s) + 1} - \frac{3}{5} \right].$$

The derivative is 0 at  $s = \log(3/2)$ , and the second derivative is positive there, so  $s = \log(3/2)$  provides the minimum. The minimum value of (S.6.7) is  $-0.02014$ , and the Chernoff bound is  $\exp(-0.02014n) = (0.98)^n$  for  $\Pr(Y > n/10)$ . Similarly, for  $\Pr(-Y > n/10)$ , we need to minimize

$$\log[\psi(-s)e^{-sn/10}] = n \left[ \log(1/2) + \log[\exp(-s) + 1] + \frac{2s}{5} \right]. \quad (\text{S.6.8})$$

The derivative is

$$n \left[ \frac{-\exp(-s)}{\exp(-s) + 1} + \frac{2}{5} \right],$$

which equals 0 at  $s = \log(3/2)$ . The minimum value of (S.6.8) is again  $-0.02014$ , and the Chernoff bound for the entire probability is  $2(0.98)^n$ , a bit smaller than in the example.

21. (a) The m.g.f. of the exponential distribution with parameter 1 is  $1/(1-s)$  for  $s < 1$ , hence the m.g.f. of  $Y_n$  is  $1/(1-s)^n$  for  $t < 1$ . The Chernoff bound is the minimum (over  $s > 0$ ) of  $e^{-nus}/(1-s)^n$ . The logarithm of this is  $-n[us + \log(1-s)]$ , which is minimized at  $s = (u-1)/u$ , which is positive if and only if  $u > 1$ . The Chernoff bound is  $[u \exp(1-u)]^n$ .
- (b) If  $u < 1$ , then the expression in Theorem 6.2.7 is minimized over  $s > 0$  near  $s = 0$ , which provides a useless bound of 1 for  $\Pr(Y_n > nu)$ .
22. (a) The numbers  $(k-1)k/2$  for  $k = 1, 2, \dots$  form a strictly increasing sequence starting at 0. Hence, every integer  $n$  falls between a unique pair of these numbers. So,  $k_n$  is the value of  $k$  such that  $n$  is larger than  $(k-1)k/2$  but no larger than  $k(k+1)/2$ .
- (b) Clearly  $j_n$  is the excess of  $n$  over the lower bound in part (a), hence  $j_n$  runs from 1 up to the difference between the bounds, which is easily seen to be  $k_n$ .
- (c) The intervals where  $h_n$  equals 1 are defined to be disjoint for  $j_n = 1, \dots, k_n$ , and they cover the whole interval  $[0, 1]$ . Hence, for each  $x$   $h_n(x) = 1$  for one and only one of these intervals, which correspond to  $n$  between the bounds in part (a).
- (d) For every  $x \in [0, 1]$ ,  $h_n(x) = 1$  for one  $n$  between the bounds in part (a). Since there are infinitely many values of  $k_n$ ,  $h_n(x) = 1$  infinitely often for every  $x \in [0, 1]$ , and  $\Pr(X \in [0, 1]) = 1$ .
- (e) For every  $\epsilon > 0$   $|Z_n - 0| > \epsilon$  whenever  $Z_n = 1$ . Since  $\Pr(Z_n = 1 \text{ infinitely often}) = 1$ , the probability is 1 that  $Z_n$  fails to converge to 0. Hence, the probability is 0 that  $Z_n$  does converge to 0.
- (f) Notice that  $h_n(x) = 1$  on an interval of length  $1/k_n$ . Hence, for each  $n$ ,  $\Pr(|Z_n - 0| > \epsilon) = 1/k_n$ , which goes to 0. So,  $Z_n \xrightarrow{P} 0$ .
23. Each  $Z_n$  has the Bernoulli distribution with parameter  $1/k_n$ , hence  $E[(Z_n - 0)^2] = 1/k_n$ , which goes to 0.
24. (a) By construction,  $\{Z_n \text{ converges to } 0\} = \{X > 0\}$ . Since  $\Pr(X > 0) = 1$ , we have  $Z_n$  converges to 0 with probability 1.
- (b)  $E[(Z_n - 0)^2] = E(Z_n^2) = n^4/n$ , which does not go to 0.

### 6.3 The Central Limit Theorem

#### Commentary

The delta method is introduced as a practical application of the central limit theorem. The examples of the delta method given in this section are designed to help pave the way for some approximate confidence interval calculations that arise in Sec. 8.5. The delta method also helps in calculating the approximate distributions of some summaries of simulations that arise in Sec. 12.2. This section ends with two theoretical topics that might be of interest only to the more mathematically inclined students. The first is a central limit theorem for random variables that don't have identical distributions. The second is an outline of the proof of the i.i.d. central limit theorem that makes use of moment generating functions.

## Solutions to Exercises

- The length of rope produced in one hour  $X$  has a mean of  $60 \times 4 = 240$  feet and a standard deviation of  $60^{1/2} \times 5 = 38.73$  inches, which is 3.23 feet. The probability that  $X \geq 250$  is approximately the probability that a normal random variable with mean 240 and standard deviation 3.23 is at least 250, namely  $1 - \Phi([250 - 240]/3.23) = 1 - \Phi(3.1) = 0.001$ .
- The total number of people  $X$  from the suburbs attending the concert can be regarded as the sum of 1200 independent random variables, each of which has a Bernoulli distribution with parameter  $p = 1/4$ . Therefore, the distribution of  $X$  will be approximately a normal distribution with mean  $1200(1/4) = 300$  and variance  $1200(1/4)(3/4) = 225$ . If we let  $Z = (X - 300)/15$ , then the distribution of  $Z$  will be approximately a standard normal distribution. Hence,

$$\Pr(X < 270) = \Pr(Z < -2) \simeq 1 - \Phi(2) = 0.0227.$$

- Since the variance of a Poisson distribution is equal to the mean, the number of defects on any bolt has mean 5 and variance 5. Therefore, the distribution of the average number  $\bar{X}_n$  on the 125 bolts will be approximately the normal distribution with mean 5 and variance  $5/125 = 1/25$ . If we let  $Z = (\bar{X}_n - 5)/(1/5)$ , then the distribution of  $Z$  will be approximately a standard normal distribution. Hence,

$$\Pr(\bar{X}_n < 5.5) = \Pr(Z < 2.5) \simeq \Phi(2.5) = 0.9938.$$

- The distribution of  $Z = \sqrt{n}(\bar{X}_n - \mu)/3$  will be approximately the standard normal distribution. Therefore,

$$\Pr(|\bar{X}_n - \mu| < 0.3) = \Pr(|Z| < 0.1\sqrt{n}) \simeq 2\Phi(0.1\sqrt{n}) - 1.$$

But  $2\Phi(0.1\sqrt{n}) - 1 \geq 0.95$  if and only if  $\Phi(0.1\sqrt{n}) \geq (1 + 0.95)/2 = 0.975$ , and this inequality is satisfied if and only if  $0.1\sqrt{n} \geq 1.96$  or, equivalently,  $n \geq 384.16$ . Hence, the smallest possible value of  $n$  is 385.

- The distribution of the proportion  $\bar{X}_n$  of defective items in the sample will be approximately the normal distribution with mean 0.1 and variance  $(0.1)(0.9)/n = 0.09/n$ . Therefore, the distribution of  $Z = \sqrt{n}(\bar{X}_n - 0.1)/0.3$  will be approximately the standard normal distribution. It follows that

$$\Pr(\bar{X}_n < 0.13) = \Pr(Z < 0.1\sqrt{n}) \simeq \Phi(0.1\sqrt{n}).$$

For this value to be at least 0.99, we must have  $0.1\sqrt{n} \geq 2.327$  or, equivalently,  $n \geq 541.5$ . Hence, the smallest possible value of  $n$  is 542.

- The distribution of the total number of times  $X$  that the target is hit will be approximately the normal distribution with mean  $10(0.3) + 15(0.2) + 20(0.1) = 8$  and variance  $10(0.3)(0.7) + 15(0.2)(0.8) + 20(0.1)(0.9) = 6.3$ . Therefore, the distribution of  $Z = (X - 8)/\sqrt{6.3} = (X - 8)/2.51$  will be approximately a standard normal distribution. It follows that

$$\Pr(X \geq 12) = \Pr(Z \geq 1.5936) \simeq 1 - \Phi(1.5936) = 0.0555.$$

- The mean of a random digit  $X$  is

$$E(X) = \frac{1}{10}(0 + 1 + \dots + 9) = 4.5.$$

Also,

$$E(X^2) = \frac{1}{10}(0^2 + 1^2 + \dots + 9^2) = \frac{1}{10} \cdot \frac{(9)(10)(19)}{6} = 28.5.$$

Therefore,  $\text{Var}(X) = 28.5 - (4.5)^2 = 8.25$ . The distribution of the average  $\bar{X}_n$  of 16 random digits will therefore be approximately the normal distribution with mean 4.5 and variance  $8.25/16 = 0.5156$ . Hence, the distribution of

$$Z = \frac{\bar{X}_n - 4.5}{\sqrt{0.5156}} = \frac{\bar{X}_n - 4.5}{0.7181}$$

will be approximately a standard normal distribution. It follows that

$$\begin{aligned}\Pr(4 \leq \bar{X}_n \leq 6) &= \Pr(-0.6963 \leq Z \leq 2.0888) \\ &= \Phi(2.0888) - [1 - \Phi(0.6963)] \\ &= 0.9816 - 0.2431 = 0.7385.\end{aligned}$$

8. The distribution of the total amount  $X$  of 36 drinks will be approximately the normal distribution with mean  $36(2) = 72$  and variance  $36(1/4) = 9$ . Therefore, the distribution of  $Z = (X - 72)/3$  will be approximately a standard normal distribution. It follows that

$$\Pr(X < 63) = \Pr(Z < -3) = 1 - \Phi(3) = 0.0013.$$

9. (a) By Eq. (6.2.4),

$$\Pr\left(|\bar{X}_n - \mu| \geq \frac{\sigma}{4}\right) \leq \frac{\sigma^2}{n} \cdot \frac{16}{\sigma^2} = \frac{16}{25}.$$

$$\text{Therefore, } \Pr\left(|\bar{X}_n - \mu| \leq \frac{\sigma}{4}\right) \geq 1 - \frac{16}{25} = 0.36.$$

- (b) The distribution of

$$Z = \frac{\bar{X}_n - \mu}{\sigma/\sqrt{n}} = \frac{5}{\sigma}(\bar{X}_n - \mu)$$

will be approximately a standard normal distribution. Therefore,

$$\Pr\left(|\bar{X}_n - \mu| \leq \frac{\sigma}{4}\right) = \Pr\left(|Z| \leq \frac{5}{4}\right) \simeq 2\Phi(1.25) - 1 = 0.7887.$$

10. (a) As in part (a) of Exercise 9,

$$\Pr\left(|\bar{X}_n - \mu| \leq \frac{\sigma}{4}\right) \geq 1 - \frac{16}{n}.$$

Now  $1 - 16/n \geq 0.99$  if and only if  $n \geq 1600$ .

- (b) As in part (b) of Exercise 9,

$$\Pr\left(|\bar{X}_n - \mu| \leq \frac{\sigma}{4}\right) = \Pr\left(|Z| \leq \frac{\sqrt{n}}{4}\right) = 2\Phi\left(\frac{\sqrt{n}}{4}\right) - 1.$$

Now  $2\Phi(\sqrt{n}/4) - 1 \geq 0.99$  if and only if  $\Phi(\sqrt{n}/4) \geq 0.995$ . This inequality will be satisfied if and only if  $\sqrt{n}/4 \geq 2.567$  or, equivalently,  $n \geq 105.4$ . Therefore, the smallest possible sample size is 106.

11. For a student chosen at random, the number of parents  $X$  who will attend the graduation ceremony has mean  $\mu = 0/3 + 1/3 + 2/3 = 1$  and variance  $\sigma^2 = E[(X - \mu)^2] = (0 - 1)^2/3 + (1 - 1)^2/3 + (2 - 1)^2/3 = 2/3$ . Therefore, the distribution of the total number of parents  $W$  who attend the ceremony will be approximately the normal distribution with mean  $(600)(1) = 600$  and variance  $600(2/3) = 400$ . Therefore, the distribution of  $Z = (W - 600)/20$  will be approximately a standard normal distribution. It follows that

$$\Pr(W \leq 650) = \Pr(Z \leq 2.5) = \Phi(2.5) = 0.9938.$$

12. The m.g.f. of the binomial distribution with parameters  $n$  and  $p_n$  is  $\psi_n(t) = (p_n \exp(t) + 1 - p_n)^n$ . If  $np_n \rightarrow \lambda$ ,

$$\lim_{n \rightarrow \infty} \psi_n(t) = \lim_{n \rightarrow \infty} \left(1 + \frac{np_n}{n} [\exp(t) - 1]\right)^n.$$

This converges to  $\exp(\lambda[e^t - 1])$ , which is the m.g.f. of the Poisson distribution with mean  $\lambda$ .

13. We are asking for the asymptotic distribution of  $g(\bar{X}_n)$ , where  $g(x) = x^3$ . The distribution of  $\bar{X}_n$  is normal with mean  $\theta$  and variance  $\sigma^2/n$ . According to the delta method, the asymptotic distribution of  $g(\bar{X}_n)$  should be the normal distribution with mean  $g(\theta) = \theta^3$  and variance  $(\sigma^2/n)[g'(\theta)]^2 = 9\theta^4\sigma^2/n$ .
14. First, note that  $Y_n = \sum_{i=1}^n X_i^2/n$  has asymptotically the normal distribution with mean  $\sigma^2$  and variance  $2\sigma^4/n$ . Here, we have used the fact that  $E(X_i^2) = \sigma^2$  and  $E(X_i^4) = 2\sigma^4$ .

- (a) Let  $g(x) = 1/x$ . Then  $g'(x) = -1/x^2$ . So, the asymptotic distribution of  $g(Y_n)$  is the normal distribution with mean  $1/\sigma^2$  and variance  $(2\sigma^4/n)/\sigma^8 = 2/[n\sigma^4]$ .
- (b) Let  $h(\mu) = 2\mu^2$ . If the asymptotic mean of  $Y_n$  is  $\mu$  the asymptotic variance of  $Y_n$  is  $h(\mu)/n$ . So, a variance stabilizing transformation is

$$\alpha(\mu) = \int_a^\mu \frac{dx}{2^{1/2}x} = \frac{1}{2^{1/2}} \log(\mu),$$

where we have taken  $a = 1$  to make the integral finite. So the asymptotic distribution of  $\log(Y_n)/2^{1/2}$  is the normal distribution with mean  $2\log(\sigma)/2^{1/2}$  and variance  $1/n$ .

15. (a) Clearly,  $Y_n \leq y$  if and only if  $X_i \leq y$  for  $i = 1, \dots, n$ . Hence,

$$\Pr(Y_n \leq y) = \Pr(X_1 \leq y)^n = \begin{cases} (y/\theta)^n & \text{if } 0 < y < \theta, \\ 0 & \text{if } y \leq 0, \\ 1 & \text{if } y \geq \theta. \end{cases}$$

- (b) The c.d.f. of  $Z_n$  is, for  $z < 0$ ,

$$\Pr(Z_n \leq z) = \Pr(Y_n \leq \theta + z/n) = (1 + z/[n\theta])^n. \quad (\text{S.6.9})$$

Since  $Z_n \leq 0$ , the c.d.f. is 1 for  $z \geq 0$ . According to Theorem 5.3.3, the expression in (S.6.9) converges to  $\exp(z/\theta)$ .

- (c) Let  $\alpha(y) = y^2$ . Then  $\alpha'(y) = 2y$ . We have  $n(Y_n - \theta)$  converging in distribution to the c.d.f. in part (b). The delta method says that, for  $\theta > 0$ ,  $n(Y_n^2 - \theta^2)/[2\theta]$  converges in distribution to the same c.d.f.

## 6.4 The Correction for Continuity

### Solutions to Exercises

1. The mean of  $X_i$  is 1 and the mean of  $X_i^2$  is 1.5. So, the variance of  $X_i$  is 0.5. The central limit theorem says that  $Y = X_1 + \dots + X_{30}$  has approximately the normal distribution with mean 30 and variance 15. We want the probability that  $Y \leq 33$ . Using the correction for continuity, we would assume that  $Y$  has the normal distribution with mean 30 and variance 15 and compute the probability that  $Y \leq 33.5$ . This is  $\Phi([33.5 - 30]/15^{1/2}) = \Phi(0.904) = 0.8169$ .

2. (a)  $E(X) = 15(.3) = 4.5$  and  $\sigma_X = [(15)(.3)(.7)]^{1/2} = 1.775$ . Therefore,

$$\begin{aligned}\Pr(X = 4) &= \Pr(3.5 \leq X \leq 4.5) = \Pr\left(\frac{3.5 - 4.5}{1.775} \leq Z \leq 0\right) \\ &= \Pr(-.5634 \leq Z \leq 0) \approx \Phi(.5634) - .5 \approx .214.\end{aligned}$$

- (b) The exact value is found from the table of binomial probabilities ( $n = 15$ ,  $p = 0.3$ ,  $k = 4$ ) to be .2186.

3. In the notation of Example 2,

$$\Pr(H > 495) = \Pr(H \geq 495.5) = \Pr\left(Z \geq \frac{495.5 - 450}{15}\right) \approx 1 - \Phi(3.033) \approx .0012.$$

4. We follow the notation of the solution to Exercise 2 of Sec. 6.3:

$$\Pr(X < 270) = \Pr(X \leq 269.5) = \Pr\left(Z \leq \frac{269.5 - 300}{15}\right) \approx 1 - \Phi(2.033) \approx .0210.$$

5. Let  $X$  denote the total number of defects in the sample. Then  $X$  has a Poisson distribution with mean  $5(125) = 625$ , so  $\sigma_X$  is  $(625)^{1/2} = 25$ . Hence,

$$\Pr(\bar{X}_n < 5.5) = \Pr[X < 125(5.5)] = \Pr(X < 687.5).$$

Since this final probability is just the value that would be used with the correction for continuity, the probability to be found here is the same as that originally found in Exercise 3 of Sec. 6.3.

6. We follow the notation of the solution to Exercise 6 of Sec. 6.3:

$$\Pr(X \geq 12) = \Pr(X \geq 11.5) = \Pr\left(Z \geq \frac{11.5 - 8}{2.51}\right) \approx 1 - \Phi(1.394) \approx .082.$$

7. Let  $S$  denote the sum of the 16 digits. Then

$$E(S) = 16(4.5) = 72 \quad \text{and} \quad \sigma_X = [16(8.25)]^{1/2} = 11.49.$$

Hence,

$$\begin{aligned}\Pr(4 \leq \bar{X}_n \leq 6) &= \Pr(64 \leq S \leq 96) = \Pr(63.5 \leq S \leq 96.5) \\ &= \Pr\left(\frac{63.5 - 72}{11.49} \leq Z \leq \frac{96.5 - 72}{11.49}\right) \\ &\approx \Phi(2.132) - \Phi(-.740) \approx .9835 - .2296 = .7539.\end{aligned}$$

## 6.5 Supplementary Exercises

### Solutions to Exercises

- By the central limit theorem, the distribution of  $X$  is approximately normal with mean  $(120)(1/6) = 20$  and standard deviation  $[120(1/6)(5/6)]^{1/2} = 4.082$ . Let  $Z = (X - 20)/4.082$ . Then from the table of the standard normal distribution we find that  $\Pr(|Z| \leq 1.96) = .95$ . Hence,  $k = (1.96)(4.082) = 8.00$ .
- Because of the property of the Poisson distribution described in Theorem 5.4.4, the random variable  $X$  can be thought of as the sum of a large number of i.i.d. random variables, each of which has a Poisson distribution. Hence, the central limit theorem (Lindeberg and Lévy) implies the desired result. It can also be shown that the m.g.f. of  $X$  converges to the m.g.f. of the standard normal distribution.
- By the previous exercise,  $X$  has approximately a normal distribution with mean 10 and standard deviation  $(10)^{1/2} = 3.162$ . Thus, without the correction for continuity,

$$\Pr(8 \leq X \leq 12) = \Pr\left(\frac{8 - 10}{3.162} \leq Z \leq \frac{12 - 10}{3.162}\right) \approx \Phi(.6325) - \Phi(-.6325) = .473.$$

With the correction for continuity, we find

$$\Pr(7.5 \leq X \leq 12.5) = \Pr\left(-\frac{2.5}{3.162} \leq Z \leq \frac{2.5}{3.162}\right) \approx \Phi(.7906) - \Phi(-.7906) = .571.$$

The exact probability is found from the Poisson table to be

$$(.1126) + (.1251) + (.1251) + (.1137) + (.0948) = .571.$$

Thus, the approximation with the correction for continuity is almost perfect.

- If  $X$  has p.d.f.  $f(x)$ , then

$$E(X^k) = \int_0^\infty x^k f(x) dx \geq \int_t^\infty x^k f(x) dx \geq t^k \int_t^\infty f(x) dx = t^k \Pr(X \geq t).$$

A similar proof holds if  $X$  has a discrete distribution.

- The central limit theorem says that  $\bar{X}_n$  has approximately the normal distribution with mean  $p$  and variance  $p(1-p)/n$ . A variance stabilizing transformation will be

$$\alpha(x) = \int_a^x [p(1-p)]^{-1/2} dp.$$

To perform this integral, transform to  $z = p^{1/2}$ , that is,  $p = z^2$ . Then

$$\alpha(x) = \int_{a^{1/2}}^{x^{1/2}} \frac{dz}{(1-z^2)^{1/2}}.$$

Next, transform so that  $z = \sin(w)$  or  $w = \arcsin(z)$ . Then  $dz = \cos(w)dw$  and

$$\alpha(x) = \int_{\arcsin a^{1/2}}^{\arcsin x^{1/2}} dw = \arcsin x^{1/2},$$

where we have chosen  $a = 0$ . The variance stabilizing transformation is  $\alpha(x) = \arcsin(x^{1/2})$ .

6. According to the central limit theorem,  $\bar{X}_n$  has approximately the normal distribution with mean  $\theta$  and variance  $\theta^2$ . A variance stabilizing transformation will be

$$\alpha(x) = \int_a^x \theta^{-1} d\theta = \log(x),$$

where we have used  $a = 1$ .

7. Let  $F_n$  be the c.d.f. of  $X_n$ . The most direct proof is to show that  $\lim_{n \rightarrow \infty} F_n(x) = F(x)$  for every point at which  $F$  is continuous. Since  $F$  is the c.d.f. of an integer-valued distribution, the continuity points are all non-integer values of  $x$  together with those integer values of  $x$  to which  $F$  assigns probability 0. It is clear, that it suffices to prove that  $\lim_{n \rightarrow \infty} F_n(x) = F(x)$  for every non-integer  $x$ , because continuity of  $F$  from the right and the fact that  $F$  is nondecreasing will take care of the integers with zero probability. For each non-integer  $x$ , let  $m_x$  be the largest integer such that  $m < x$ . Then

$$F_n(x) = \sum_{k=1}^m \Pr(X_n = k) \rightarrow \sum_{k=1}^m f(k) = F(m) = F(x),$$

where the convergence follows because the sums are finite.

8. We know that  $\Pr(X_n = m) = \binom{k}{m} p_n^m (1 - p_n)^{k-m}$  for  $m = 0, \dots, k$  and all  $n$ . We also know that

$$\lim_{n \rightarrow \infty} \binom{k}{m} p_n^m (1 - p_n)^{k-m} = \binom{k}{m} p^m (1 - p)^{k-m},$$

for all  $m$ . By Exercise 7,  $X_n$  converges in distribution to the binomial distribution with parameters  $k$  and  $p$ .

9. Let  $X_1, \dots, X_{16}$  be the times required to serve the 16 customers. The parameter of the exponential distribution is  $1/3$ . According to Theorem 5.7.8, the mean and variance of each  $X_i$  are 3 and 9 respectively. Let  $\sum_{k=1}^{16} X_k = Y$  be the total time. The central limit theorem approximation to the distribution of  $Y$  is the normal distribution with mean  $16 \times 3 = 48$  and variance  $16 \times 9 = 144$ . The approximate probability that  $Y > 60$  is

$$1 - \Phi\left(\frac{60 - 48}{(144)^{1/2}}\right) = 1 - \Phi(1) = 0.1587.$$

The actual distribution of  $Y$  is the gamma distribution with parameters 16 and  $1/3$ . Using the gamma c.d.f., the probability is 0.1565.

10. The number of defects in 2000 square-feet has the Poisson distribution with mean  $2000 \times 0.01 = 20$ . The central limit theorem approximation is the normal distribution with mean 20 and variance 20. Without correction for continuity, the approximate probability of at least 15 defects is

$$1 - \Phi\left(\frac{15 - 20}{(20)^{1/2}}\right) = 1 - \Phi(-1.1180) = 0.8682.$$

With the continuity correction, we get

$$1 - \Phi\left(\frac{14.5 - 20}{(20)^{1/2}}\right) = 1 - \Phi(-1.2298) = 0.8906.$$

The actual Poisson probability is 0.8951.

11. (a) The gamma distribution with parameters  $n$  and 3 is the distribution of the sum of  $n$  i.i.d. exponential random variables with parameter 3. If  $n$  is large, the central limit theorem should apply to approximate the distribution of the sum of  $n$  exponentials.  
(b) The mean and variance of each exponential random variable are  $1/3$  and  $1/9$  respectively. The distribution of the sum of  $n$  of these has approximately the normal distribution with mean  $n/3$  and variance  $n/9$ .
12. (a) The exponential distribution with parameters  $n$  and 0.2 is the distribution of the sum of  $n$  i.i.d. geometric random variables with parameter 0.2. If  $n$  is large, the central limit theorem should apply to approximate the distribution of the sum of  $n$  geometrics.  
(b) The mean and variance of each geometric random variable are  $0.8/0.2 = 4$  and  $0.8/(0.2)^2 = 20$ . The distribution of the sum of  $n$  of these has approximately the normal distribution with mean  $4n$  and variance  $20n$ .

## Estimation

### 7.1 Statistical Inference

#### Commentary

Many students find statistical inference much more difficult to comprehend than elementary probability theory. For this reason, many examples of statistical inference problems have been introduced in the early chapters of this text. This will give instructors the opportunity to point back to relatively easy-to-understand examples that the students have already learned as a preview of what is to come. In addition to the examples mentioned in Sec. 7.1, some additional examples are Examples 2.3.3–2.3.5, 3.6.9, 3.7.14, 3.7.18, 4.8.9–4.8.10, and 5.8.1–5.8.2. In addition, the discussion of M.S.E. and M.A.E. in Sec. 4.5 and the discussion of the variance of the sample mean in Sec. 6.2 contain inferential ideas. Most of these are examples of Bayesian inference because the most common part of a Bayesian inference is the calculation of a conditional distribution or a conditional mean.

#### Solutions to Exercises

1. The random variables of interest are the observables  $X_1, X_2, \dots$  and the hypothetically observable (parameter)  $P$ . The  $X_i$ 's are i.i.d. Bernoulli with parameter  $p$  given  $P = p$ .
2. The statistical inferences mentioned in Example 7.1.3 are computing the conditional distribution of  $P$  given observed data, computing the conditional mean of  $P$  given the data, and computing the M.S.E. of predictions of  $P$  both before and after observing data.
3. The random variables of interest are the observables  $Z_1, Z_2, \dots$ , the times at which successive particles hit the target, and  $\beta$ , the hypothetically observable (parameter) rate of the Poisson process. The hit times occur according to a Poisson process with rate  $\beta$  conditional on  $\beta$ . Other random variables of interest are the observable inter-arrival times  $Y_1 = Z_1$ , and  $Y_k = Z_k - Z_{k-1}$  for  $k \geq 2$ .
4. The random variables of interest are the observable heights  $X_1, \dots, X_n$ , the hypothetically observable mean (parameter)  $\mu$ , and the sample mean  $\bar{X}_n$ . The  $X_i$ 's are modeled as normal random variables with mean  $\mu$  and variance 9 given  $\mu$ .
5. The statement that the interval  $(\bar{X}_n - 0.98, \bar{X}_n + 0.98)$  has probability 0.95 of containing  $\mu$  is an inference.
6. The random variables of interest are the observable number  $X$  of Mexican-American grand jurors and the hypothetically observable (parameter)  $P$ . The conditional distribution of  $X$  given  $P = p$  is the

binomial distribution with parameters 220 and  $p$ . Also,  $P$  has the beta distribution with parameters  $\alpha$  and  $\beta$ , which have not yet been specified.

- The random variables of interest are  $Y$ , the hypothetically observable number of oocysts in  $t$  liters, the hypothetically observable indicators  $X_1, X_2, \dots$  of whether each oocyst is counted,  $X$  the observable count of oocysts, the probability (parameter)  $p$  of each oocyst being counted, and the (parameter)  $\lambda$  the rate of oocysts per liter. We model  $Y$  as a Poisson random variable with mean  $t\lambda$  given  $\lambda$ . We model  $X_1, \dots, X_y$  as i.i.d. Bernoulli random variables with parameter  $p$  given  $p$  and given  $Y = y$ . We define  $X = X_1 + \dots + X_y$ .

## 7.2 Prior and Posterior Distributions

### Commentary

This section introduces some common terminology that is used in Bayesian inference. The concepts should all be familiar already to the students under other names. The prior distribution is just a marginal distribution while the posterior distribution is just a conditional distribution. The likelihood function might seem strange since it is a conditional density for the data given  $\theta$  but thought of as a function of  $\theta$  after the data have been observed.

### Solutions to Exercises

- We still have  $y = 16178$ , the sum of the five observed values. The posterior distribution of  $\beta$  is now the gamma distribution with parameters 6 and 21178. So,

$$\begin{aligned} f(x_6 | \mathbf{x}) &= \int_0^\infty 7.518 \times 10^{23} \beta^5 \exp(-21178\beta) \beta \exp(-x_6\beta) d\beta \\ &= 7.518 \times 10^{23} \int_0^\infty \beta^6 \exp(-\beta[21178 + x_6]) d\beta \\ &= 7.518 \times 10^{23} \frac{\Gamma(7)}{(21178 + x_6)^7} = \frac{5.413 \times 10^{26}}{(21178 + x_6)^7}, \end{aligned}$$

for  $x_6 > 0$ . We can now compute  $\Pr(X_6 > 3000 | \mathbf{x})$  as

$$\Pr(X_6 > 3000 | \mathbf{x}) = \int_{3000}^\infty \frac{5.413 \times 10^{26}}{(21178 + x_6)^7} dx_6 = \frac{5.413 \times 10^{26}}{6 \times 24178^6} = 0.4516.$$

- The joint p.f. of the eight observations is given by Eq. (7.2.11). Since  $n = 8$  and  $y = 2$  in this exercise,

$$f_n(\mathbf{x} | \theta) = \theta^2(1 - \theta)^6.$$

Therefore,

$$\begin{aligned} \xi(0.1 | \mathbf{x}) = \Pr(\theta = 0.1 | \mathbf{x}) &= \frac{\xi(0.1)f_n(\mathbf{x} | 0.1)}{\xi(0.1)f_n(\mathbf{x} | 0.1) + \xi(0.2)f_n(\mathbf{x} | 0.2)} \\ &= \frac{(0.7)(0.1)^2(0.9)^6}{(0.7)(0.1)^2(0.9)^6 + (0.3)(0.2)^2(0.8)^6} \\ &= 0.5418. \end{aligned}$$

It follows that  $\xi(0.2 | \mathbf{x}) = 1 - \xi(0.1 | \mathbf{x}) = 0.4582$ .

3. Let  $X$  denote the number of defects on the selected roll of tape. Then for any given value of  $\lambda$ , the p.f. of  $X$  is.

$$f(x | \lambda) = \frac{\exp(-\lambda)\lambda^x}{x!} \quad \text{for } x = 0, 1, 2, \dots$$

Therefore,

$$\xi(1.0 | X = 3) = \Pr(\lambda = 1.0 | X = 3) = \frac{\xi(1.0)f(3 | 1.0)}{\xi(1.0)f(3 | 1.0) + \xi(1.5)f(3 | 1.5)}.$$

From the table of the Poisson distribution in the back of the book it is found that

$$f(3 | 1.0) = 0.0613 \quad \text{and} \quad f(3 | 1.5) = 0.1255.$$

Therefore,  $\xi(1.0 | X = 3) = 0.2456$  and  $\xi(1.5 | X = 3) = 1 - \xi(1.0 | X = 3) = 0.7544$ .

4. If  $\alpha$  and  $\beta$  denote the parameters of the gamma distribution, then we must have

$$\frac{\alpha}{\beta} = 10 \quad \text{and} \quad \frac{\alpha}{\beta^2} = 5.$$

Therefore,  $\alpha = 20$  and  $\beta = 2$ . Hence, the prior p.d.f. of  $\theta$  is as follows, for  $\theta > 0$ :

$$\xi(\theta) = \frac{2^{20}}{\Gamma(20)} \theta^{19} \exp(-2\theta).$$

5. If  $\alpha$  and  $\beta$  denote the parameters of the beta distribution, then we must have

$$\frac{\alpha}{\alpha + \beta} = \frac{1}{3} \quad \text{and} \quad \frac{\alpha\beta}{(\alpha + \beta)^2(\alpha + \beta + 1)} = \frac{2}{90}.$$

Since  $\frac{\alpha}{\alpha + \beta} = \frac{1}{3}$ , it follows that  $\frac{\beta}{\alpha + \beta} = \frac{2}{3}$ . Therefore,

$$\frac{\alpha\beta}{(\alpha + \beta)^2} = \frac{\alpha}{\alpha + \beta} \cdot \frac{\beta}{\alpha + \beta} = \frac{1}{3} \cdot \frac{2}{3} = \frac{2}{9}.$$

It now follows from the second equation that  $\frac{2}{9(\alpha + \beta + 1)} = \frac{2}{90}$  and, hence, that  $\alpha + \beta + 1 = 10$ . Therefore,  $\alpha + \beta = 9$  and it follows from the first equation that  $\alpha = 3$  and  $\beta = 6$ . Hence, the prior p.d.f. of  $\theta$  is as follows, for  $0 < \theta < 1$ :

$$\xi(\theta) = \frac{\Gamma(9)}{\Gamma(3)\Gamma(6)} \theta^2(1 - \theta)^5.$$

6. The conditions of this exercise are precisely the conditions of Example 7.2.7 with  $n = 8$  and  $y = 3$ . Therefore, the posterior distribution of  $\theta$  is a beta distribution with parameters  $\alpha = 4$  and  $\beta = 6$ .
7. Since  $f_n(\mathbf{x} | \theta)$  is given by Eq. (7.2.11) with  $n = 8$  and  $y = 3$ , then

$$f_n(\mathbf{x} | \theta)\xi(\theta) = 2\theta^3(1 - \theta)^6.$$

When we compare this expression with Eq. (5.8.3), we see that it has the same form as the p.d.f. of a beta distribution with parameters  $\alpha = 4$  and  $\beta = 7$ . Therefore, this beta distribution is the posterior distribution of  $\theta$ .

8. By Eq. (7.2.14),

$$\xi(\theta | x_1) \propto f(x_1 | \theta) \xi(\theta),$$

and by Eq. (7.2.15),

$$\xi(\theta | x_1, x_2) \propto f(x_2 | \theta) \xi(\theta | x_1).$$

Hence,

$$\xi(\theta | x_1, x_2) \propto f(x_1 | \theta) f(x_2 | \theta) \xi(\theta).$$

By continuing in this way, we find that

$$\xi(\theta | x_1, x_2, x_3) \propto f(x_3 | \theta) \xi(\theta | x_1, x_2) \propto f(x_1 | \theta) f(x_2 | \theta) f(x_3 | \theta) \xi(\theta).$$

Ultimately, we will find that

$$\xi(\theta | x_1, \dots, x_n) \propto f(x_1 | \theta) \dots f(x_n | \theta) \xi(\theta).$$

From Eq. (7.2.4) it follows that, in vector notation, this relation can be written as

$$\xi(\theta | \mathbf{x}) \propto f_n(\mathbf{x} | \theta) \xi(\theta),$$

which is precisely the relation (7.2.10). Hence, when the appropriate factor is introduced on the right side of this relation so that the proportionality symbol can be replaced by an equality,  $\xi(\theta | \mathbf{x})$  will be equal to the expression given in Eq. (7.2.7).

9. It follows from Exercise 8 that if the experiment yields a total of three defectives and five nondefectives, the posterior distribution will be the same regardless of whether the eight items were selected in one batch or one at a time in accordance with some stopping rule. Therefore, the posterior distribution in this exercise will be the same beta distribution as that obtained in Exercise 6.

10. In this exercise

$$f(x|\theta) = \begin{cases} 1 & \text{for } \theta - \frac{1}{2} < x < \theta + \frac{1}{2}, \\ 0 & \text{otherwise,} \end{cases}$$

and

$$\xi(\theta) = \begin{cases} \frac{1}{10} & \text{for } 10 < \theta < 20, \\ 0 & \text{otherwise.} \end{cases}$$

The condition that  $\theta - 1/2 < x < \theta + 1/2$  is the same as the condition that  $x - 1/2 < \theta < x + 1/2$ . Therefore,  $f(x | \theta) \xi(\theta)$  will be positive only for values of  $\theta$  which satisfy both the requirement that  $x - 1/2 < \theta < x + 1/2$  and the requirement that  $10 < \theta < 20$ . Since  $X = 12$  in this exercise,  $f(x | \theta) \xi(\theta)$  is positive only for  $11.5 < \theta < 12.5$ . Furthermore, since  $f(x | \theta) \xi(\theta)$  is constant over this interval, the posterior p.d.f.  $\xi(\theta | x)$  will also be constant over this interval. In other words, the posterior distribution of  $\theta$  must be a uniform distribution on this interval.

11. Let  $y_1$  denote the smallest and let  $y_6$  denote the largest of the six observations. Then the joint p.d.f. of the six observations is

$$f_n(\mathbf{x} | \theta) = \begin{cases} 1 & \text{for } \theta - \frac{1}{2} < y_1 < y_6 < \theta + \frac{1}{2}, \\ 0 & \text{otherwise.} \end{cases}$$

The condition that  $\theta - \frac{1}{2} < y_1 < y_6 < \theta + \frac{1}{2}$  is the same as the condition that  $y_6 - 1/2 < \theta < y_1 + 1/2$ . Since  $\xi(\theta)$  is again as given in Exercise 10, it follows that  $f_n(\mathbf{x} | \theta)\xi(\theta)$  will be positive only for values of  $\theta$  which satisfy both the requirement that  $10 < \theta < 20$ . Since  $y_1 = 10.9$  and  $y_6 = 11.7$  in this exercise,  $f_n(\mathbf{x} | \theta)\xi(\theta)$  is positive only for  $y_6 - 1/2 < \theta < y_1 + 1/2$  and the requirement that  $10 < \theta < 20$ . Since  $y_1 = 10.9$  and  $y_6 = 11.7$  in this exercise,  $f_n(\mathbf{x} | \theta)\xi(\theta)$  is positive only for  $11.2 < \theta < 11.4$ . Furthermore, since  $f_n(\mathbf{x} | \theta)\xi(\theta)$  is constant over this interval, the posterior p.d.f.  $\xi(\theta | \mathbf{x})$  will also be constant over the interval. In other words, the posterior distribution of  $\theta$  must be a uniform distribution on this interval.

## 7.3 Conjugate Prior Distributions

### Commentary

This section introduces some convenient prior distributions that make Bayesian inferences mathematically tractable. The instructor can remind the student that numerical methods are available for performing Bayesian inferences even when other prior distributions are used. Mathematical tractability is useful when introducing a new concept so that attention can focus on the meaning and interpretation of the new concept rather than the numerical methods required to perform the calculations. Although conjugate priors for the parameter of the uniform distribution are not discussed in the body of the section, Exercises ‘17 and 18 illustrate how the general concept extends to these distributions.

### Solutions to Exercises

1. The posterior mean of  $\theta$  will be

$$\frac{100 \times 0 + 20v^2 \times 0.125}{100 + 20v^2} = 0.12.$$

We can solve this equation for  $v^2$  by multiplying both sides by  $100 + 20v^2$  and collecting terms. The result is  $v^2 = 120$ .

2. If we let  $\gamma = (y + 1)(y + z + 2)$ , then  $1 - \gamma = (z + 1)(y + z + 2)$  and  $V = \gamma(1 - \gamma)/(y + z + 3)$ . The maximum value of  $\gamma(1 - \gamma)$  is  $1/4$ , and is attained when  $\gamma = 1/2$ . Therefore,  $V \leq 1/[4(y + z + 3)]$ . It now follows that if  $1/[4(y + z + 3)] \leq 0.01$ , then  $V \leq 0.01$ . But the first inequality will be satisfied if  $y + z \geq 22$ . Since  $y + z$  is the total number of items that have been selected, it follows that this number need not exceed 22.
3. Since the observed number of defective items is 3 and the observed number of nondefective items is 97, it follows from Theorem 7.3.1 that the posterior distribution of  $\theta$  is a beta distribution with parameters  $2 + 3 = 5$  and  $200 + 97 = 297$ .

4. Let  $\alpha_1$  and  $\beta_1$  denote the parameters of the posterior beta distribution, and let  $\gamma = \alpha_1/(\alpha_1 + \beta_1)$ . Then  $\gamma$  is the mean of the posterior distribution and we are told that  $\gamma = 2/51$ . The variance of the posterior distribution is

$$\begin{aligned}\frac{\alpha_1\beta_1}{(\alpha_1 + \beta_1)^2(\alpha_1 + \beta_1 + 1)} &= \frac{\alpha_1}{\alpha_1 + \beta_1} \cdot \frac{\beta_1}{\alpha_1 + \beta_1} \cdot \frac{1}{\alpha_1 + \beta_1 + 1} \\ &= \gamma(1 - \gamma) \frac{1}{\alpha_1 + \beta_1 + 1} \\ &= \frac{2}{51} \cdot \frac{49}{51} \cdot \frac{1}{\alpha_1 + \beta_1 + 1} = \frac{98}{(51)^2} \cdot \frac{1}{\alpha_1 + \beta_1 + 1}.\end{aligned}$$

From the value of this variance given in the exercise it is now evident that  $\alpha_1 + \beta_1 + 1 = 103$ . Hence,  $\alpha_1 + \beta_1 = 102$  and  $\alpha_1 = \gamma(\alpha_1 + \beta_1) = 2(102)/51 = 4$ . In turn, it follows that  $\beta_1 = 102 - 4 = 98$ . Since the posterior distribution is a beta distribution, it follows from Theorem 7.3.1 that the prior distribution must have been a beta distribution with parameters  $\alpha$  and  $\beta$  such that  $\alpha + 3 = \alpha_1$  and  $\beta + 97 = \beta_1$ . Therefore,  $\alpha = \beta = 1$ . But the beta distribution for which  $\alpha = \beta = 1$  is the uniform distribution on the interval  $[0,1]$ .

5. By Theorem 7.3.2, the posterior distribution will be the gamma distribution for which the parameters are  $3 + \sum_{i=1}^n x_i = 3 + 13 = 16$  and  $1 + n = 1 + 5 = 6$ .
6. The number of defects on a 1200-foot roll of tape has the same distribution as the total number of defects on twelve 100-foot rolls, and it is assumed that the number of defects on a 100-foot roll has the Poisson distribution with mean  $\theta$ . By Theorem 7.3.2, the posterior distribution of  $\theta$  is the gamma distribution for which the parameters are  $2 + 4 = 6$  and  $10 + 12 = 22$ .
7. In the notation of Theorem 7.3.3, we have  $\sigma^2 = 4$ ,  $\mu = 68$ ,  $v^2 = 1$ ,  $n = 10$ , and  $\bar{x}_n = 69.5$ . Therefore, the posterior distribution of  $\theta$  is the normal distribution with mean  $\mu_1 = 967/14$  and variance  $v_1^2 = 2/7$ .
8. Since the p.d.f. of a normal distribution attains its maximum value at the mean of the distribution and then drops off on each side of the mean, among all intervals of length 1 unit, the interval that is centered at the mean will contain the most probability. Therefore, the answer in part (a) is the interval centered at the mean of the prior distribution of  $\theta$  and the answer in part (b) is the interval centered at the mean of the posterior distribution of  $\theta$ . In part (c), if the distribution of  $\theta$  is specified by its prior distribution, then  $Z = \theta - 68$  will have a standard normal distribution. Therefore,

$$\Pr(67.5 \leq \theta \leq 68.5) = \Pr(-0.5 \leq Z \leq 0.5) = 2\Phi(0.5) - 1 = 0.3830.$$

Similarly, if the distribution of  $\theta$  is specified by its posterior distribution, then  $Z = (\theta - \mu_1)/v_1 = (\theta - 69.07)/0.5345$  will have a standard normal distribution. Therefore,

$$\begin{aligned}\Pr(68.57 \leq \theta \leq 69.57 | \theta) &= \Pr(-0.9355 \leq Z \leq 0.9355) \\ &= 2\Phi(0.9355) - 1 = 0.6506.\end{aligned}$$

9. Since the posterior distribution of  $\theta$  is normal, the prior distribution of  $\theta$  must also have been normal. Furthermore, from Eqs. (7.3.1) and (7.3.2), we obtain the relations:

$$8 = \frac{\mu + (20)(10)v^2}{1 + 20v^2}$$

and

$$\frac{1}{25} = \frac{v^2}{1 + 20v^2}.$$

It follows that  $v^2 = 1/5$  and  $\mu = 0$ .

10. In this exercise,  $\sigma^2 = 4$  and  $v^2 = 1$ . Therefore, by Eq. (7.3.2)

$$v_1^2 = \frac{4}{4+n}.$$

It follows that  $v_1^2 \leq 0.01$  if and only if  $n \geq 396$ .

11. In this exercise,  $\sigma^2 = 4$  and  $n = 100$ . Therefore, by Eq. (7.3.2),

$$v_1^2 = \frac{4v^2}{4 + 100v^2} = \frac{1}{25 + (1/v^2)} < \frac{1}{25}.$$

Since the variance of the posterior distribution is less than  $1/25$ , the standard deviation must be less than  $1/5$ .

12. Let  $\alpha$  and  $\beta$  denote the parameters of the prior gamma distribution of  $\theta$ . Then  $\alpha/\beta = 0.2$  and  $\alpha/\beta^2 = 1$ . Therefore,  $\beta = 0.2$  and  $\alpha = 0.04$ . Furthermore, the total time required to serve the sample of 20 customers is  $y = 20(3.8) = 76$ . Therefore, by Theorem 7.3.4, the posterior distribution of  $\theta$  is the gamma distribution for which the parameters are  $0.04 + 20 = 20.04$  and  $0.2 + 76 = 76.2$ .
13. The mean of the gamma distribution with parameters  $\alpha$  and  $\beta$  is  $\alpha/\beta$  and the standard deviation is  $\alpha^{1/2}/\beta$ . Therefore, the coefficient of variation is  $\alpha^{-1/2}$ . Since the coefficient of variation of the prior gamma distribution of  $\theta$  is 2, it follows that  $\alpha = 1/4$  in the prior distribution. Furthermore, it now follows from Theorem 7.3.4 that the coefficient of variation of the posterior gamma distribution of  $\theta$  is  $(\alpha + n)^{-1/2} = (n + 1/4)^{-1/2}$ . This value will be less than 0.1 if and only if  $n \geq 99.75$ . Thus, the required sample size is  $n \geq 100$ .
14. Consider a single observation  $X$  from a negative binomial distribution with parameters  $r$  and  $p$ , where the value of  $r$  is known and the value of  $p$  is unknown. Then the p.f. of  $X$  has the form  $f(x | p) \propto p^r q^x$ . If the prior distribution of  $p$  is the beta distribution with parameters  $\alpha$  and  $\beta$ , then the prior p.d.f.  $\xi(p)$  has the form  $\xi(p) \propto p^{\alpha-1} q^{\beta-1}$ . Therefore, the posterior p.d.f.  $\xi(p | x)$  has the form

$$\xi(p | x) \propto \xi(p) f(p | x) \propto p^{\alpha+r-1} q^{\beta+x-1}.$$

This expression can be recognized as being, except for a constant factor, the p.d.f. of the beta distribution with parameters  $\alpha + r$  and  $\beta + x$ . Since this distribution will be the prior distribution of  $p$  for future observations, it follows that the posterior distribution after any number of observations will also be a beta distribution.

15. (a) Let  $y = 1/\theta$ . Then  $\theta = 1/y$  and  $d\theta = -dy/y^2$ . Hence,

$$\int_0^\infty \xi(\theta) d\theta = \int_0^\infty \frac{\beta^\alpha}{\Gamma(\alpha)} y^{\alpha-1} \exp(-\beta y) dy = 1.$$

- (b) If an observation  $X$  has a normal distribution with a known value of the mean  $\mu$  and an unknown value of the variance  $\theta$ , then the p.d.f. of  $X$  has the form

$$f(x | \theta) \propto \frac{1}{\theta^{1/2} \exp \left[ -\frac{(x-\mu)^2}{2\theta} \right]}.$$

Also, the prior p.d.f. of  $\theta$  has the form

$$\xi(\theta) \propto \theta^{-(\alpha+1)} \exp(-\beta/\theta).$$

Therefore, the posterior p.d.f.  $\xi(\theta | x)$  has the form

$$\xi(\theta | x) \propto \xi(\theta) f(x | \theta) \propto \theta^{-(\alpha+3/2)} \exp \left\{ -\left[ \beta + \frac{1}{2}(x-\mu)^2 \right] \cdot \frac{1}{\theta} \right\}.$$

Hence, the posterior p.d.f. of  $\theta$  has the same form as  $\xi(\theta)$  with  $\alpha$  replaced by  $\alpha + 1/2$  and  $\beta$  replaced by  $\beta + 1/2(x-\mu)^2$ . Since this distribution will be the prior distribution of  $\theta$  for future observations, it follows that the posterior distribution after any number of observations will also belong to the same family of distributions.

16. If  $X$  has the normal distribution with a known value of the mean  $\mu$  and an unknown value of the standard deviation  $\sigma$ , then the p.d.f. of  $X$  has the form

$$f(x | \sigma) \propto \frac{1}{\sigma} \exp \left[ -\frac{(x-\mu)^2}{2\sigma^2} \right].$$

Therefore, if the prior p.d.f.  $\xi(\sigma)$  has the form

$$\xi(\sigma) \propto \sigma^{-a} \exp(-b/\sigma^2),$$

then the posterior p.d.f. of  $\sigma$  will also have the same form, with  $a$  replaced by  $a + 1$  and  $b$  replaced by  $b + (x-\mu)^2/2$ . It remains to determine the precise form of  $\xi(\sigma)$ . If we let  $y = 1/\sigma^2$ , then  $\sigma = y^{-1/2}$  and  $d\sigma = -dy/(2y^{3/2})$ . Therefore,

$$\int_0^\infty \sigma^{-a} \exp(-b/\sigma^2) d\sigma = \frac{1}{2} \int_0^\infty y^{(a-3)/2} \exp(-by) dy.$$

The integral will be finite if  $a > 1$  and  $b > 0$ , and its value will be

$$\frac{\Gamma \left[ \frac{1}{2}(a-1) \right]}{b^{(a-1)/2}}.$$

Hence, for  $a > 1$  and  $b > 0$ , the following function will be a p.d.f. for  $\sigma > 0$ :

$$\xi(\sigma) = \frac{2b^{(a-1)/2}}{\Gamma \left[ \frac{1}{2}(a-1) \right]} \sigma^{-a} \exp(-b/\sigma^2).$$

Finally, we can obtain a more standard form for this p.d.f. by replacing  $a$  and  $b$  by  $\alpha = (a-1)/2$  and  $\beta = b$ . Then

$$\xi(\sigma) = \frac{2\beta^\alpha}{\Gamma(\alpha)} \sigma^{-(2\alpha+1)} \exp(-\beta/\sigma^2) \quad \text{for } \sigma > 0.$$

The family of distributions for which the p.d.f. has this form, for all values of  $\alpha > 0$  and  $\beta > 0$ , will be a conjugate family of prior distributions.

17. The joint p.d.f. of the three observations is

$$f(x_1, x_2, x_3 | \theta) = \begin{cases} 1/\theta^3 & \text{for } 0 < x_i < \theta \ (i = 1, 2, 3), \\ 0 & \text{otherwise.} \end{cases}$$

Therefore, the posterior p.d.f.  $\xi(\theta | x_1, x_2, x_3)$  will be positive only if  $\theta \geq 4$ , as required by the prior p.d.f., and also  $\theta > 8$ , the largest of the three observed values. Hence, for  $\theta > 8$ ,

$$\xi(\theta | x_1, x_2, x_3) \propto \xi(\theta) f(x_1, x_2, x_3 | \theta) \propto 1/\theta^7.$$

Since

$$\int_8^\infty \frac{1}{\theta^7} d\theta = \frac{1}{6(8)^6},$$

it follows that

$$\xi(\theta | x_1, x_2, x_3) = \begin{cases} 6(8^6)/\theta^7 & \text{for } \theta > 8 \\ 0 & \text{for } \theta \leq 8. \end{cases}$$

18. Suppose that the prior distribution of  $\theta$  is the Pareto distribution with parameters  $x_0$  and  $\alpha$  ( $x_0 > 0$  and  $\alpha > 0$ ). Then the prior p.d.f.  $\xi(\theta)$  has the form

$$\xi(\theta) \propto 1/\theta^{\alpha+1} \quad \text{for } \theta \geq x_0.$$

If  $X_1, \dots, X_n$  form a random sample from a uniform distribution on the interval  $[0, \theta]$ , then

$$f_n(\mathbf{x} | \theta) \propto 1/\theta^n \quad \text{for } \theta > \max\{x_1, \dots, x_n\}.$$

Hence, the posterior p.d.f. of  $\theta$  has the form

$$\xi(\theta | \mathbf{x}) \propto \xi(\theta) f_n(\mathbf{x} | \theta) \propto 1/\theta^{\alpha+n+1},$$

for  $\theta > \max\{x_0, x_1, \dots, x_n\}$ , and  $\xi(\theta | \mathbf{x}) = 0$  for  $\theta \leq \max\{x_0, x_1, \dots, x_n\}$ . This posterior p.d.f. can now be recognized as also being the Pareto distribution with parameters  $\alpha+n$  and  $\max\{x_0, x_1, \dots, x_n\}$ .

*Commentary:* Exercise 17 provides a numerical illustration of the general result presented in Exercise 18.

19. The joint p.d.f. of  $X_1, \dots, X_n$  has the following form, for  $0 < x_i < 1$  ( $i = 1, \dots, n$ ):

$$\begin{aligned} f_n(\mathbf{x} | \theta) &= \theta^n \left( \prod_{i=1}^n x_i \right)^{\theta-1} \propto \theta^n \left( \prod_{i=1}^n x_i \right)^\theta \\ &= \theta^n \exp \left( \theta \sum_{i=1}^n \log x_i \right). \end{aligned}$$

The prior p.d.f. of  $\theta$  has the form

$$\xi(\theta) \propto \theta^{\alpha-1} \exp(-\beta\theta).$$

Hence, the posterior p.d.f. of  $\theta$  has the form

$$\xi(\theta | \mathbf{x}) \propto \xi(\theta) f_n(\mathbf{x} | \theta) \propto \theta^{\alpha+n-1} \exp \left[ -\left( \beta - \sum_{i=1}^n \log x_i \right) \theta \right].$$

This expression can be recognized as being, except for a constant factor, the p.d.f. of the gamma distribution with parameters  $\alpha_1 = \alpha + n$  and  $\beta_1 = \beta - \sum_{i=1}^n \log x_i$ . Therefore, the mean of the posterior distribution is  $\alpha_1/\beta_1$  and the variance is  $\alpha_1/\beta_1^2$ .

20. The mean lifetime conditional on  $\beta$  is  $1/\beta$ . The mean lifetime is then the mean of  $1/\beta$ . Prior to observing the data, the distribution of  $\beta$  is the gamma distribution with parameters  $a$  and  $b$ , so the mean of  $1/\beta$  is  $b/(a-1)$  according to Exercise 21 in Sec. 5.7. After observing the data, the distribution of  $\beta$  is the gamma distribution with parameters  $a+10$  and  $b+60$ , so the mean of  $1/\beta$  is  $(b+60)/(a+9)$ . So, we must solve the following equations:

$$\begin{aligned} \frac{b}{a-1} &= 4, \\ \frac{b+60}{a+9} &= 5. \end{aligned}$$

These equations convert easily to the equations  $b = 4a - 4$  and  $b = 5a - 15$ . So  $a = 11$  and  $b = 40$ .

21. The posterior p.d.f. is proportional to the likelihood  $\theta^n \exp \left( -\theta \sum_{i=1}^n x_i \right)$  times  $1/\theta$ . This product can be written as  $\theta^{n-1} \exp(-\theta n \bar{x}_n)$ . As a function of  $\theta$  this is recognizable as the p.d.f. of the gamma distribution with parameters  $n$  and  $n \bar{x}_n$ . The mean of this posterior distribution is then  $n/[n \bar{x}_n] = 1/\bar{x}_n$ .
22. The posterior p.d.f. is proportional to the likelihood since the prior “p.d.f.” is constant. The likelihood is proportional to

$$\exp \left[ -\frac{20}{2 \times 60} (\theta - (-0.95))^2 \right],$$

using the same reasoning as in the proof of Theorem 7.3.3 of the text. As a function of  $\theta$  this is easily recognized as being proportional to the p.d.f. of the normal distribution with mean  $-0.95$  and variance  $60/20 = 3$ . The posterior probability that  $\theta > 1$  is then

$$1 - \Phi \left( \frac{1 - (-0.95)}{3^{1/2}} \right) = 1 - \Phi(1.126) = 0.1301.$$

23. (a) Let the prior p.d.f. of  $\theta$  be  $\xi_{\alpha, \beta}(\theta)$ . Suppose that  $X_1, \dots, X_n$  are i.i.d. with conditional p.d.f.  $f(x|\theta)$  given  $\theta$ , where  $f$  is as stated in the exercise. The posterior p.d.f. after observing these data is

$$\xi(\theta | \mathbf{x}) = \frac{a(\theta)^{\alpha+n} \exp \left[ c(\theta) \left\{ \beta + \sum_{i=1}^n d(x_i) \right\} \right]}{\int_{\Omega} a(\theta)^{\alpha+n} \exp \left[ c(\theta) \left\{ \beta + \sum_{i=1}^n d(x_i) \right\} \right] d\theta}. \quad (\text{S.7.1})$$

Eq. (S.7.1) is of the form of  $\xi_{\alpha', \beta'}(\theta)$  with  $\alpha' = \alpha + n$  and  $\beta' = \beta + \sum_{i=1}^n d(x_i)$ . The integral in the denominator of (S.7.1) must be finite with probability 1 (as a function of  $x_1, \dots, x_n$ ) because  $\prod_{i=1}^n b(x_i)$  times this denominator is the marginal (joint) p.d.f. of  $X_1, \dots, X_n$ .

- (b) This was essentially the calculation done in part (a).

24. In each part of this exercise we shall first present the p.d.f. or the p.f.  $f$ , and then we shall identify the functions  $a$ ,  $b$ ,  $c$ , and  $d$  in the form for an exponential family given in Exercise 23.

(a)  $f(x | p) = p^x(1-p)^{1-x} = (1-p) \left(\frac{p}{1-p}\right)^x$ . Therefore,  $a(p) = 1-p$ ,  $b(x) = 1$ ,  $c(p) = \log\left(\frac{p}{1-p}\right)$ ,  $d(x) = x$ .

(b)  $f(x | \theta) = \frac{\exp(-\theta)\theta^x}{x!}$ . Therefore,  $a(\theta) = \exp(-\theta)$ ,  $b(x) = 1/x!$ ,  $c(\theta) = \log \theta$ ,  $d(x) = x$ .

(c)  $f(x | p) = \binom{r+x-1}{x} p^r (1-p)^x$ . Therefore,  $a(p) = p^r$ ,  $b(x) = \binom{r+x-1}{x}$ ,  $c(p) = \log(1-p)$ ,  $d(x) = x$ .

(d)

$$\begin{aligned} f(x | \mu) &= \frac{1}{(2\pi\sigma^2)^{1/2}} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] \\ &= \frac{1}{(2\pi\sigma^2)^{1/2}} \exp\left(-\frac{x^2}{2\sigma^2}\right) \exp\left(-\frac{\mu^2}{2\sigma^2}\right) \exp\left(\frac{\mu x}{\sigma^2}\right). \end{aligned}$$

Therefore,  $a(\mu) = \frac{1}{(2\pi\sigma^2)^{1/2}} \exp(-\frac{\mu^2}{2\sigma^2})$ ,  $b(x) = \exp(-\frac{x^2}{2\sigma^2})$ ,  $c(\mu) = \frac{\mu}{\sigma^2}$ ,  $d(x) = x$ .

(e)  $f(x | \sigma^2) = \frac{1}{(2\pi\sigma^2)^{1/2}} \exp[-\frac{(x-\mu)^2}{2\sigma^2}]$ . Therefore,  $a(\sigma^2) = \frac{1}{(2\pi\sigma^2)^{1/2}}$ ,  $b(x) = 1$ ,  $c(\sigma^2) = -\frac{1}{2\sigma^2}$ ,  $d(x) = (x-\mu)^2$ .

(f)  $f(x | \alpha) = \frac{\beta^\alpha}{\Gamma(\alpha)} x^{\alpha-1} \exp(-\beta x)$ . Therefore,  $a(\alpha) = \frac{\beta^\alpha}{\Gamma(\alpha)}$ ,  $b(x) = \exp(-\beta x)$ ,  $c(\alpha) = \alpha - 1$ ,  $d(x) = \log x$ .

(g)  $f(x | \beta)$  in this part is the same as the p.d.f. in part (f). Therefore,  $a(\beta) = \beta^\alpha$ ,  $b(x) = \frac{x^{\alpha-1}}{\Gamma(\alpha)}$ ,  $c(\beta) = -\beta$ ,  $d(x) = x$ .

(h)  $f(x | \alpha) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1} (1-x)^{\beta-1}$ . Therefore,  $a(\alpha) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)}$ ,  $b(x) = \frac{(1-x)^{\beta-1}}{\Gamma(\beta)}$ ,  $c(\alpha) = \alpha - 1$ ,  $d(x) = \log x$ .

(i)  $f(x | \beta)$  in this part is the same as the p.d.f. given in part (h). Therefore,  $a(\beta) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\beta)}$ ,  $b(x) = \frac{x^{\alpha-1}}{\Gamma(\alpha)}$ ,  $c(\beta) = \beta - 1$ ,  $d(x) = \log(1-x)$ .

25. For every  $\theta$ , the p.d.f. (or p.f.)  $f(x|\theta)$  for an exponential family is strictly positive for all  $x$  such that  $b(x) > 0$ . That is, the set of  $x$  for which  $f(x|\theta) > 0$  is the same for all  $\theta$ . This is not true for uniform distributions where the set of  $x$  such that  $f(x|\theta) > 0$  is  $[0, \theta]$ .
26. The same reasoning applies as in the previous exercise, for uniform distributions, the set of  $x$  such that  $f(x|\theta) > 0$  depends on  $\theta$ . For exponential families, the set of  $x$  such that  $f(x|\theta) > 0$  is the same for all  $\theta$ .

## 7.4 Bayes Estimators

### Commentary

We introduce the fundamental concepts of Bayesian decision theory. The use of a loss function arises again in Bayesian hypothesis testing in Sec. 9.8. This section ends with foundational discussion of the limitations of Bayes estimators. This material is included for those instructors who want their students to have both a working and a critical understanding of the topic.

If you are using the statistical software *R*, the function mentioned in Example 7.4.5 to compute the median of a beta distribution is `qbeta` with the first argument equal to 0.5 and the next two equal to  $\alpha + y$  and  $\beta + n - y$ , in the notation of the example.

### Solutions to Exercises

1. The posterior distribution of  $\theta$  would be the beta distribution with parameters 2 and 1. The mean of the posterior distribution is 2/3, which would be the Bayes estimate under squared error loss. The median of the posterior distribution would be the Bayes estimate under absolute error loss. To find the median, write the c.d.f. as

$$F(\theta) = \int_0^\theta 2t dt = \theta^2,$$

for  $0 < \theta < 1$ . The quantile function is then  $F^{-1}(p) = p^{1/2}$ , so the median is  $(1/2)^{1/2} = 0.7071$ .

2. The posterior distribution of  $\theta$  is the beta distribution with parameters  $5 + 1 = 6$  and  $10 + 19 = 29$ . The mean of this distribution is  $6/(6 + 29) = 6/35$ . Therefore, the Bayes estimate of  $\theta$  is  $6/35$ .
3. If  $y$  denotes the number of defective items in the sample, then the posterior distribution of  $\theta$  will be the beta distribution with parameters  $5 + y$  and  $10 + 20 - y = 30 - y$ . The variance  $V$  of this beta distribution is

$$V = \frac{(5+y)(30-y)}{(35)^2(36)}.$$

Since the Bayes estimate of  $\theta$  is the mean  $\mu$  of the posterior distribution, the mean squared error of this estimate is  $E[(\theta - \mu)^2 | \mathbf{x}]$ , which is the variance  $V$  of the posterior distribution.

- (a)  $V$  will attain its maximum at a value of  $y$  for which  $(5+y)(30-y)$  is a maximum. By differentiating with respect to  $y$  and setting the derivative equal to 0, we find that the maximum is attained when  $y = 12.5$ . Since the number of defective items  $y$  must be an integer, the maximum of  $V$  will be attained for  $y = 12$  or  $y = 13$ . When these values are substituted into  $(5+y)(30-y)$ , it is found that they both yield the same value.
  - (b) Since  $(5+y)(30-y)$  is a quadratic function of  $y$  and the coefficient of  $y^2$  is negative, its minimum value over the interval  $0 \leq y \leq 20$  will be attained at one of the endpoints of the interval. It is found that the value for  $y = 0$  is smaller than the value for  $y = 20$ .
4. Suppose that the parameters of the prior beta distribution of  $\theta$  are  $\alpha$  and  $\beta$ . Then  $\mu_0 = \alpha/(\alpha + \beta)$ . As shown in Example 7.4.3, the mean of the posterior distribution of  $\theta$  is

$$\frac{\alpha + \sum_{i=1}^n X_i}{\alpha + \beta + n} = \frac{\alpha + \beta}{\alpha + \beta + n} \mu_0 + \frac{n}{\alpha + \beta + n} \bar{X}_n.$$

Hence,  $\gamma_n = n/(\alpha + \beta + n)$  and  $\gamma_n \rightarrow 1$  as  $n \rightarrow \infty$ .

5. It was shown in Exercise 5 of Sec. 7.3 that the posterior distribution of  $\theta$  is the gamma distribution with parameters  $\alpha = 16$  and  $\beta = 6$ . The Bayes estimate of  $\theta$  is the mean of this distribution and is equal to  $16/6 = 8/3$ .
6. Suppose that the parameters of the prior gamma distribution of  $\theta$  are  $\alpha$  and  $\beta$ . Then  $\mu_0 = \alpha/\beta$ . The posterior distribution of  $\theta$  was given in Theorem 7.3.2. The mean of this posterior distribution is

$$\frac{\alpha + \sum_{i=1}^n X_i}{\beta + n} = \frac{\beta}{\beta + n} \mu_0 + \frac{n}{\beta + n} \bar{X}_n.$$

Hence,  $\gamma_n = n/(\beta + n)$  and  $\gamma_n \rightarrow 1$  as  $n \rightarrow \infty$ .

7. The Bayes estimator is the mean of the posterior distribution of  $\theta$ , as given in Exercise 6. Since  $\theta$  is the mean of the Poisson distribution, it follows from the law of large numbers that  $\bar{X}_n$  converges to  $\theta$  in probability as  $n \rightarrow \infty$ . It now follows from Exercise 6 that, since  $\gamma_n \rightarrow 1$ , the Bayes estimators will also converge to  $\theta$  in probability as  $n \rightarrow \infty$ . Hence, the Bayes estimators form a consistent sequence of estimators of  $\theta$ .
  8. It was shown in Exercise 7 of Sec. 7.3 that the posterior distribution of  $\theta$  is the normal distribution with mean 69.07 and variance 0.286.
    - (a) The Bayes estimate is the mean of this distribution and is equal to 69.07.
    - (b) The Bayes estimate is the median of the posterior distribution and is therefore again equal to 69.07.
  9. For any given values in the random sample, the Bayes estimate of  $\theta$  is the mean of the posterior distribution of  $\theta$ . Therefore, the mean squared error of the estimate will be the variance of the posterior distribution of  $\theta$ . It was shown in Exercise 10 of Sec. 7.3 that this variance will be 0.01 or less for  $n \geq 396$ .
  10. It was shown in Exercise 12 of Sec. 7.3 that the posterior distribution of  $\theta$  will be a gamma distribution with parameters  $\alpha = 20.04$  and  $\beta = 76.2$ . The Bayes estimate is the mean of this distribution and is equal to  $20.04/76.2 = 0.263$ .
  11. Let  $X_1, \dots, X_n$  denote the observations in the random sample, and let  $\alpha$  and  $\beta$  denote the parameters of the prior gamma distribution of  $\theta$ . It was shown in Theorem 7.3.4 that the posterior distribution of  $\theta$  will be the gamma distribution with parameters  $\alpha + n$  and  $\beta + n\bar{X}_n$ . The Bayes estimator, which is the mean of this posterior distribution is, therefore,
- $$\frac{\alpha + n}{\beta + n\bar{X}_n} = \frac{1 + (\alpha/n)}{\bar{X}_n + (\beta/n)}.$$
- Since the mean of the exponential distribution is  $1/\theta$ , it follows from the law of large numbers that  $\bar{X}_n$  will converge in probability to  $1/\theta$  as  $n \rightarrow \infty$ . It follows, therefore, that the Bayes estimators will converge in probability to  $\theta$  as  $n \rightarrow \infty$ . Hence, the Bayes estimators form a consistent sequence of estimators of  $\theta$ .
12. (a) A's prior distribution for  $\theta$  is the beta distribution with parameters  $\alpha = 2$  and  $\beta = 1$ . Therefore, A's posterior distribution for  $\theta$  is the beta distribution with parameters  $2+710 = 712$  and  $1+290 = 291$ . B's prior distribution for  $\theta$  is a beta distribution with parameters  $\alpha = 4$  and  $\beta = 1$ . Therefore, B's posterior distribution for  $\theta$  is the beta distribution with parameters  $4+710 = 714$  and  $1+290 = 291$ .

- (b)  $A$ 's Bayes estimate of  $\theta$  is  $712/(712+291) = 712/1003$ .  $B$ 's Bayes estimate of  $\theta$  is  $714/(714+291) = 714/1005$ .
- (c) If  $y$  denotes the number in the sample who were in favor of the proposition, then  $A$ 's posterior distribution for  $\theta$  will be the beta distribution with parameters  $2+y$  and  $1+1000-y=1001-y$ , and  $B$ 's posterior distribution will be a beta distribution with parameters  $4+y$  and  $1+1000-y=1001-y$ . Therefore,  $A$ 's Bayes estimate of  $\theta$  will be  $(2+y)/1003$  and  $B$ 's Bayes estimate of  $\theta$  will be  $(4+y)/1005$ . But

$$\left| \frac{4+y}{1005} - \frac{2+y}{1003} \right| = \frac{2(1001-y)}{(1005)(1003)}.$$

This difference is a maximum when  $y=0$ , but even then its value is only

$$\frac{2(1001)}{(1005)(1003)} < \frac{2}{1000}.$$

13. If  $\theta$  has the Pareto distribution with parameters  $\alpha > 1$  and  $x_0 > 0$ , then

$$E(\theta) = \int_{x_0}^{\infty} \theta \cdot \frac{\alpha x_0^{\alpha}}{\theta^{\alpha+1}} d\theta = \frac{\alpha}{\alpha-1} x_0.$$

It was shown in Exercise 18 of Sec. 7.3 that the posterior distribution of  $\theta$  will be a Pareto distribution with parameters  $\alpha+n$  and  $\max\{x_0, X_1, \dots, X_n\}$ . The Bayes estimator is the mean of this posterior distribution and is, therefore, equal to  $(\alpha+n)\max\{x_0, X_1, \dots, X_n\}/(\alpha+n-1)$ .

14. Since  $\psi = \theta^2$ , the posterior distribution of  $\psi$  can be derived from the posterior distribution of  $\theta$ . The Bayes estimator  $\hat{\psi}$  will then be the mean  $E(\psi)$  of the posterior distribution of  $\psi$ . But  $E(\psi) = E(\theta)^2$ , where the first expectation is calculated with respect to the posterior distribution of  $\psi$  and the second with respect to the posterior distribution of  $\theta$ . Since  $\hat{\theta}$  is the mean of the posterior distribution of  $\theta$ , it is also true that  $\hat{\theta} = E(\theta)$ . Finally, since the posterior distribution of  $\theta$  is a continuous distribution, it follows from the hint given in this exercise that

$$\hat{\psi} = E(\theta^2) > [E(\theta)]^2 = \hat{\theta}^2.$$

15. Let  $a_0$  be a  $1/(1+c)$  quantile of the posterior distribution, and let  $a_1$  be some other value. Assume that  $a_1 < a_0$ . The proof for  $a_1 > a_0$  is similar. Let  $g(\theta|x)$  denote the posterior p.d.f. The posterior mean of the loss for action  $a$  is

$$h(a) = c \int_{-\infty}^a (a - \theta) g(\theta|x) d\theta + \int_a^{\infty} (\theta - a) g(\theta|x) d\theta.$$

We shall now show that  $h(a_1) \geq h(a_0)$ , with strict inequality if  $a_1$  is not a  $1/(1+c)$  quantile.

$$\begin{aligned} h(a_1) - h(a_0) &= c \int_{-\infty}^{a_0} (a_1 - a_0) g(\theta|x) d\theta + \int_{a_0}^{a_1} (ca_1 - (1+c)\theta + a_0) g(\theta|x) d\theta \\ &\quad + \int_{a_1}^{\infty} (a_0 - a_1) g(\theta|x) d\theta \end{aligned} \tag{S.7.2}$$

The first integral in (S.7.2) equals  $c(a_1 - a_0)/(1+c)$  because  $a_0$  is a  $1/(1+c)$  quantile of the posterior distribution, and the posterior distribution is continuous. The second integral in (S.7.2) is at least as large as  $(a_0 - a_1) \Pr(a_0 < \theta \leq a_1|x)$  since  $-(1+c)\theta > -(1+c)a_1$  for all  $\theta$  in that integral. In fact, the

integral will be strictly larger than  $(a_0 - a_1) \Pr(a_0 < \theta \leq a_1 | x)$  if this probability is positive. The last integral in (S.7.2) equals  $(a_0 - a_1) \Pr(\theta > a_1 | x)$ . So

$$h(a_1) - h(a_0) \geq c \frac{a_1 - a_0}{1 + c} + (a_0 - a_1) \Pr(\theta > a_0 | x) = 0. \quad (\text{S.7.3})$$

The equality follows from the fact that  $\Pr(\theta > a_0 | x) = c/(1 + c)$ . The inequality in (S.7.3) will be strict if and only if  $\Pr(a_0 < \theta \leq a_1 | x) > 0$ , which occurs if and only if  $a_1$  is not another  $1/(1 + c)$  quantile.

## 7.5 Maximum Likelihood Estimators

### Commentary

Although maximum likelihood is a popular method of estimation, it can be valuable for the more capable students to see some limitations that are described at the end of this section. These limitations arise only in more complicated situations than those that are typically encountered in practice. This material is probably not suitable for students with a limited mathematical background who are learning statistical inference for the first time.

### Solutions to Exercises

1. We can easily compute

$$\begin{aligned} E(Y) &= \frac{1}{n} \sum_{i=1}^n x_i = \bar{x}_n, \\ E(Y^2) &= \frac{1}{n} \sum_{i=1}^n x_i^2. \end{aligned}$$

Then

$$\text{Var}(Y) = \frac{1}{n} \sum_{i=1}^n x_i^2 - \bar{x}_n^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x}_n)^2.$$

2. It was shown in Example 7.5.4 that the M.L.E. is  $\bar{x}_n$ . In this exercise,  $\bar{x}_n = 58/70 = 29/35$ .
3. The likelihood function for the given sample is  $p^{58}(1-p)^{12}$ . Among all values of  $p$  in the interval  $1/2 \leq p \leq 2/3$ , this function is a maximum when  $p = 2/3$ .
4. Let  $y$  denote the sum of the observations in the sample. Then the likelihood function is  $p^y(1-p)^{n-y}$ . If  $y = 0$ , this function is a decreasing function of  $p$ . Since  $p = 0$  is not a value in the parameter space, there is no M.L.E. Similarly, if  $y = n$ , then the likelihood function is an increasing function of  $p$ . Since  $p = 1$  is not a value in the parameter space, there is no M.L.E.
5. Let  $y$  denote the sum of the observed values  $x_1, \dots, x_n$ . Then the likelihood function is

$$f_n(\mathbf{x} | \theta) = \frac{\exp(-n\theta)\theta^y}{\prod_{i=1}^n (x_i!)}$$

- (a) If  $y > 0$  and we let  $L(\theta) = \log f_n(\mathbf{x} | \theta)$ , then

$$\frac{\partial}{\partial \theta} L(\theta) = -n + \frac{y}{\theta}.$$

The maximum of  $L(\theta)$  will be attained at the value of  $\theta$  for which this derivative is equal to 0. In this way, we find that  $\hat{\theta} = y/n = \bar{x}_n$ .

- (b) If  $y = 0$ , then  $f_n(\mathbf{x} | \theta)$  is a decreasing function of  $\theta$ . Since  $\theta = 0$  is not a value in the parameter space, there is no M.L.E.

6. Let  $\theta = \sigma^2$ . Then the likelihood function is

$$f_n(\mathbf{x} | \theta) = \frac{1}{(2\pi\theta)^{n/2}} \exp \left\{ -\frac{1}{2\theta} \sum_{i=1}^n (x_i - \mu)^2 \right\}.$$

If we let  $L(\theta) = \log f_n(\mathbf{x} | \theta)$ , then

$$\frac{\partial}{\partial \theta} L(\theta) = -\frac{n}{2\theta} + \frac{1}{2\theta^2} \sum_{i=1}^n (x_i - \mu)^2.$$

The maximum of  $L(\theta)$  will be attained at a value of  $\theta$  for which this derivative is equal to 0. In this way, we find that

$$\hat{\theta} = \frac{1}{n} \sum_{i=1}^n (x_i - \mu)^2.$$

7. Let  $y$  denote the sum of the observed values  $x_1, \dots, x_n$ . Then the likelihood function is

$$f_n(\mathbf{x} | \beta) = \beta^n \exp(-\beta y).$$

If we let  $L(\beta) = \log f_n(\mathbf{x} | \beta)$ , then

$$\frac{\partial L(\beta)}{\partial \beta} = \frac{n}{\beta} - y.$$

The maximum of  $L(\beta)$  will be attained at the value of  $\beta$  for which this derivative is equal to 0. Therefore,  $\hat{\beta} = n/y = 1/\bar{x}_n$ .

8. Let  $y$  denote the sum of the observed values  $x_1, \dots, x_n$ . Then the likelihood function is

$$f_n(\mathbf{x} | \theta) = \begin{cases} \exp(n\theta - y) & \text{for } \min\{x_1, \dots, x_n\} > \theta \\ 0 & \text{otherwise.} \end{cases}$$

- (a) For each value of  $\mathbf{x}$ ,  $f_n(\mathbf{x} | \theta)$  will be a maximum when  $\theta$  is made as large as possible subject to the strict inequality  $\theta < \min\{x_1, \dots, x_n\}$ . Therefore, the value  $\theta = \min\{x_1, \dots, x_n\}$  cannot be used and there is no M.L.E.
- (b) Suppose that the p.d.f. given in this exercise is replaced by the following equivalent p.d.f., in which strict and weak inequalities have been changed:

$$f(x | \theta) = \begin{cases} \exp(\theta - x) & \text{for } x \geq \theta, \\ 0 & \text{for } x < \theta. \end{cases}$$

Then the likelihood function  $f_n(\mathbf{x} | \theta)$  will be nonzero for  $\theta \leq \min\{x_1, \dots, x_n\}$  and the M.L.E. will be  $\hat{\theta} = \min\{x_1, \dots, x_n\}$ .

9. If  $0 < x_i < 1$  for  $i = 1, \dots, n$ , then the likelihood function will be as follows:

$$f_n(\mathbf{x} | \theta) = \theta^n \left( \prod_{i=1}^n x_i \right)^{\theta-1}.$$

If we let  $L(\theta) = \log f_n(\mathbf{x} | \theta)$ , then

$$\frac{\partial}{\partial \theta} L(\theta) = \frac{n}{\theta} + \sum_{i=1}^n \log x_i.$$

Therefore,  $\hat{\theta} = -n / \sum_{i=1}^n \log x_i$ . It should be noted that  $\hat{\theta} > 0$ .

10. The likelihood function is

$$f_n(\mathbf{x} | \theta) = \frac{1}{2^n} \exp \left\{ - \sum_{i=1}^n |x_i - \theta| \right\}.$$

Therefore, the M.L.E. of  $\theta$  will be the value that minimizes  $\sum_{i=1}^n |x_i - \theta|$ . The solution to this minimization problem was given in the solution to Exercise 10 of Sec. 4.5.

11. The p.d.f. of each observation can be written as follows:

$$f(x | \theta_1, \theta_2) = \begin{cases} \frac{1}{\theta_2 - \theta_1} & \text{for } \theta_1 \leq x \leq \theta_2, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore, the likelihood function is

$$f_n(\mathbf{x} | \theta_1, \theta_2) = \frac{1}{(\theta_2 - \theta_1)^n}$$

for  $\theta_1 \leq \min\{x_1, \dots, x_n\} < \max\{x_1, \dots, x_n\} \leq \theta_2$ , and  $f_n(\mathbf{x} | \theta_1, \theta_2) = 0$  otherwise. Hence,  $f_n(\mathbf{x} | \theta_1, \theta_2)$  will be a maximum when  $\theta_2 - \theta_1$  is made as small as possible. Since the smallest possible value of  $\theta_2$  is  $\max\{x_1, \dots, x_n\}$  and the largest possible value of  $\theta_1$  is  $\min\{x_1, \dots, x_n\}$ , these values are the M.L.E.'s.

12. The likelihood function is

$$f_n(\mathbf{x} | \theta_1, \dots, \theta_k) = \theta_1^{n_1} \cdots \theta_k^{n_k}.$$

If we let  $L(\theta_1, \dots, \theta_k) = \log f_n(\mathbf{x} | \theta_1, \dots, \theta_k)$  and let  $\theta_k = 1 - \sum_{i=1}^{k-1} \theta_i$ , then

$$\frac{\partial L(\theta_1, \dots, \theta_k)}{\partial \theta_i} = \frac{n_i}{\theta_i} - \frac{n_k}{\theta_k} \quad \text{for } i = 1, \dots, k-1.$$

If each of these derivatives is set equal to 0, we obtain the relations

$$\frac{\theta_1}{n_1} = \frac{\theta_2}{n_2} = \cdots = \frac{\theta_k}{n_k}.$$

If we let  $\theta_i = \alpha n_i$  for  $i = 1, \dots, k$ , then

$$1 = \sum_{i=1}^k \theta_i = \alpha \sum_{i=1}^k n_i = \alpha n.$$

Hence  $\alpha = 1/n$ . It follows that  $\hat{\theta}_i = n_i/n$  for  $i = 1, \dots, k$ .

13. It follows from Eq. (5.10.2) (with  $x_1$  and  $x_2$  now replaced by  $x$  and  $y$ ) that the likelihood function is

$$f_n(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2) \propto \exp \left\{ -\frac{1}{2(1-\rho^2)} \sum_{i=1}^n \left[ \left( \frac{x_i - \mu_1}{\sigma_1} \right)^2 - 2\rho \left( \frac{x_i - \mu_1}{\sigma_1} \right) \left( \frac{y_i - \mu_2}{\sigma_2} \right) + \left( \frac{y_i - \mu_2}{\sigma_2} \right)^2 \right] \right\}.$$

If we let  $L(\mu_1, \mu_2) = \log f(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2)$ , then

$$\begin{aligned} \frac{\partial L(\mu_1, \mu_2)}{\partial \mu_1} &= \frac{1}{1-\rho^2} \left[ \frac{1}{\sigma_1^2} \left( \sum_{i=1}^n x_i - n\mu_1 \right) - \frac{\rho}{\sigma_1 \sigma_2} \left( \sum_{i=1}^n y_i - n\mu_2 \right) \right], \\ \frac{\partial L(\mu_1, \mu_2)}{\partial \mu_2} &= \frac{1}{1-\rho^2} \left[ \frac{1}{\sigma_2^2} \left( \sum_{i=1}^n y_i - n\mu_2 \right) - \frac{\rho}{\sigma_1 \sigma_2} \left( \sum_{i=1}^n x_i - n\mu_1 \right) \right]. \end{aligned}$$

When these derivatives are set equal to 0, the unique solution is  $\mu_1 = \bar{x}_n$  and  $\mu_2 = \bar{y}_n$ . Hence, these values are the M.L.E.'s.

## 7.6 Properties of Maximum Likelihood Estimators

### Commentary

The material on sampling plans at the end of this section is a bit more subtle than the rest of the section, and should only be introduced to students who are capable of a deeper understanding of the material.

If you are using the software *R*, the digamma function mentioned in Example 7.6.4 can be computed with the function `digamma` which takes only one argument. The trigamma function mentioned in Example 7.6.6 can be computed with the function `trigamma` which takes only one argument. *R* also has several functions like `nlm` and `optim` for minimizing general functions. The required arguments to `nlm` are the name of another *R* function with a vector argument over which the minimization is done, and a starting value for the argument. If the function has additional arguments that remain fixed during the minimization, those can be listed after the starting vector, but they must be named explicitly. For `optim`, the first two arguments are reversed. Both functions have an optional argument `hessian` which, if set to `TRUE`, will tell the function to compute a matrix of numerical second partial derivatives. For example, if we want to minimize a function `f(x,y)` over `x` with `y` fixed at `c(3,1.2)` starting from `x=x0`, we could use

`optim(x0, f, y=c(3,1.2))`. If we wish to maximize a function `g`, we can define `f` to be  $-g$  and pass that to either `optim` or `nlm`.

### Solutions to Exercises

1. The M.L.E. of  $\exp(-1/\theta)$  is  $\exp(-1/\hat{\theta})$ , where  $\hat{\theta} = -n/\sum_{i=1}^n \log(x_i)$  is the M.L.E. of  $\theta$ . That is, the M.L.E. of  $\exp(-1/\theta)$  is

$$\exp \left( \sum_{i=1}^n \log(x_i)/n \right) = \exp \left( \log \left[ \prod_{i=1}^n x_i \right]^{1/n} \right) = \left( \prod_{i=1}^n x_i \right)^{1/n}.$$

2. The standard deviation of the Poisson distribution with mean  $\theta$  is  $\sigma = \theta^{1/2}$ . Therefore,  $\hat{\sigma} = \hat{\theta}^{1/2}$ . It was found in Exercise 5 of Sec. 7.5 that  $\hat{\theta} = \bar{X}_n$ .

3. The median of an exponential distribution with parameter  $\beta$  is the number  $m$  such that

$$\int_0^m \beta \exp(-\beta x) dx = \frac{1}{2}.$$

Therefore,  $m = (\log 2)/\beta$ , and it follows that  $\hat{m} = (\log 2)/\hat{\beta}$ . It was shown in Exercise 7 of Sec. 7.5 that  $\hat{\beta} = 1/\bar{X}_n$ .

4. The probability that a given lamp will fail in a period of  $T$  hours is  $p = 1 - \exp(-\beta T)$ , and the probability that exactly  $x$  lamps will fail is  $\binom{n}{x} p^x (1-p)^{n-x}$ . It was shown in Example 7.5.4 that  $\hat{p} = x/n$ . Since  $\beta = -\log(1-p)/T$ , it follows that  $\hat{\beta} = -\log(1-x/n)/T$ .
5. Since the mean of the uniform distribution is  $\mu = (a+b)/2$ , it follows that  $\hat{\mu} = (\hat{a} + \hat{b})/2$ . It was shown in Exercise 11 of Sec. 7.5 that  $\hat{a} = \min\{X_1, \dots, X_n\}$  and  $\hat{b} = \max\{X_1, \dots, X_n\}$ .
6. The distribution of  $Z = (X - \mu)/\sigma$  will be a standard normal distribution. Therefore,

$$0.95 = \Pr(X < \theta) = \Pr\left(Z < \frac{\theta - \mu}{\sigma}\right) = \Phi\left(\frac{\theta - \mu}{\sigma}\right).$$

Hence, from a table of the values of  $\Phi$  it is found that  $(\theta - \mu)/\sigma = 1.645$ . Since  $\theta = \mu + 1.645\sigma$ , it follows that  $\hat{\theta} = \hat{\mu} + 1.645\hat{\sigma}$ . By example 6.5.4, we have

$$\hat{\mu} = \bar{X}_n \quad \text{and} \quad \hat{\sigma} = \left[ \frac{1}{n} \sum_{i=1}^n (X_i - \bar{X}_n)^2 \right]^{1/2}.$$

$$7. \nu = \Pr(X > 2) = \Pr\left(Z > \frac{2 - \mu}{\sigma}\right) = 1 - \Phi\left(\frac{2 - \mu}{\sigma}\right) = \Phi\left(\frac{\mu - 2}{\sigma}\right).$$

Therefore,  $\hat{\nu} = \Phi((\hat{\mu} - 2)/\hat{\sigma})$ .

8. Let  $\theta = \Gamma'(\alpha)/\Gamma(\alpha)$ . Then  $\hat{\theta} = \Gamma'(\hat{\alpha})/\Gamma(\hat{\alpha})$ . It follows from Eq. (7.6.5) that  $\hat{\theta} = \sum_{i=1}^n (\log X_i)/n$ .
9. If we let  $y = \sum_{i=1}^n x_i$ , then the likelihood function is

$$f_n(\mathbf{x} | \alpha, \beta) = \frac{\beta^{n\alpha}}{[\Gamma(\alpha)]^n} \left( \prod_{i=1}^n x_i \right)^{\alpha-1} \exp(-\beta y).$$

If we now let  $L(\alpha, \beta) = \log f_n(\mathbf{x} | \alpha, \beta)$ , then

$$L(\alpha, \beta) = n\alpha \log \beta - n \log \Gamma(\alpha) + (\alpha - 1) \log \left( \prod_{i=1}^n x_i \right) - \beta y.$$

Hence,

$$\frac{\partial L(\alpha, \beta)}{\partial \beta} = \frac{n\alpha}{\beta} - y.$$

Since  $\hat{\alpha}$  and  $\hat{\beta}$  must satisfy the equation  $\partial L(\alpha, \beta)/\partial \beta = 0$  [as well as the equation  $\partial L(\alpha, \beta)/\partial \alpha = 0$ ], it follows that  $\hat{\alpha}/\hat{\beta} = y/n = \bar{x}_n$ .

10. The likelihood function is

$$f_n(\mathbf{x} | \alpha, \beta) = \left[ \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} \right]^n \left( \prod_{i=1}^n x_i \right)^{\alpha-1} \left[ \prod_{i=1}^n (1 - x_i) \right]^{\beta-1}.$$

If we let  $L(\alpha, \beta) = \log f_n(\mathbf{x} | \alpha, \beta)$ , then

$$\begin{aligned} L(\alpha, \beta) &= n \log \Gamma(\alpha + \beta) - n \log \Gamma(\alpha) - n \log \Gamma(\beta) \\ &\quad + (\alpha - 1) \sum_{i=1}^n \log x_i + (\beta - 1) \sum_{i=1}^n \log(1 - x_i). \end{aligned}$$

Hence,

$$\frac{\partial L(\alpha, \beta)}{\partial \alpha} = n \frac{\Gamma'(\alpha + \beta)}{\Gamma(\alpha + \beta)} - n \frac{\Gamma'(\alpha)}{\Gamma(\alpha)} + \sum_{i=1}^n \log x_i$$

and

$$\frac{\partial L(\alpha, \beta)}{\partial \beta} = n \frac{\Gamma'(\alpha + \beta)}{\Gamma(\alpha + \beta)} - n \frac{\Gamma'(\beta)}{\Gamma(\beta)} + \sum_{i=1}^n \log(1 - x_i).$$

The estimates  $\hat{\alpha}$  and  $\hat{\beta}$  must satisfy the equations  $\partial L(\alpha, \beta)/\partial \alpha = 0$  and  $\partial L(\alpha, \beta)/\partial \beta = 0$ . Therefore,  $\hat{\alpha}$  and  $\hat{\beta}$  must also satisfy the equation  $\partial L(\alpha, \beta)/\partial \alpha = \partial L(\alpha, \beta)/\partial \beta$ . This equation reduces to the one given in the exercise.

11. Let  $Y_n = \max\{X_1, \dots, X_n\}$ . It was shown in Example 7.5.7 that  $\hat{\theta} = Y_n$ . Therefore, for  $\varepsilon > 0$ ,

$$\Pr(|\hat{\theta} - \theta| < \varepsilon) = \Pr(Y_n > \theta - \varepsilon) = 1 - \left( \frac{\theta - \varepsilon}{\theta} \right)^n.$$

It follows that  $\lim_{n \rightarrow \infty} \Pr(|\hat{\theta} - \theta| < \varepsilon) = 1$ . Therefore,  $\hat{\theta} \xrightarrow{P} \theta$ .

12. We know that  $\hat{\beta} = 1/\bar{X}_n$ . Also, since the mean of the exponential distribution is  $\mu = 1/\beta$ , it follows from the law of large numbers that  $\bar{X}_n \xrightarrow{P} 1/\beta$ . Hence,  $\hat{\beta} \xrightarrow{P} \beta$ .
13. Let  $Z_i = -\log X_i$  for  $i = 1, \dots, n$ . Then by Exercise 9 of Sec. 7.5,  $\hat{\theta} = 1/\bar{Z}_n$ . If  $X_i$  has the p.d.f.  $f(x | \theta)$  specified in that exercise, then the p.d.f.  $g(z | \theta)$  of  $Z_i$  will be as follows, for  $z > 0$ :

$$g(z | \theta) = f(\exp(-z) | \theta) \left| \frac{dx}{dz} \right| = \theta(\exp(-z))^{\theta-1} \exp(-z) = \theta \exp(-\theta z).$$

Therefore,  $Z_i$  has an exponential distribution with parameter  $\theta$ . It follows that  $E(Z_i) = 1/\theta$ . Furthermore, since  $X_1, \dots, X_n$  form a random sample from a distribution for which the p.d.f. is  $f(x | \theta)$ , it follows that  $Z_1, \dots, Z_n$  will have the same joint distribution as a random sample from an exponential distribution with parameter  $\theta$ . Therefore, by the law of large numbers,  $\bar{Z}_n \xrightarrow{P} 1/\theta$ . It follows that  $\hat{\theta} \xrightarrow{P} \theta$ .

14. The M.L.E.  $\hat{p}$  is equal to the proportion of butterflies in the sample that have the special marking, regardless of the sampling plan. Therefore, (a)  $\hat{p} = 5/43$  and (b)  $\hat{p} = 3/58$ .

15. As explained in this section, the likelihood function for the 21 observations is equal to the joint p.d.f. of the 20 observations for which the exact value is known, multiplied by the probability  $\exp(-15/\mu)$  that the 21st observation is greater than 15. If we let  $y$  denote the sum of the first 20 observations, then the likelihood function is

$$\frac{1}{\mu^{20}} \exp(-y/\mu) \exp(-15/\mu).$$

Since  $y = (20)(6) = 120$ , this likelihood function reduces to

$$\frac{1}{\mu^{20}} \exp(-135/\mu).$$

The value of  $\mu$  which maximizes this likelihood function is  $\hat{\mu} = 6.75$ .

16. The likelihood function determined by any observed value  $x$  of  $X$  is  $\theta^3 x^2 \exp(-\theta x)/2$ . The likelihood function determined by any observed value  $y$  of  $Y$  is  $(2\theta)^y \exp(-2\theta)/y!$ . Therefore, when  $X = 2$  and  $Y = 3$ , each of these functions is proportional to  $\theta^3 \exp(-2\theta)$ . The M.L.E. obtained by either statistician will be the value of  $\theta$  which maximizes this expression. That value is  $\hat{\theta} = 3/2$ .
17. The likelihood function determined by any observed value  $x$  of  $X$  is  $\binom{10}{x} p^x (1-p)^{10-x}$ . By Eq. (5.5.1) the likelihood function determined by any observed value  $y$  of  $Y$  is  $\binom{3+y}{y} p^4 (1-p)^y$ . Therefore, when  $X = 4$  and  $Y = 6$ , each of these likelihood functions is proportional to  $p^4 (1-p)^6$ . The M.L.E. obtained by either statistician will be the value of  $p$  which maximizes this expression. That value is  $\hat{p} = 2/5$ .
18. The mean of a Bernoulli random variable with parameter  $p$  is  $p$ . Hence, the method of moments estimator is the sample mean, which is also the M.L.E.
19. The mean of an exponential random variable with parameter  $\beta$  is  $1/\beta$ , so the method of moments estimator is one over the sample mean, which is also the M.L.E.
20. The mean of a Poisson random variable is  $\theta$ , hence the method of moments estimator of  $\theta$  is the sample mean, which is also the M.L.E.
21. The M.L.E. of the mean is the sample mean, which is the method of moments estimator. The M.L.E. of  $\sigma^2$  is the mean of the  $X_i^2$ 's minus the square of the sample mean, which is also the method of moments estimator of the variance.
22. The mean of  $X_i$  is  $\theta/2$ , so the method of moments estimator is  $2\bar{X}_n$ . The M.L.E. is the maximum of the  $X_i$  values.
23. (a) The means of  $X_i$  and  $X_i^2$  are respectively  $\alpha/(\alpha + \beta)$  and  $\alpha(\alpha + 1)/[(\alpha + \beta)(\alpha + \beta + 1)]$ . We set these equal to the sample moments  $\bar{x}_n$  and  $\bar{x}^2_n$  and solve for  $\alpha$  and  $\beta$ . After some tedious algebra, we get

$$\begin{aligned}\hat{\alpha} &= \frac{\bar{x}_n(\bar{x}_n - \bar{x}^2_n)}{\bar{x}^2_n - \bar{x}_n^2}, \\ \hat{\beta} &= \frac{(1 - \bar{x}_n)(\bar{x}_n - \bar{x}^2_n)}{\bar{x}^2_n - \bar{x}_n^2}.\end{aligned}$$

- (b) The M.L.E. involves derivatives of the gamma function and the products  $\prod_{i=1}^n x_i$  and  $\prod_{i=1}^n (1-x_i)$ .
24. The p.d.f. of each  $(X_i, Y_i)$  pair can be factored as

$$\frac{1}{(2\pi)^{1/2}\sigma_1} \exp\left(-\frac{1}{2\sigma_1^2}(x_i - \mu_1)^2\right) \frac{1}{(2\pi)^{1/2}\sigma_{2.1}} \exp\left(-\frac{1}{2\sigma_{2.1}^2}(y_i - \alpha - \beta x_i)^2\right), \quad (\text{S.7.4})$$

where the new parameters are defined in the exercise. The product of  $n$  factors of the form (S.7.4) can be factored into the product of the  $n$  first factors times the product of the  $n$  second factors, each of which can be maximized separately because there are no parameters in common. The product of the first factors is the same as the likelihood of a sample of normal random variables, and the M.L.E.'s are  $\hat{\mu}_1$  and  $\widehat{\sigma_1^2}$  as stated in the exercise. The product of the second factors is slightly more complicated than the likelihood from a sample of normal random variables, but not much more so. Take the logarithm to get

$$-\frac{n}{2}[\log(2\pi) + \log(\sigma_{2.1}^2)] - \frac{1}{2\sigma_{2.1}^2} \sum_{i=1}^n (y_i - \alpha - \beta x_i)^2. \quad (\text{S.7.5})$$

Taking the partial derivatives with respect to  $\alpha$  and  $\beta$  yields

$$\begin{aligned} \frac{\partial}{\partial \alpha} &= \frac{1}{\sigma_{2.1}^2} \sum_{i=1}^n (y_i - \alpha - \beta x_i), \\ \frac{\partial}{\partial \beta} &= \frac{1}{\sigma_{2.1}^2} \sum_{i=1}^n x_i(y_i - \alpha - \beta x_i). \end{aligned}$$

Setting the first line equal to 0 and solving for  $\alpha$  yields

$$\alpha = \bar{y}_n - \beta \bar{x}_n. \quad (\text{S.7.6})$$

Plug (S.7.6) into the second of the partial derivatives to get (after a bit of algebra)

$$\hat{\beta} = \frac{\sum_{i=1}^n (x_i - \bar{x}_n)(y_i - \bar{y}_n)}{\sum_{i=1}^n (x_i - \bar{x}_n)^2}. \quad (\text{S.7.7})$$

Substitute (S.7.7) back into (S.7.6) to get

$$\hat{\alpha} = \bar{y}_n - \hat{\beta} \hat{\mu}_1.$$

Next, take the partial derivative of (S.7.5) with respect to  $\sigma_{2.1}^2$  to get

$$-\frac{n}{2\sigma_{2.1}^2} + \frac{1}{2\sigma_{2.1}^4} \sum_{i=1}^n (y_i - \alpha - \beta x_i)^2. \quad (\text{S.7.8})$$

Now, substitute both  $\hat{\alpha}$  and  $\hat{\beta}$  into (S.7.8) and solve for  $\sigma_{2.1}^2$ . The result is

$$\widehat{\sigma_{2.1}^2} = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{\alpha} - \hat{\beta} x_i)^2.$$

Finally, we can solve for the M.L.E.'s of the original parameters. We already have  $\hat{\mu}_1$  and  $\widehat{\sigma_1^2}$ . The equation  $\alpha = \mu_2 - \rho\sigma_2\mu_1/\sigma_1$  can be rewritten  $\alpha = \mu_2 - \beta\mu_1$ . It follows that

$$\hat{\mu}_2 = \hat{\alpha} + \hat{\beta}\hat{\mu}_1 = \bar{y}_n.$$

The equation  $\beta = \rho\sigma_2/\sigma_1$  can be rewritten  $\rho\sigma_2 = \beta\sigma_1$ . Plugging this into  $\sigma_{2.1}^2 = (1 - \rho^2)\sigma_2^2$  yields  $\sigma_{2.1}^2 = \sigma_2^2 - \beta^2\sigma_1^2$ . Hence,

$$\begin{aligned}\widehat{\sigma_2^2} &= \widehat{\sigma_{2.1}^2} + \hat{\beta}^2\widehat{\sigma_1^2} \\ &= \frac{1}{m} \sum_{i=1}^n (y_i - \hat{\alpha} - \hat{\beta}x_i)^2 + \frac{[\sum_{i=1}^n (y_i - \bar{y}_n)(x_i - \bar{x}_n)]^2}{\sum_{i=1}^n (x_i - \bar{x}_n)^2} \\ &= \frac{1}{n} \sum_{i=1}^n (y_i - \bar{y}_n)^2,\end{aligned}$$

where the final equality is tedious but straightforward algebra. Finally,

$$\hat{\rho} = \frac{\hat{\beta}\widehat{\sigma_1}}{\widehat{\sigma_2}} = \frac{\sum_{i=1}^n (y_i - \bar{y}_n)(x_i - \bar{x}_n)}{[\sum_{i=1}^n (x_i - \bar{x}_n)^2]^{1/2} [\sum_{i=1}^n (y_i - \bar{y}_n)^2]^{1/2}}.$$

25. When we observe only the first  $n - k$   $Y_i$ 's, the M.L.E.'s of  $\mu_1$  and  $\sigma_1^2$  are not affected. The M.L.E.'s of  $\alpha$ ,  $\beta$  and  $\sigma_{2.1}^2$  are just as in the previous exercise but with  $n$  replaced by  $n - k$ . The M.L.E.'s of  $\mu_2$ ,  $\sigma_2^2$  and  $\rho$  are obtained by substituting  $\hat{\alpha}$ ,  $\hat{\beta}$  and  $\widehat{\sigma_{2.1}^2}$  into the three equations Exercise 24:

$$\begin{aligned}\hat{\mu}_2 &= \hat{\alpha} + \hat{\beta}\hat{\mu}_1 \\ \widehat{\sigma_2^2} &= \widehat{\sigma_{2.1}^2} + \hat{\beta}^2\widehat{\sigma_1^2} \\ \hat{\rho} &= \frac{\hat{\beta}\widehat{\sigma_1}}{\widehat{\sigma_2}}.\end{aligned}$$

## 7.7 Sufficient Statistics

### Commentary

The concept of sufficient statistics is fundamental to much of the traditional theory of statistical inference. However, it plays little or no role in the most common practice of statistics. For the most popular distributional models for real data, the most obvious data summaries are sufficient statistics. In Bayesian inference, the posterior distribution is automatically a function of every sufficient statistic, so one does not even have to think about sufficiency in Bayesian inference. For these reasons, the material in Secs. 7.7–7.9 should only be covered in courses that place a great deal of emphasis on the mathematical theory of statistics.

### Solutions to Exercises

In Exercises 1–11, let  $t$  denote the value of the statistic  $T$  when the observed values of  $X_1, \dots, X_n$  are  $x_1, \dots, x_n$ . In each exercise, we shall show that  $T$  is a sufficient statistic by showing that the joint p.f. or joint p.d.f. can be factored as in Eq. (7.7.1).

1. The joint p.f. is

$$f_n(\mathbf{x} | p) = p^t(1 - p)^{n-t}.$$

2. The joint p.f. is

$$f_n(\mathbf{x} \mid p) = p^n(1-p)^t.$$

3. The joint p.f. is

$$f_n(\mathbf{x} \mid p) = \left[ \prod_{i=1}^n \binom{r+x_i-1}{x_i} \right] [p^{nr}(1-p)^t].$$

Since the expression inside the first set of square brackets does not depend on the parameter  $p$ , it follows that  $T$  is a sufficient statistic for  $p$ .

4. The joint p.d.f. is

$$f_n(\mathbf{x} \mid \sigma^2) = \frac{1}{(2\pi\sigma^2)^{n/2}} \exp \left\{ -\frac{t}{2\sigma^2} \right\}.$$

5. The joint p.d.f. is

$$f_n(\mathbf{x} \mid \beta) = \left\{ \frac{1}{[\Gamma(\alpha)]^n} \left( \prod_{i=1}^n x_i \right)^{\alpha-1} \right\} \{ \beta^{n\alpha} \exp(-n\beta t) \}.$$

6. The joint p.d.f. in this exercise is the same as that given in Exercise 5. However, since the unknown parameter is now  $\alpha$  instead of  $\beta$ , the appropriate factorization is now as follows:

$$f_n(\mathbf{x} \mid \alpha) = \left\{ \exp \left( -\beta \sum_{i=1}^n x_i \right) \right\} \left\{ \frac{\beta^{n\alpha}}{[\Gamma(\alpha)]^n} t^{\alpha-1} \right\}.$$

7. The joint p.d.f. is

$$f_n(\mathbf{x} \mid \alpha) = \left\{ \frac{1}{[\Gamma(\beta)]^n} \left[ \prod_{i=1}^n (1-x_i) \right]^{\beta-1} \right\} \left\{ \left[ \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)} \right]^n t^{\alpha-1} \right\}$$

8. The p.f. of an individual observation is

$$f(x \mid \theta) = \begin{cases} \frac{1}{\theta} & \text{for } x = 1, 2, \dots, \theta, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore, the joint p.f. is

$$f_n(\mathbf{x} \mid \theta) = \begin{cases} \frac{1}{\theta^n} & \text{for } t \leq \theta, \\ 0 & \text{otherwise.} \end{cases}$$

If the function  $h(t, \theta)$  is defined as in Example 7.7.5, with the values of  $t$  and  $\theta$  now restricted to positive integers, then it follows that

$$f_n(\mathbf{x} \mid \theta) = \frac{1}{\theta^n} h(t, \theta).$$

9. The joint p.d.f. is

$$f_n(\mathbf{x} | b) = \frac{h(t, b)}{(b - a)^n},$$

where  $h$  is defined in Example 7.7.5.

10. The joint p.d.f. is

$$f_n(\mathbf{x} | a) = \frac{h(a, t)}{(b - a)^n},$$

where  $h$  is defined in Example 7.7.5.

11. The joint p.d.f. or joint p.f. is

$$f_n(\mathbf{x} | \theta) = \left\{ \prod_{i=1}^n b(x_i) \right\} \{ [a(\theta)]^n \exp[c(\theta)t]\}.$$

12. The likelihood function is

$$\frac{\alpha^n x_0^{\alpha n}}{\prod_{i=1}^n x_i]^{\alpha+1}}, \quad (\text{S.7.9})$$

for all  $x_i \geq x_0$ .

- (a) If  $x_0$  is known,  $\alpha$  is the parameter, and (S.7.9) has the form  $u(\mathbf{x})v[r(\mathbf{x}), \alpha]$ , with  $u(\mathbf{x}) = 1$  if all  $x_i \geq x_0$  and 0 if not,  $r(\mathbf{x}) = \prod_{i=1}^n x_i$ , and  $v[t, \alpha] = \alpha^n x_0^{\alpha n} / t^{\alpha+1}$ . So  $\prod_{i=1}^n X_i$  is a sufficient statistic.
  - (b) If  $\alpha$  is known,  $x_0$  is the parameter, and (S.7.9) has the form  $u(\mathbf{x})v[r(\mathbf{x}), x_0]$ , with  $u(\mathbf{x}) = \alpha^n / [\prod_{i=1}^n x_i]^{\alpha+1}$ ,  $r(\mathbf{x}) = \min\{x_1, \dots, x_n\}$ , and  $v[t, x_0] = 1$  if  $t \geq x_0$  and 0 if not. Hence  $\min\{X_1, \dots, X_n\}$  is a sufficient statistic.
13. The statistic  $T$  will be a sufficient statistic for  $\theta$  if and only if  $f_n(\mathbf{x} | \theta)$  can be factored as in Eq. (7.7.1). However, since  $r(\mathbf{x})$  can be expressed as a function of  $r'(\mathbf{x})$ , and conversely, there will be a factorization of the form given in Eq. (7.7.1) if and only if there is a similar factorization in which the function  $v$  is a function of  $r'(\mathbf{x})$  and  $\theta$ . Therefore,  $T$  will be a sufficient statistic if and only if  $T'$  is a sufficient statistic.
14. This result follows from previous exercises in two different ways. First, by Exercise 6, the statistic  $T' = \prod_{i=1}^n X_i$  is a sufficient statistic. Hence, by Exercise 13,  $T = \log T'$  is also a sufficient statistic. A second way to establish the same result is to note that, by Exercise 24(g) of Sec. 7.3, the gamma distributions form an exponential family with  $d(x) = \log x$ . Therefore, by Exercise 11, the statistic  $T = \sum_{i=1}^n d(X_i)$  is a sufficient statistic.
15. It follows from Exercise 11 and Exercise 24(i) of Sec. 7.3 that the statistic  $T' = \sum_{i=1}^n \log(1 - X_i)$  is a sufficient statistic. Since  $T$  is a one-to-one function of  $T'$ , it follows from Exercise 13 that  $T$  is also a sufficient statistic.
16. Let  $f(\theta)$  be a prior p.d.f. for  $\theta$ . The posterior p.d.f. of  $\theta$  is, according to Bayes' theorem,

$$g(\theta | \mathbf{x}) = \frac{f_n(\mathbf{x} | \theta) f(\theta)}{\int f_n(\mathbf{x} | \psi) f(\psi) d\psi} = \frac{u(\mathbf{x}) v[r(\mathbf{x}), \theta] f(\theta)}{\int u(\mathbf{x}) v[r(\mathbf{x}, \psi)] f(\psi) d\psi} = \frac{v[r(\mathbf{x}), \theta] f(\theta)}{\int v[r(\mathbf{x}), \psi] f(\psi) d\psi},$$

where the second equality uses the factorization criterion. One can see that this last expression depends on  $\mathbf{x}$  only through  $r(\mathbf{x})$ .

17. First, suppose that  $T$  is sufficient. Then the likelihood function from observing  $\mathbf{X} = \mathbf{x}$  is  $u(\mathbf{x})v[r(\mathbf{x}), \theta]$ , which is proportional to  $v[r(\mathbf{x}), \theta]$ . The likelihood from observing  $T = t$  (when  $t = r(\mathbf{x})$ ) is

$$\sum u(\mathbf{x})v[r(\mathbf{x}), \theta] = v[t, \theta] \sum u(\mathbf{x}), \quad (\text{S.7.10})$$

where the sums in (S.7.10) are over all  $\mathbf{x}$  such that  $t = r(\mathbf{x})$ . Notice that the right side of (S.7.10) is proportional to  $v[t, \theta] = v[r(\mathbf{x}), \theta]$ . So the two likelihoods are proportional. Next, suppose that the two likelihoods are proportional. That is, let  $f(\mathbf{x}|\theta)$  be the p.f. of  $\mathbf{X}$  and let  $h(t|\theta)$  be the p.f. of  $T$ . If  $t = r(\mathbf{x})$  then there exists  $c(\mathbf{x})$  such that

$$f(\mathbf{x}|\theta) = u(\mathbf{x})h(t|\theta).$$

Let  $v[t, \theta] = h(t|\theta)$  and apply the factorization criterion to see that  $T$  is sufficient.

## 7.8 Jointly Sufficient Statistics

### Commentary

Even those instructors who wish to cover the concept of sufficient statistic in Sec. 7.7, may decide not to cover jointly sufficient statistics. This material is at a slightly more mathematical level than most of the text.

### Solutions to Exercises

In Exercises 1–4, let  $t_1$  and  $t_2$  denote the values of  $T_1$  and  $T_2$  when the observed values of  $X_1, \dots, X_n$  are  $x_1, \dots, x_n$ . In each exercise, we shall show that  $T_1$  and  $T_2$  are jointly sufficient statistics by showing that the joint p.d.f. of  $X_1, \dots, X_n$  can be factored as in Eq. (7.8.1).

1. The joint p.d.f. is

$$f_n(\mathbf{x} | \alpha, \beta) = \frac{\beta^{n\alpha}}{[\Gamma(\alpha)]^n} t_1^{\alpha-1} \exp(-\beta t_2).$$

2. The joint p.d.f. is

$$f_n(\mathbf{x} | \alpha, \beta) = \left[ \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} \right]^n t_1^{\alpha-1} t_2^{\beta-1}.$$

3. Let the function  $h$  be as defined in Example 7.8.4. Then the joint p.d.f. can be written in the following form:

$$f_n(x | x_0, \alpha) = \frac{(\alpha x_0^\alpha)^n}{t_2^{\alpha+1}} h(x_0, t_1).$$

4. Again let the function  $h$  be as defined in Example 7.8.4. Then the joint p.d.f. can be written as follows:

$$f_n(\mathbf{x} | \theta) = \frac{h(\theta, t_1)h(t_2, \theta + 3)}{3^n}.$$

5. The joint p.d.f. of the vectors  $(X_i, Y_i)$ , for  $i = 1, \dots, n$ , was given in Eq. (5.10.2). The following relations hold:

$$\begin{aligned}\sum_{i=1}^n (x_i - \mu_1)^2 &= \sum_{i=1}^n x_i^2 - 2\mu_1 \sum_{i=1}^n x_i + n\mu_1^2, \\ \sum_{i=1}^n (y_i - \mu_2)^2 &= \sum_{i=1}^n y_i^2 - 2\mu_2 \sum_{i=1}^n y_i + n\mu_2^2, \\ \sum_{i=1}^n (x_i - \mu_1)(y_i - \mu_2) &= \sum_{i=1}^n x_i y_i - \mu_2 \sum_{i=1}^n x_i - \mu_1 \sum_{i=1}^n y_i + n\mu_1\mu_2.\end{aligned}$$

Because of these relations, it can be seen that the joint p.d.f. depends on the observed values of the  $n$  vectors in the sample only through the values of the five statistics given in this exercise. Therefore, they are jointly sufficient statistics.

6. The joint p.d.f. or joint p.f. is

$$f_n(\mathbf{x} | \theta) = \left\{ \prod_{j=1}^n b(x_j) \right\} \left\{ [a(\theta)]^n \exp \left[ \sum_{i=1}^k c_i(\theta) \sum_{j=1}^k d_i(x_j) \right] \right\}.$$

It follows from the factorization criterion that  $T_1, \dots, T_k$  are jointly sufficient statistics for  $\theta$ .

7. In each part of this exercise we shall first present the p.d.f.  $f$ , and then we shall identify the functions  $a, b, c_1, d_1, c_2$ , and  $d_2$  in the form for a two-parameter exponential family given in Exercise 6.
- (a) Let  $\theta = (\mu, \sigma^2)$ . Then  $f(x | \theta)$  is as given in the solution to Exercise 24(d) of Sec. 7.3. Therefore,  

$$a(\theta) = \frac{1}{(2\pi\sigma^2)^{1/2}} \exp\left(-\frac{\mu^2}{2\sigma^2}\right), b(x) = 1, c_1(\theta) = -\frac{1}{2\sigma^2}, d_1(x) = x^2, c_2(\theta) = \frac{\mu}{\sigma^2}, d_2(x) = x.$$
  - (b) Let  $\theta = (\alpha, \beta)$ . Then  $f(x | \theta)$  is as given in the solution to Exercise 24(f) of Sec. 7.3. Therefore,  

$$a(\theta) = \frac{\beta^\alpha}{\Gamma(\alpha)}, b(x) = 1, c_1(\theta) = \alpha - 1, d_1(x) = \log x, c_2(\theta) = -\beta, d_2(x) = x.$$
  - (c) Let  $\theta = (\alpha, \beta)$ . Then  $f(x | \theta)$  is as given in the solution to Exercise 24(h) of Sec. 7.3. Therefore,  

$$a(\theta) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)}, b(x) = 1, c_1(\theta) = \alpha - 1, d_1(x) = \log x, c_2(\theta) = \beta - 1, \text{ and } d_2(x) = \log(1 - x).$$
8. The M.L.E. of  $\beta$  is  $n/\sum_{i=1}^n X_i$ . (See Exercise 7 in Sec. 7.5.) This is a one-to-one function of the sufficient statistic found in Exercise 5 of Sec. 7.7. Hence, the M.L.E. is sufficient. This makes it minimal sufficient.
9. By Example 7.5.4,  $\hat{p} = \bar{X}_n$ . By Exercise 1 of Sec. 7.7,  $\hat{p}$  is a sufficient statistic. Therefore,  $\hat{p}$  is a minimal sufficient statistic.
10. By Example 7.5.7,  $\hat{\theta} = \max\{X_1, \dots, X_n\}$ . By Example 7.7.5,  $\hat{\theta}$  is a sufficient statistic. Therefore,  $\hat{\theta}$  is a minimal sufficient statistic.
11. By Example 7.8.5, the order statistics are minimal jointly sufficient statistics. Therefore, the M.L.E. of  $\theta$ , all by itself, cannot be a sufficient statistic. (We know from Example 7.6.5 that there is no simple expression for this M.L.E., so we cannot solve this exercise by first deriving the M.L.E. and then checking to see whether it is a sufficient statistic.)

12. If we let  $T = \max\{X_1, \dots, X_n\}$ , let  $t$  denote the observed value of  $T$ , and let the function  $h$  be as defined in Example 7.8.4, then the likelihood function can be written as follows:

$$f_n(\mathbf{x} | \theta) = \frac{2^n \left( \prod_{i=1}^n x_i \right)}{\theta^{2n}} h(t, \theta).$$

This function will be a maximum when  $\theta$  is chosen as small as possible, subject to the constraint that  $h(t, \theta) = 1$ . Therefore, the M.L.E. of  $\theta$  is  $\hat{\theta} = t$ . The median  $m$  of the distribution will be the value such that

$$\int_0^m f(x | \theta) dx = \frac{1}{2}.$$

Hence,  $m = \theta/\sqrt{2}$ . It follows from the invariance principle that the M.L.E. of  $m$  is  $\hat{m} = \hat{\theta}/\sqrt{2} = t/\sqrt{2}$ .

By applying the factorization criterion to  $f_n(\mathbf{x} | \theta)$ , it can be seen that the statistic  $T$  is a sufficient statistic for  $\theta$ . Therefore, the statistic  $T/\sqrt{2}$  which is the M.L.E. of  $m$ , is also a sufficient statistic for  $\theta$ .

13. By Exercise 11 of Sec. 7.5,  $\hat{a} = \min\{X_1, \dots, X_n\}$  and  $\hat{b} = \max\{X_1, \dots, X_n\}$ . By Example 7.8.4,  $\hat{a}$  and  $\hat{b}$  are jointly sufficient statistics. Therefore,  $\hat{a}$  and  $\hat{b}$  are minimal jointly sufficient statistics.
14. It can be shown that the values of the five M.L.E.'s given in Exercise 24 of Sec. 7.6 can be derived from the values of the five statistics given in Exercise 5 of this section by a one-to-one transformation. Since the five statistics in Exercise 5 are jointly sufficient statistics, the five M.L.E.'s are also jointly sufficient statistics. Hence, the M.L.E.'s will be minimal jointly sufficient statistics.
15. The Bayes estimator of  $p$  is given by Eq. (7.4.5). Since  $\sum_{i=1}^n x_i$  is a sufficient statistic for  $p$ , the Bayes estimator is also a sufficient statistic for  $p$ . Hence, this estimator will be a minimal sufficient statistic.
16. It follows from Theorem 7.3.2 that the Bayes estimator of  $\lambda$  is  $(\alpha + \sum_{i=1}^n X_i)/(\beta + n)$ . Since  $\sum_{i=1}^n X_i$  is a sufficient statistic for  $\lambda$ , the Bayes estimator is also a sufficient statistic for  $\lambda$ . Hence, this estimator will be a minimal sufficient statistic.
17. The Bayes estimator of  $\mu$  is given by Eq. (7.4.6). Since  $\bar{X}_n$  is a sufficient statistic for  $\mu$ , the Bayes estimator is also a sufficient statistic. Hence, this estimator will be a minimal sufficient statistic.

## 7.9 Improving an Estimator

### Commentary

If you decided to cover the material in Secs. 7.7 and 7.8, this section gives one valuable application of that material, Theorem 7.9.1 of Blackwell and Rao. This section ends with some foundational discussion of the use of sufficient statistics. This material is included for those instructors who want their students to have both a working and a critical understanding of the topic.

### Solutions to Exercises

- The statistic  $Y_n = \sum_{i=1}^n X_i^2$  is a sufficient statistic for  $\theta$ . Since the value of the estimator  $\delta_1$  cannot be determined from the value of  $Y_n$  alone,  $\delta_1$  is inadmissible.

2. A sufficient statistic in this example is  $\max\{X_1, \dots, X_n\}$ . Since  $2\bar{X}_n$  is not a function of the sufficient statistic, it cannot be admissible.
3. The mean of the uniform distribution on the interval  $[0, \theta]$  is  $\theta/2$  and the variance is  $\theta^2/12$ . Therefore,  $E_\theta(\bar{X}_n) = \theta/2$  and  $\text{Var}_\theta(\bar{X}_n) = \theta^2/(12n)$ . In turn, it now follows that

$$E_\theta(\delta_1) = \theta \text{ and } \text{Var}_\theta(\delta_1) = \frac{\theta^2}{3n}.$$

Hence, for  $\theta > 0$ ,

$$R(\theta, \delta_1) = E_\theta[(\delta_1 - \theta)^2] = \text{Var}_\theta(\delta_1) = \frac{\theta^2}{3n}.$$

4. (a) It follows from the discussion given in Sec. 3.9 that the p.d.f. of  $Y_n$  is as follows:

$$g(y | \theta) = \begin{cases} \frac{ny^{n-1}}{\theta^n} & \text{for } 0 \leq y \leq \theta, \\ 0 & \text{otherwise.} \end{cases}$$

Hence, for  $\theta > 0$ ,

$$R(\theta, \delta_2) = E_\theta[(Y_n - \theta)^2] = \int_0^\theta (y - \theta)^2 \frac{ny^{n-1}}{\theta^n} dy = \frac{2\theta^2}{(n+1)(n+2)}.$$

- (b) if  $n = 2$ ,  $R(\theta, \delta_1) = R(\theta, \delta_2) = \theta^2/6$ .
- (c) Suppose  $n \geq 3$ . Then  $R(\theta, \delta_2) < R(\theta, \delta_1)$  for any given value of  $\theta > 0$  if and only if  $2/[(n+1)(n+2)] < 1/(3n)$  or, equivalently, if and only if  $6n < (n+1)(n+2) = n^2 + 3n + 2$ . Hence,  $R(\theta, \delta_2) < R(\theta, \delta_1)$  if and only if  $n^2 - 3n + 2 > 0$  or, equivalently, if and only if  $(n-2)(n-1) > 0$ . Since this inequality is satisfied for all values of  $n \geq 3$ , it follows that  $R(\theta, \delta_2) < R(\theta, \delta_1)$  for every value of  $\theta > 0$ . Hence,  $\delta_2$  dominates  $\delta_1$ .
5. For any constant  $c$ ,

$$\begin{aligned} R(\theta, cY_n) &= E_\theta[(cY_n - \theta)^2] = c^2 E_\theta(Y_n^2) - 2c\theta E_\theta(Y_n) + \theta^2 \\ &= \left( \frac{n}{n+2}c^2 - \frac{2n}{n+1}c + 1 \right) \theta^2. \end{aligned}$$

Hence, for any given value of  $n$  and any given value of  $\theta > 0$ ,  $R(\theta, cY_n)$  will be a minimum when  $c$  is chosen so that the coefficient of  $\theta^2$  in this expression is a minimum. By differentiating with respect to  $c$ , we find that the minimizing value of  $c$  is  $c = (n+2)(n+1)$ . Hence, the estimator  $(n+2)Y_n/(n+1)$  dominates every other estimator of the form  $cY_n$ .

6. It was shown in Exercise 6 of Sec. 7.7 that  $\prod_{i=1}^n X_i$  is a sufficient statistic in this problem. Since the value of  $\bar{X}_n$  cannot be determined from the value of the sufficient statistic alone,  $\bar{X}_n$  is inadmissible.
7. (a) Since the value of  $\delta$  is always 3,  $R(\beta, \delta) = (\beta - 3)^2$ .
- (b) Since  $R(3, \delta) = 0$ , no other estimator  $\delta_1$  can dominate  $\delta$  unless it is also true that  $R(3, \delta_1) = 0$ . But the only way that the M.S.E. of an estimator  $\delta_1$  can be 0 is for the estimator  $\delta_1$  to be equal to 3 with probability 1. In other words, the estimator  $\delta_1$  must be the same as the estimator  $\delta$ . Therefore,  $\delta$  is not dominated by any other estimator and it is admissible.
- In other words, the estimator that always estimates the value of  $\beta$  to be 3 is admissible because it is the best estimator to use if  $\beta$  happens to be equal to 3. Of course, it is a poor estimator to use if  $\beta$  happens to be different from 3.

8. It was shown in Example 7.7.2 that  $\sum_{i=1}^n X_i$  is a sufficient statistic in this problem. Since the proportion  $\hat{\beta}$  of observations that have the value 0 cannot be determined from the value of the sufficient statistic alone,  $\hat{\beta}$  is inadmissible.
9. Suppose that  $X$  has a continuous distribution for which the p.d.f. is  $f$ . Then

$$E(X) = \int_{-\infty}^0 xf(x) dx + \int_0^\infty xf(x) dx.$$

Suppose first that  $E(X) \leq 0$ . Then

$$\begin{aligned} |E(X)| = -E(X) &= \int_{-\infty}^0 (-x)f(x) dx - \int_0^\infty xf(x) dx \\ &\leq \int_{-\infty}^0 (-x)f(x) dx + \int_0^\infty xf(x) dx \\ &= \int_{-\infty}^\infty |x|f(x) dx = E(|X|). \end{aligned}$$

A similar proof can be given if  $X$  has a discrete distribution or a more general type of distribution, or if  $E(X) > 0$ .

Alternatively, the result is immediate from Jensen's inequality, Theorem 4.2.5.

10. We shall follow the steps of the proof of Theorem 7.9.1. It follows from Exercise 9 that

$$E_\theta(|\delta - \theta| | T) \geq |E_\theta(\delta - \theta | T)| = |E_\theta(\delta | T) - \theta| = |\delta_0 - \theta|.$$

Therefore,

$$E_\theta(|\delta_0 - \theta|) \leq E_\theta[E_\theta(|\delta - \theta| | T)] = E_\theta(|\delta - \theta|).$$

11. Since  $\hat{\theta}$  is the M.L.E. of  $\theta$ , we know from the discussion in Sec. 7.8 that  $\hat{\theta}$  is a function of  $T$  alone. Since  $\hat{\theta}$  is already a function of  $T$ , taking the conditional expectation  $E(\hat{\theta}|T)$  will not affect  $\hat{\theta}$ . Hence,  $\delta_0 = E(\hat{\theta}|T) = \hat{\theta}$ .
12. Since  $X_1$  must be either 0 or 1,

$$E(X_1 | T = t) = \Pr(X_1 = 1 | T = t).$$

If  $t = 0$  then every  $X_i$  must be 0. Therefore,

$$E(X_1 | T = 0) = 0.$$

Suppose now that  $t > 0$ . Then

$$\Pr(X_1 = 1 | T = t) = \frac{\Pr(X_1 = 1 \text{ and } T = t)}{\Pr(T = t)} = \frac{\Pr\left(X_1 = 1 \text{ and } \sum_{i=2}^n X_i = t - 1\right)}{\Pr(T = t)}.$$

Since  $X_1$  and  $\sum_{i=2}^n X_i$  are independent,

$$\begin{aligned}\Pr\left(X_1 = 1 \text{ and } \sum_{i=2}^n X_i = t - 1\right) &= \Pr(X_1 = 1) \Pr\left(\sum_{i=2}^n X_i = t - 1\right) \\ &= p \cdot \binom{n-1}{t-1} p^{t-1} (1-p)^{(n-1)-(t-1)} \\ &= \binom{n-1}{t-1} p^t (1-p)^{n-t}.\end{aligned}$$

Also,  $\Pr(T = t) = \binom{n}{t} p^t (1-p)^{n-t}$ . It follows that

$$\Pr(X_1 = 1 | T = t) = \binom{n-1}{t-1} / \binom{n}{t} = \frac{t}{n}.$$

Therefore, for any value of  $T$ ,

$$E(X_1 | T) = T/n = \bar{X}_n.$$

A more elegant way to solve this exercise is as follows: By symmetry,  $E(X_1 | T) = E(X_2 | T) = \dots = E(X_n | T)$ . Therefore,  $nE(X_1 | T) = \sum_{i=1}^n E(X_i | T)$ . But

$$\sum_{i=1}^n E(X_i | T) = E\left(\sum_{i=1}^n X_i | T\right) = E(T | T) = T.$$

Hence,  $E(X_1 | T) = T/n$ .

13. We shall carry out the analysis for  $Y_1$ . The analysis for every other value of  $i$  is similar. Since  $Y_1$  must be 0 or 1,

$$\begin{aligned}E(Y_1 | T = t) &= \Pr(Y_1 = 1 | T = t) = \Pr(X_1 = 0 | T = t) \\ &= \frac{\Pr(X_1 = 0 \text{ and } T = t)}{\Pr(T = t)} = \frac{\Pr\left(X_1 = 0 \text{ and } \sum_{i=2}^n X_i = t\right)}{\Pr(T = t)}.\end{aligned}$$

The random variables  $X_1$  and  $\sum_{i=2}^n X_i$  are independent,  $X_1$  has a Poisson distribution with mean  $\theta$ , and  $\sum_{i=2}^n X_i$  has a Poisson distribution with mean  $(n-1)\theta$ . Therefore,

$$\Pr\left(X_1 = 0 \text{ and } \sum_{i=2}^n X_i = t\right) = \Pr(X_1 = 0) \Pr\left(\sum_{i=2}^n X_i = t\right) = \exp(-\theta) \cdot \frac{\exp(-(n-1)\theta)[(n-1)\theta]^t}{t!}.$$

Also, since  $T$  has a Poisson distribution with mean  $n\theta$ ,

$$\Pr(T = t) = \frac{\exp(-n\theta)(n\theta)^t}{t!}$$

It now follows that  $E(Y_1 | T = t) = ([n-1]/n)^t$ .

14. If  $Y_i$  is defined as in Exercise 12 for  $i = 1, \dots, n$ , then  $\hat{\beta} = \sum_{i=1}^n Y_i/n$ . Also, we know from Exercise 12 that  $E(Y_i|T) = ([n-1]/n)^T$  for  $i = 1, \dots, n$ . Therefore,

$$E(\hat{\beta} | T) = E\left(\frac{1}{n} \sum_{i=1}^n Y_i | T\right) = \frac{1}{n} \sum_{i=1}^n E(Y_i | T) = \frac{1}{n} \cdot n \left(\frac{n-1}{n}\right)^T = \left(\frac{n-1}{n}\right)^T.$$

15. Let  $\hat{\theta}$  be the M.L.E. of  $\theta$ . Then the M.L.E. of  $\exp(\theta + 0.125)$  is  $\exp(\hat{\theta} + 0.125)$ . The M.L.E. of  $\theta$  is  $\bar{X}_n$ , so the M.L.E. of  $\exp(\theta + 0.125)$  is  $\exp(\bar{X}_n + 0.125)$ . The M.S.E. of an estimator of the form  $\exp(\bar{X}_n + c)$  is

$$\begin{aligned} & E[(\exp[\bar{X}_n + c] - \exp[\theta + 0.125])^2] \\ &= \text{Var}(\exp[\bar{X}_n + c]) + [E(\exp[\bar{X}_n + c]) - \exp(\theta + 0.125)]^2 \\ &= \exp(2\theta + 0.25/n + 2c)[\exp(0.25/n) - 1] + [\exp(\theta + 0.125/n + c) - \exp(\theta + 0.125)]^2 \\ &= \exp(2\theta)\{\exp(0.25/n + 2c)[\exp(0.25/n) - 1] + \exp(0.25/n + 2c) - 2\exp(0.125[1 + 1/n] + c) \\ &\quad + \exp(0.5)\} \\ &= \exp(2\theta)[\exp(2c)\exp(0.5/n) - 2\exp(c)\exp(0.125[1 + 1/n]) + \exp(0.5)]. \end{aligned}$$

Let  $a = \exp(c)$  in this last expression. Then we can minimize the M.S.E. simultaneously for all  $\theta$  by minimizing

$$a^2 \exp(0.5/n) - 2a \exp(0.125[1 + 1/n]) + \exp(0.5).$$

The minimum occurs at  $a = \exp(0.125 - 0.375/n)$ , so  $c = 0.125 - 0.375/n$ .

16.  $p = \Pr(X_i = 1|\theta) = \exp(-\theta)\theta$ . The M.L.E. of  $\theta$  is the number of arrivals divided by the observation time, namely  $\bar{X}_n$ . So, the M.L.E. of  $p$  is  $\exp(-\bar{X}_n)\bar{X}_n$ . In Example 7.9.2,  $T/n = \bar{X}_n$ . If  $n$  is large, then  $T$  should also be large so that  $(1 - 1/n)^T \approx \exp(-T/n)$  according to Theorem 5.3.3.

## 7.10 Supplementary Exercises

### Solutions to Exercises

1. (a) The prior distribution of  $\theta$  is the beta distribution with parameters 1 and 1, so the posterior distribution of  $\theta$  is the beta distribution with parameters  $1+10=11$  and  $1+25-10=16$ .  
(b) With squared error loss, the estimate to use is the posterior mean, which is  $11/27$  in this case.
2. We know that the M.L.E. of  $\theta = \bar{X}_n$ . Hence, by the invariance property described in Sec. 7.6, the M.L.E. of  $\theta^2$  is  $\bar{X}_n^2$ .
3. The prior distribution of  $\theta$  is the beta distribution with  $\alpha = 3$  and  $\beta = 4$ , so it follows from Theorem 7.3.1 that the posterior distribution is the beta distribution with  $\alpha = 3+3=6$  and  $\beta = 4+7=11$ . The Bayes estimate is the mean of this posterior distribution, namely  $6/17$ .
4. Since the joint p.d.f. of the observations is equal to  $1/\theta^n$  provided that  $\theta \leq x_i \leq 2\theta$  for  $i = 1, \dots, n$ , the M.L.E. will be the smallest value of  $\theta$  that satisfies these restrictions. Since we can rewrite the restrictions in the form

$$\frac{1}{2} \max\{x_1, \dots, x_n\} \leq \theta \leq \min\{x_1, \dots, x_n\}$$

it follows that the smallest possible value of  $\theta$  is

$$\hat{\theta} = \frac{1}{2} \max\{x_1, \dots, x_n\}.$$

5. The joint p.d.f. of  $X_1$  and  $X_2$  is

$$\frac{1}{2\pi\sigma_1\sigma_2} \exp\left[-\frac{1}{2\sigma_1^2}(x_1 - b_1\mu)^2 - \frac{1}{2\sigma_2^2}(x_2 - b_2\mu)^2\right].$$

If we let  $L(\mu)$  denote the logarithm of this expression, and solve the equation  $dL(\mu)/d\mu = 0$ , we find that

$$\hat{\mu} = \frac{\sigma_2^2 b_1 x_1 + \sigma_1^2 b_2 x_2}{\sigma_2^2 b_1^2 + \sigma_1^2 b_2^2}.$$

6. Since  $\Gamma(\alpha + 1) = \alpha\Gamma(\alpha)$ , it follows that  $\Gamma'(\alpha + 1) = \alpha\Gamma'(\alpha) + \Gamma(\alpha)$ . Hence,

$$\begin{aligned}\psi(\alpha + 1) &= \frac{\Gamma'(\alpha + 1)}{\Gamma(\alpha + 1)} = \frac{\alpha\Gamma'(\alpha)}{\Gamma(\alpha + 1)} + \frac{\Gamma(\alpha)}{\Gamma(\alpha + 1)} \\ &= \frac{\Gamma'(\alpha)}{\Gamma(\alpha)} + \frac{1}{\alpha} = \psi(\alpha) + \frac{1}{\alpha}.\end{aligned}$$

7. The joint p.d.f. of  $X_1, X_2, X_3$  is

$$f(\mathbf{x}|\theta) = \frac{1}{\theta} \exp\left(-\frac{1}{\theta}x_1\right) \cdot \frac{1}{2\theta} \exp\left(-\frac{1}{2\theta}x_2\right) \cdot \frac{1}{3\theta} \exp\left(-\frac{1}{3\theta}x_3\right) = \frac{1}{6\theta^3} \exp\left[-\left(x_1 + \frac{x_2}{2} + \frac{x_3}{3}\right)\frac{1}{\theta}\right].$$

(a) By solving the equation  $\partial \log(f)/\partial\theta = 0$ , we find that

$$\hat{\theta} = \frac{1}{3} \left( X_1 + \frac{1}{2}X_2 + \frac{1}{3}X_3 \right).$$

(b) In terms of  $\psi$ , the joint p.d.f. of  $X_1, X_2, X_3$  is

$$f(\mathbf{x} | \psi) = \frac{\psi^3}{6} \exp\left[-\left(x_1 + \frac{1}{2}x_2 + \frac{1}{3}x_3\right)\psi\right].$$

Since the prior p.d.f. of  $\psi$  is

$$\xi(\psi) \propto \psi^{\alpha-1} \exp(-\beta\psi),$$

it follows that the posterior p.d.f. is

$$\xi(\psi | \mathbf{x}) \propto f(\mathbf{x} | \psi)\xi(\psi) \propto \psi^{\alpha+2} \exp\left[-\left(\beta + x_1 + \frac{1}{2}x_2 + \frac{1}{3}x_3\right)\psi\right].$$

Hence, the posterior distribution of  $\psi$  is the gamma distribution with parameters  $\alpha + 3$  and  $\beta + x_1 + x_2/2 + x_3/3$ .

8. The joint p.f. of  $X_2, \dots, X_{n+1}$  is the product of  $n$  factors. If  $X_i = x_i$  and  $X_{i+1} = x_{i+1}$ , then the  $i$ th factor will be the transition probability of going from state  $x_i$  to state  $x_{i+1}$  ( $i = 1, \dots, n$ ). Hence, each transition from  $s_1$  to  $s_1$  will introduce the factor  $\theta$ , each transition from  $s_1$  to  $s_2$  will introduce the factor  $1 - \theta$ , and every other transition will introduce either the constant factor  $3/4$  or the constant factor  $1/4$ . Hence, if  $A$  denotes the number of transitions from  $s_1$  to  $s_1$  among the  $n$  transitions and  $B$  denotes the number from  $s_1$  to  $s_2$ , then the joint p.f. of  $X_2, \dots, X_{n+1}$  has the form (const.)  $\theta^A(1 - \theta)^B$ . Therefore, this joint p.f., or likelihood function, is maximized when

$$\hat{\theta} = \frac{A}{A + B}.$$

9. The posterior p.d.f. of  $\theta$  given  $X = x$  satisfies the relation

$$\xi(\theta | x) \propto f(x | \theta) \xi(\theta) \propto \exp(-\theta), \text{ for } \theta > x.$$

Hence,

$$\xi(\theta | x) = \begin{cases} \exp(x - \theta) & \text{for } \theta > x, \\ 0 & \text{otherwise.} \end{cases}$$

- (a) The Bayes estimator is the mean of this posterior distribution,  $\hat{\theta} = x + 1$ .  
 (b) The Bayes estimator is the median of this posterior distribution,  $\hat{\theta} = x + \log 2$ .
10. In this exercise,  $\theta$  must lie in the interval  $1/3 \leq \theta \leq 2/3$ . Hence, as in Exercise 3 of Sec. 7.5, the M.L.E. of  $\theta$  is

$$\hat{\theta} = \begin{cases} \bar{X}_n & \text{if } \frac{1}{3} \leq \bar{X}_n \leq \frac{2}{3}, \\ \frac{1}{3} & \text{if } \bar{X}_n < \frac{1}{3}, \\ \frac{2}{3} & \text{if } \bar{X}_n > \frac{2}{3}. \end{cases}$$

It then follows from Sec. 7.6 that  $\hat{\beta} = 3\hat{\theta} - 1$ .

11. Under these conditions,  $X$  has a binomial distribution with parameters  $n$  and  $\theta = \frac{1}{2} \cdot \frac{1}{2} + \frac{1}{2}p = \frac{1}{4} + \frac{1}{2}p$ . Since  $0 \leq p \leq 1$ , it follows that  $1/4 \leq \theta \leq 3/4$ . Hence, as in Exercise 3 of Sec. 7.5, the M.L.E. of  $\hat{\theta}$  is

$$\hat{\theta} = \begin{cases} \frac{X}{n} & \text{if } \frac{1}{4} \leq \frac{X}{n} \leq \frac{3}{4}, \\ \frac{1}{4} & \text{if } \frac{X}{n} < \frac{1}{4}, \\ \frac{3}{4} & \text{if } \frac{X}{n} > \frac{3}{4}. \end{cases}$$

It then follows from Theorem 7.6.1 that the M.L.E. of  $p$  is  $\hat{p} = 2(\hat{\theta} - 1/4)$ .

12. The prior distribution of  $\theta$  is the Pareto distribution with parameters  $x_0 = 1$  and  $\alpha = 1$ . Therefore, it follows from Exercise 18 of Sec. 7.3 that the posterior distribution of  $\theta$  will be a Pareto distribution with parameters  $\alpha + n$  and  $\max\{x_0, x_1, \dots, x_n\}$ . In this exercise  $n = 4$  and  $\max\{x_0, x_1, \dots, x_n\} = 1$ . Hence, the posterior Pareto distribution has parameters  $\alpha = 5$  and  $x_0 = 1$ . The Bayes estimate of  $\theta$  will be the mean of this posterior distribution, namely

$$\hat{\theta} = \int_1^\infty \theta \frac{5}{\theta^6} d\theta = \frac{5}{4}.$$

13. The Bayes estimate of  $\theta$  will be the median of the posterior Pareto distribution. This will be the value  $m$  such that

$$\frac{1}{2} = \int_m^\infty \frac{5}{\theta^6} d\theta = \frac{1}{m^5}.$$

Hence,  $\hat{\theta} = m = 2^{1/5}$ .

14. The joint p.d.f. of  $X_1, \dots, X_n$  can be written in the form

$$f_n(\mathbf{x}|\beta, \theta) = \beta^n \exp\left(n\beta\theta - \beta \sum_{i=1}^n x_i\right)$$

for  $\min\{x_1, \dots, x_n\} \geq \theta$ , and  $f_n(\mathbf{x}|\beta, \theta) = 0$  otherwise. Hence, by the factorization criterion,  $\sum_{i=1}^n X_i$  and  $\min\{X_1, \dots, X_n\}$  is a pair of jointly sufficient statistics and so is any other pair of statistics that is a one-to-one function of this pair.

15. The joint p.d.f. of the observations is  $\alpha^n x_0^{n\alpha} / \left(\prod_{i=1}^n x_i\right)^{\alpha+1}$  for  $\min\{x_1, \dots, x_n\} \geq x_0$ . This p.d.f. is maximized when  $x_0$  is made as large as possible. Thus,

$$\hat{x}_0 = \min\{X_1, \dots, X_n\}.$$

16. Since  $\alpha$  is known in Exercise 15, it follows from the factorization criterion, by a technique similar to that used in Example 7.7.5 or Exercise 12 of Sec. 7.8, that  $\min\{X_1, \dots, X_n\}$  is a sufficient statistic. Thus, from Theorem 7.8.3, since the M.L.E.  $\hat{x}_0$  is a sufficient statistic, it is a minimal sufficient statistic.

17. It follows from Exercise 15 that  $\hat{x}_0 = \min\{X_1, \dots, X_n\}$  will again be the M.L.E. of  $x_0$ , since this value of  $x_0$  maximizes the likelihood function regardless of the value of  $\alpha$ . If we substitute  $\hat{x}_0$  for  $x_0$  and let  $L(\alpha)$  denote the logarithm of the resulting likelihood function, which was given in Exercise 15, then

$$L(\alpha) = n \log \alpha + n \alpha \log \hat{x}_0 - (\alpha + 1) \sum_{i=1}^n \log x_i$$

and

$$\frac{dL(\alpha)}{d\alpha} = \frac{n}{\alpha} + n \log \hat{x}_0 - \sum_{i=1}^n \log x_i.$$

Hence, by setting this expression equal to 0, we find that

$$\hat{\alpha} = \left( \frac{1}{n} \sum_{i=1}^n \log x_i - \log \hat{x}_0 \right)^{-1}.$$

18. It can be shown that the pair of estimators  $\hat{x}_0$  and  $\hat{\alpha}$  found in Exercise 17 form a one-to-one transform of the pair of jointly sufficient statistics  $T_1$  and  $T_2$  given in Exercise 3 of Sec. 7.8. Hence,  $\hat{x}_0$  and  $\hat{\alpha}$  are themselves jointly sufficient statistics. It now follows from Sec. 7.8 that  $\hat{x}_0$  and  $\hat{\alpha}$  must be minimal jointly sufficient statistics.
19. The p.f. of  $X$  is

$$f(x|n,p) = \binom{n}{x} p^x (1-p)^{n-x}.$$

The M.L.E. of  $n$  will be the value that maximizes this expression for given values of  $x$  and  $p$ . The ratio given in the hint to this exercise reduces to

$$R = \frac{n+1}{n+1-x} (1-p).$$

Since  $R$  is a decreasing function of  $n$ , it follows that  $f(x|n,p)$  will be maximized at the smallest value of  $n$  for which  $R < 1$ . After some algebra, it is found that  $R < 1$  if and only if  $n > x/p - 1$ . Hence,  $n$  will be the smallest integer greater than  $x/p - 1$ . If  $x/p - 1$  is itself an integer, then  $x/p - 1$  and  $x/p$  are both M.L.E.'s.

20. The joint p.d.f. of  $X_1$  and  $X_2$  is  $1/(4\theta^2)$  provided that each of the observations lies in either the interval  $(0, \theta)$  or the interval  $(2\theta, 3\theta)$ . Thus, the M.L.E. of  $\theta$  will be the smallest value of  $\theta$  for which these restrictions are satisfied.
- (a) If we take  $3\hat{\theta} = 9$ , or  $\hat{\theta} = 3$ , then  $\hat{\theta}$  will be as small as possible, and the restrictions will be satisfied because both observed values will lie in the interval  $(2\hat{\theta}, 3\hat{\theta})$ .
  - (b) It is not possible that both  $X_1$  and  $X_2$  lie in the interval  $(2\theta, 3\theta)$ , because for that to be true it is necessary that  $X_2/X_1 \leq 3/2$ . Here, however,  $X_2/X_1 = 9/4$ . Therefore, if we take  $\hat{\theta} = 4$ , then  $\hat{\theta}$  will be as small as possible and the restrictions will be satisfied because  $X_1$  will lie in the interval  $(0, \hat{\theta})$  and  $X_2$  will lie in  $(2\hat{\theta}, 3\hat{\theta})$ .
  - (c) It is not possible that both  $X_1$  and  $X_2$  lie in the interval  $(2\theta, 3\theta)$  for the reason given in part (b). It is also not possible that  $X_1$  lies in  $(0, \theta)$  and  $X_2$  lies in  $(2\theta, 3\theta)$ , because for that to be true it is necessary that  $X_2/X_1 \geq 2$ . Here, however,  $X_2/X_1 = 9/5$ . Hence, it must be true that both  $X_1$  and  $X_2$  lie in the interval  $(0, \theta)$ . Under this condition, the smallest possible value of  $\theta$  is  $\hat{\theta} = 9$ .
21. The Bayes estimator of  $\theta$  is the mean of the posterior distribution of  $\theta$ , and the expected loss or M.S.E. of this estimator is the variance of the posterior distribution. This variance, as given by Eq. (7.3.2), is

$$\nu_1^2 = \frac{(100)(25)}{100 + 25n} = \frac{100}{n+4}.$$

Hence,  $n$  must be chosen to minimize

$$\frac{100}{n+4} + \frac{1}{4} n.$$

By setting the first derivative equal to 0, it is found that the minimum occurs when  $n = 16$ .

22. It was shown in Example 7.7.2 that  $T = \sum_{i=1}^n X_i$  is a sufficient statistic in this problem. Since the sample variance is not a function of  $T$  alone, it follows from Theorem 7.9.1 that it is inadmissible.

# Chapter 8

## Sampling Distributions of Estimators

### 8.1 The Sampling Distribution of a Statistic

#### Solutions to Exercises

1. The c.d.f. of  $U = \max\{X_1, \dots, X_n\}$  is

$$F(u) = \begin{cases} 0 & \text{for } u \leq 0, \\ (u/\theta)^n & \text{for } 0 < u < \theta, \\ 1 & \text{for } u \geq \theta. \end{cases}$$

Since  $U \leq \theta$  with probability 1, the event that  $|U - \theta| \leq 0.1\theta$  is the same as the event that  $U \geq 0.9\theta$ . The probability of this is  $1 - F(0.9\theta) = 1 - 0.9^n$ . In order for this to be at least 0.95, we need  $0.9^n \leq 0.05$  or  $n \geq \log(0.05)/\log(0.9) = 28.43$ . So  $n \geq 29$  is needed.

2. It is known that  $\bar{X}_n$  has the normal distribution with mean  $\theta$  and variance  $4/n$ . Therefore,

$$E_\theta(|\bar{X}_n - \theta|^2) = \text{Var}_\theta(\bar{X}_n) = 4/n,$$

and  $4/n \leq 0.1$  if and only if  $n \geq 40$ .

3. Once again,  $\bar{X}_n$  has the normal distribution with mean  $\theta$  and variance  $4/n$ . Hence, the random variable  $Z = (\bar{X}_n - \theta)/(2/\sqrt{n})$  will have the standard normal distribution. Therefore,

$$\begin{aligned} E_\theta(|\bar{X}_n - \theta|) &= \frac{2}{\sqrt{n}} E_\theta(|Z|) = \frac{2}{\sqrt{n}} \int_{-\infty}^{\infty} |z| \frac{1}{\sqrt{2\pi}} \exp(-z^2/2) dz = 2\sqrt{\frac{2}{n\pi}} \int_0^{\infty} z \exp(-z^2/2) dz \\ &= 2\sqrt{\frac{2}{n\pi}}. \end{aligned}$$

But  $2\sqrt{2/(n\pi)} \leq 0.1$  if and only if  $n \geq 800/\pi = 254.6$ . Hence,  $n$  must be at least 255.

4. If  $Z$  is defined as in the solution of Exercise 3, then

$$\Pr(|\bar{X}_n - \theta| \leq 0.1) = \Pr(|Z| \leq 0.05\sqrt{n}) = 2\Phi(0.05\sqrt{n}) - 1.$$

Therefore, this value will be at least 0.95 if and only if  $\Phi(0.05\sqrt{n}) \geq 0.975$ . It is found from a table of values of  $\Phi$  that we must have  $0.05\sqrt{n} \geq 1.96$ . Therefore, we must have  $n \geq 1536.64$  or, since  $n$  must be an integer,  $n \geq 1537$ .

5. When  $p = 0.2$ , the random variable  $Z_n = n\bar{X}_n$  will have a binomial distribution with parameters  $n$  and  $p = 0.2$ , and

$$\Pr(|\bar{X}_n - p| \leq 0.1) = \Pr(0.1n \leq Z_n \leq 0.3n).$$

The value of  $n$  for which this probability will be at least 0.75 must be determined by trial and error from the table of the binomial distribution in the back of the book. For  $n = 8$ , the probability becomes

$$\Pr(0.8 \leq Z_8 \leq 2.4) = \Pr(Z_8 = 1) + \Pr(Z_8 = 2) = 0.3355 + 0.2936 = 0.6291.$$

For  $n = 9$ , we have

$$\Pr(0.9 \leq Z_9 \leq 2.7) = \Pr(Z_9 = 1) + \Pr(Z_9 = 2) = 0.3020 + 0.3020 = 0.6040.$$

For  $n = 10$ , we have

$$\Pr(1 \leq Z_{10} \leq 3) = \Pr(Z_{10} = 1) + \Pr(Z_{10} = 2) + \Pr(Z_{10} = 3) = 0.2684 + 0.3020 + 0.2013 = 0.7717.$$

Hence,  $n = 10$  is sufficient.

It should be noted that although a sample size of  $n = 10$  will meet the required conditions, a sample size of  $n = 11$  will not meet the required conditions. For  $n = 11$ , we would have

$$\Pr(1.1 \leq Z_{11} \leq 3.3) = \Pr(Z_{11} = 2) + \Pr(Z_{11} = 3).$$

Thus, only two terms of the binomial distribution for  $n = 11$  are included, whereas three terms of binomial distribution for  $n = 10$  were included.

6. It is known that when  $p = 0.2$ ,  $E(\bar{X}_n) = p = 0.2$  and  $\text{Var}(\bar{X}_n) = (0.2)(0.8)/n = 0.16/n$ . Therefore,  $Z = (\bar{X}_n - 0.2)/(0.4/\sqrt{n})$  will have approximately a standard normal distribution. It now follows that

$$\Pr(|\bar{X}_n - p| \leq 0.1) = \Pr(|Z| \leq 0.25\sqrt{n}) \approx 2\Phi(0.25\sqrt{n}) - 1.$$

Therefore, this value will be at least 0.95 if and only if  $\Phi(0.25\sqrt{n}) \geq 0.975$  or, equivalently, if and only if  $0.25\sqrt{n} \geq 1.96$ . This final relation is satisfied if and only if  $n \geq 61.5$ . Therefore, the sample size must be  $n \geq 62$ .

7. It follows from the results given in the solution to Exercise 6 that, when  $p = 0.2$ ,

$$E_p(|\bar{X}_n - p|^2) = \text{Var}(\bar{X}_n) = \frac{0.16}{n},$$

and  $0.16/n \leq 0.01$  if and only if  $n \geq 16$ .

8. For an arbitrary value of  $p$ ,

$$E_p(|\bar{X}_n - p|^2) = \text{Var}(\bar{X}_n) = \frac{p(1-p)}{n}.$$

This variance will be a maximum when  $p = 1/2$ , at which point its value is  $1/(4n)$ . Therefore, this variance will be not greater than 0.01 for all values of  $p$  ( $0 \leq p \leq 1$ ) if and only if  $1/(4n) \leq 0.01$  or, equivalently, if and only if  $n \geq 25$ .

9. The M.L.E. is  $\hat{\theta} = n/T$ , where  $T$  was shown to have the gamma distribution with parameters  $n$  and  $\theta$ . Let  $G(\cdot)$  denote the c.d.f. of the sampling distribution of  $T$ . Let  $H(\cdot)$  be the c.d.f. of the sampling distribution of  $\hat{\theta}$ . Then  $H(t) = 0$  for  $t \leq 0$ , and for  $t > 0$ ,

$$H(t) = \Pr(\hat{\theta} \leq t) = \Pr\left(\frac{n}{T} \leq t\right) = \Pr\left(T \geq \frac{n}{t}\right) = 1 - G\left(\frac{n}{t}\right).$$

## 8.2 The Chi-Square Distributions

### Commentary

If one is using the software *R*, then the functions `dchisq`, `pchisq`, and `qchisq` give the p.d.f., the c.d.f., and the quantile function of  $\chi^2$  distributions. The syntax is that the first argument is the argument of the function, and the second is the degrees of freedom. The function `rchisq` gives a random sample of  $\chi^2$  random variables. The first argument is how many you want, and the second is the degrees of freedom. All of the solutions that require the calculation of  $\chi^2$  probabilities or quantiles can be done using these functions instead of tables.

### Solutions to Exercises

1. The distribution of  $20T/0.09$  is the  $\chi^2$  distribution with 20 degrees of freedom. We can write  $\Pr(T \leq c) = \Pr(20T/0.09 \leq 20c/0.09)$ . In order for this probability to be 0.9, we need  $20c/0.09$  to equal the 0.9 quantile of the  $\chi^2$  distribution with 20 degrees of freedom. That quantile is 28.41. Set  $28.41 = 20c/0.09$  and solve for  $c = 0.1278$ .
2. The mode will be the value of  $x$  at which the p.d.f.  $f(x)$  is a maximum or, equivalently, the value of  $x$  at which  $\log f(x)$  is a maximum. We have

$$\log f(x) = (\text{const.}) + \left(\frac{m}{2} - 1\right) \log x - \frac{x}{2}.$$

If  $m = 1$ , this function is strictly decreasing and increases without bound as  $x \rightarrow 0$ . If  $m = 2$ , this function is strictly decreasing and attains its maximum value when  $x = 0$ . If  $m \geq 3$ , the value of  $x$  at which the maximum is attained can be found by setting the derivative with respect to  $x$  equal to 0. In this way it is found that  $x = m - 2$ .

3. The median of each distribution is found from the table of the  $\chi^2$  distribution given at the end of the book.

Figure S.8.1: First figure for Exercise 3 of Sec. 8.2.

Figure S.8.2: Second figure for Exercise 3 of Sec. 8.2.

4. Let  $r$  denote the radius of the circle. The point  $(X, Y)$  will lie inside the circle if and only if  $X^2 + Y^2 < r^2$ . Also,  $X^2 + Y^2$  has a  $\chi^2$  distribution with two degrees of freedom. It is found from the table at the end of the book that  $\Pr(X^2 + Y^2 \leq 9.210) = 0.99$ . Therefore, we must have  $r^2 \geq 9.210$ .
5. We must determine  $\Pr(X^2 + Y^2 + Z^2 \leq 1)$ . Since  $X^2 + Y^2 + Z^2$  has the  $\chi^2$  distribution with three degrees of freedom, it is found from the table at the end of the book that the required probability is slightly less than 0.20.
6. We must determine the probability that, at time 2,  $X^2 + Y^2 + Z^2 \leq 16\sigma^2$ . At time 2, each of the independent variables  $X$ ,  $Y$ , and  $Z$  will have a normal distribution with mean 0 and variance  $2\sigma^2$ . Therefore, each of the variables  $X/\sqrt{2\sigma}$ ,  $Y/\sqrt{2\sigma}$ , and  $Z/\sqrt{2\sigma}$  will have a standard normal distribution. Hence,  $V = (X^2 + Y^2 + Z^2)/(2\sigma^2)$  will have a  $\chi^2$  distribution with three degrees of freedom. It now follows that

$$\Pr(X^2 + Y^2 + Z^2 \leq 16\sigma^2) = \Pr(V < 8).$$

It can now be found from the table at the end of the book that this probability is slightly greater than 0.95.

7. By the probability integral transformation, we know that  $T_i = F_i(X_i)$  has a uniform distribution on the interval  $[0, 1]$ . Now let  $Z_i = -\log T_i$ . We shall determine the p.d.f.  $g$  of  $Z_i$ . The p.d.f. of  $T_i$  is

$$f(t) = \begin{cases} 1 & \text{for } 0 < t < 1, \\ 0 & \text{otherwise.} \end{cases}$$

Since  $T_i = \exp(-Z_i)$ , we have  $dt/dz = -\exp(-z)$ . Therefore, for  $z > 0$ ,

$$g(z) = f(\exp(-z)) \left| \frac{dt}{dz} \right| = \exp(-z).$$

Thus, it is now seen that  $Z_i$  has the exponential distribution with parameter  $\beta = 1$  or, in other words, the gamma distribution with parameters  $\alpha = 1$  and  $\beta = 1$ . Therefore, by Exercise 1 of Sec. 5.7,  $2Z_i$  has the gamma distribution with parameters  $\alpha = 1$  and  $\beta = 1/2$ . Finally, by Theorem 5.7.7  $\sum_{i=1}^n 2Z_i$  will have the gamma distribution with parameters  $\alpha = n$  and  $\beta = 1/2$  or, equivalently, the  $\chi^2$  distribution with  $2n$  degrees of freedom.

8. It was shown in Sec. 3.9 that the p.d.f. of  $W$  is as follows, for  $0 < w < 1$ :

$$h_1(w) = n(n-1)w^{n-2}(1-w).$$

Let  $X = 2n(1-W)$ . Then  $W = 1-X/(2n)$  and  $dw/dx = -1/(2n)$ . Therefore, the p.d.f.  $g_n(x)$  is as follows, for  $0 < x < 2n$ :

$$\begin{aligned} g_n(x) &= h_1 \left( 1 - \frac{x}{2n} \right) \left| \frac{dw}{dx} \right| = n(n-1) \left( 1 - \frac{x}{2n} \right)^{n-2} \left( \frac{x}{2n} \right) \left( \frac{1}{2n} \right) \\ &= \left( \frac{1}{4} \right) \left( \frac{n-1}{n} \right) x \left( 1 - \frac{x}{2n} \right)^{-2} \left( 1 - \frac{x}{2n} \right)^n. \end{aligned}$$

Now, as  $n \rightarrow \infty$ ,

$$\frac{n-1}{n} \rightarrow 1 \text{ and } \left(1 - \frac{x}{2n}\right)^{-2} \rightarrow 1.$$

Also, for any real number  $t$ ,  $(1+t/n)^n \rightarrow \exp(t)$ . Therefore,  $(1-x/(2n))^n \rightarrow \exp(-x/2)$ . Hence, for  $x > 0$ ,

$$g_n(x) \rightarrow \frac{1}{4}x \exp(-x/2).$$

This limit is the p.d.f. of the  $\chi^2$  distribution with four degrees of freedom.

9. It is known that  $\bar{X}_n$  has the normal distribution with mean  $\mu$  and variance  $\sigma^2/n$ . Therefore,  $(\bar{X}_n - \mu)/(\sigma/\sqrt{n})$  has a standard normal distribution and the square of this variable has the  $\chi^2$  distribution with one degree of freedom.
10. Each of the variables  $X_1 + X_2 + X_3$  and  $X_4 + X_5 + X_6$  will have the normal distribution with mean 0 and variance 3. Therefore, if each of them is divided by  $\sqrt{3}$ , each will have a standard normal distribution. Therefore, the square of each will have the  $\chi^2$  distribution with one degree of freedom and the sum of these two squares will have the  $\chi^2$  distribution with two degrees of freedom. In other words,  $Y/3$  will have the  $\chi^2$  distribution with two degrees of freedom.
11. The simplest way to determine the mean is to calculate  $E(X^{1/2})$  directly, where  $X$  has the  $\chi^2$  distribution with  $n$  degrees of freedom. Thus,

$$\begin{aligned} E(X^{1/2}) &= \int_0^\infty x^{1/2} \frac{1}{2^{n/2}\Gamma(n/2)} x^{(n/2)-1} \exp(-x/2) dx = \frac{1}{2^{n/2}\Gamma(n/2)} \int_0^\infty x^{(n-1)/2} \exp(-x/2) dx \\ &= \frac{1}{2^{n/2}\Gamma(n/2)} \cdot 2^{(n+1)/2} \Gamma[(n+1)/2] = \frac{\sqrt{2}\Gamma[(n+1)/2]}{\Gamma(n/2)}. \end{aligned}$$

12. For general  $\sigma^2$ ,

$$\Pr(Y \leq 0.09) = \Pr\left(W \leq \frac{10 \times 0.09}{\sigma^2}\right), \quad (\text{S.8.1})$$

where  $W = 10Y/\sigma^2$  has the  $\chi^2$  distribution with 10 degrees of freedom. The probability in (S.8.1) is at least 0.9 if and only if  $0.9/\sigma^2$  is at least the 0.9 quantile of the  $\chi^2$  distribution with 10 degrees of freedom. This quantile is 15.99, so  $0.9/\sigma^2 \geq 15.99$  is equivalent to  $\sigma^2 \leq 0.0563$ .

13. We already found that the distribution of  $W = n\widehat{\sigma^2}/\sigma^2$  is the  $\chi^2$  distribution with  $n$  degrees of freedom, which is also the gamma distribution with parameters  $n/2$  and  $1/2$ . If we multiply a gamma random variable by a constant, we change its distribution to another gamma distribution with the same first parameter and the second parameter gets divided by the constant. (See Exercise 1 in Sec. 6.3.) Since  $\widehat{\sigma^2} = (\sigma^2/n)W$ , we see that the distribution of  $\widehat{\sigma^2}$  is the gamma distribution with parameters  $n/2$  and  $n/(2\sigma^2)$ .

## 8.3 Joint Distribution of the Sample Mean and Sample Variance

### Commentary

This section contains some relatively mathematical results that rely on some matrix theory. We prove the statistical independence of the sample average and sample variance. We also derive the distribution of the sample variance. If your course does not focus on the mathematical details, then you can safely cite Theorem 8.3.1 and look at the examples without going through the orthogonal matrix results. The mathematical derivations rely on a calculation involving Jacobians (Sec. 3.9) which the instructor might have skipped earlier in the course.

### Solutions to Exercises

1. We found that  $U = n\widehat{\sigma^2}/\sigma^2$  has the  $\chi^2$  distribution with  $n - 1$  degrees of freedom, which is also the gamma distribution with parameters  $(n - 1)/2$  and  $1/2$ . If we multiply a gamma random variable by a number  $c$ , we change the second parameter by dividing it by  $c$ . So, with  $c = \sigma^2/n$ , we find that  $cU = \widehat{\sigma^2}$  has the gamma distribution with parameters  $(n - 1)/2$  and  $n/(2\sigma^2)$ .
2. It can be verified that the matrices in (a), (b), and (e) are orthogonal because in each case the sum of the squares of the elements in each row is 1 and the sum of the products of the corresponding terms in any two different rows is 0. The matrix in (c) is not orthogonal because the sum of squares for the bottom row is not 1. The matrix in (d) is not orthogonal because the sum of the products for rows 1 and 2 (or any other two rows) is not 0.
3. (a) Consider the matrix

$$\mathbf{A} = \begin{bmatrix} 1/\sqrt{2} & 1/\sqrt{2} \\ a_1 & a_2 \end{bmatrix}.$$

For  $\mathbf{A}$  to be orthogonal, we must have  $a_1^2 + a_2^2 = 1$  and  $\frac{1}{\sqrt{2}}a_1 + \frac{1}{\sqrt{2}}a_2 = 0$ . It follows from the second equation that  $a_1 = -a_2$  and, in turn, from the first equation that  $a_1^2 = 1/2$ . Hence, either the pair of values  $a_1 = 1/\sqrt{2}$  and  $a_2 = -1/\sqrt{2}$  or the pair  $a_1 = -1/\sqrt{2}$  and  $a_2 = 1/\sqrt{2}$  will make  $\mathbf{A}$  orthogonal.

- (b) Consider the matrix

$$\mathbf{A} = \begin{bmatrix} 1/\sqrt{3} & 1/\sqrt{3} & 1/\sqrt{3} \\ a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \end{bmatrix}$$

For  $\mathbf{A}$  to be orthogonal, we must have

$$a_1^2 + a_2^2 + a_3^2 = 1$$

and

$$\frac{1}{\sqrt{3}}a_1 + \frac{1}{\sqrt{3}}a_2 + \frac{1}{\sqrt{3}}a_3 = 0.$$

Therefore,  $a_3 = -a_1 - a_2$  and it follows from the first equation that

$$a_1^2 + a_2^2 + (a_1 + a_2)^2 = 2a_1^2 + 2a_2^2 + 2a_1a_2 = 1.$$

Any values of  $a_1$  and  $a_2$  satisfying this equation can be chosen. We shall use  $a_1 = 2/\sqrt{6}$  and  $a_2 = -1/\sqrt{6}$ . Then  $a_3 = -1/\sqrt{6}$ .

Finally, we must have  $b_1^2 + b_2^2 + b_3^2 = 1$  as well as

$$\frac{1}{\sqrt{3}}b_1 + \frac{1}{\sqrt{3}}b_2 + \frac{1}{\sqrt{3}}b_3 = 0$$

and

$$\frac{2}{\sqrt{6}}b_1 - \frac{1}{\sqrt{6}}b_2 - \frac{1}{\sqrt{6}}b_3 = 0.$$

This final pair of equations can be rewritten as

$$b_2 + b_3 = -b_1 \quad \text{and} \quad b_2 + b_3 = 2b_1.$$

Therefore,  $b_1 = 0$  and  $b_2 = -b_3$ . Since we must have  $b_2^2 + b_3^2 = 1$ , it follows that we can use either  $b_2 = 1/\sqrt{2}$  and  $b_3 = -1/\sqrt{2}$  or  $b_2 = -1/\sqrt{2}$  and  $b_3 = 1/\sqrt{2}$ . Thus, one orthogonal matrix is

$$\mathbf{A} = \begin{bmatrix} 1/\sqrt{3} & 1/\sqrt{3} & 1/\sqrt{3} \\ 2/\sqrt{6} & -1/\sqrt{6} & -1/\sqrt{6} \\ 0 & 1/\sqrt{2} & -1/\sqrt{2} \end{bmatrix}$$

4. The  $3 \times 3$  matrix of coefficients of this transformation is

$$A = \begin{bmatrix} 0.8 & 0.6 & 0 \\ (0.3)\sqrt{2} & -(0.4)\sqrt{2} & -(0.5)\sqrt{2} \\ (0.3)\sqrt{2} & -(0.4)\sqrt{2} & (0.5)\sqrt{2} \end{bmatrix}.$$

Since the matrix  $\mathbf{A}$  is orthogonal, it follows from Theorem 8.3.4 that  $Y_1, Y_2$ , and  $Y_3$  are independent and each has a standard normal distribution.

5. Let  $Z_i = (X_i - \mu)/\sigma$  for  $i = 1, 2$ . Then  $Z_1$  and  $Z_2$  are independent and each has a standard normal distribution. Next, let  $Y_1 = (Z_1 + Z_2)/\sqrt{2}$  and  $Y_2 = (Z_1 - Z_2)/\sqrt{2}$ . Then the  $2 \times 2$  matrix of coefficients of this transformation is

$$\mathbf{A} = \begin{bmatrix} 1/\sqrt{2} & 1/\sqrt{2} \\ 1/\sqrt{2} & -1/\sqrt{2} \end{bmatrix}.$$

Since the matrix  $\mathbf{A}$  is orthogonal, it follows from Theorem 8.3.4 that  $Y_1$  and  $Y_2$  are also independent and each has a standard normal distribution. Finally, let  $W_1 = X_1 + X_2$  and  $W_2 = X_1 - X_2$ . Then  $W_1 = \sqrt{2}\sigma Y_1 + 2\mu$  and  $W_2 = \sqrt{2}\sigma Y_2$ . Since  $Y_1$  and  $Y_2$  are independent, it now follows from Exercise 15 of Sec. 3.9 that  $W_1$  and  $W_2$  are also independent.

6. (a) Since  $(X_i - \mu)/\sigma$  has a standard normal distribution for  $i = 1, \dots, n$ , then  $W = \sum_{i=1}^n \frac{(X_i - \mu)^2}{\sigma^2}$

has the  $\chi^2$  distribution with  $n$  degrees of freedom. The required probability can be rewritten as follows:

$$\Pr\left(\frac{n}{2} \leq W \leq 2n\right).$$

Thus, when  $n = 16$ , we must evaluate  $\Pr(8 \leq W \leq 32) = \Pr(W \leq 32) - \Pr(W \leq 8)$ , Where  $W$  has the  $\chi^2$  distribution with 16 degrees of freedom. It is found from the table at the end of the book that  $\Pr(W \leq 32) = 0.99$  and  $\Pr(W \leq 8) = 0.05$ .

- (b) By Theorem 8.3.1,  $V = \frac{\sum_{i=1}^n (X_i - \bar{X}_n)^2}{\sigma^2}$  has the  $\chi^2$  distribution with  $n - 1$  degrees of freedom.

The required probability can be rewritten as follows:

$$\Pr\left(\frac{n}{2} \leq V \leq 2n\right).$$

Thus, when  $n = 16$ , we must evaluate  $\Pr(8 \leq V \leq 32) = \Pr(V \leq 32) - \Pr(V \leq 8)$ , Where  $V$  has the  $\chi^2$  distribution with 15 degrees of freedom. It is found from the table that  $\Pr(V \leq 32) = 0.993$  and  $\Pr(V \leq 8) = 0.079$ .

7. (a) The random variable  $V = n\hat{\sigma}^2/\sigma^2$  has a  $\chi^2$  distribution with  $n - 1$  degrees of freedom. The required probability can be written in the form  $\Pr(V \leq 1.5n) \geq 0.95$ . By trial and error, it is found that for  $n = 20$ ,  $V$  has 19 degrees of freedom and  $\Pr(V \leq 30) < 0.95$ . However, for  $n = 21$ ,  $V$  has 20 degrees of freedom and  $\Pr(V \leq 31.5) > 0.95$ .

- (b) The required probability can be written in the form

$$\Pr\left(\frac{n}{2} \leq V \leq \frac{3n}{2}\right) = \Pr\left(V \leq \frac{3n}{2}\right) - \Pr\left(V \leq \frac{n}{2}\right),$$

where  $V$  again has the  $\chi^2$  distribution with  $n - 1$  degrees of freedom. By trial and error, it is found that for  $n = 12$ ,  $V$  has 11 degrees of freedom and

$$\Pr(V \leq 18) - \Pr(V \leq 6) = 0.915 - 0.130 < 0.8.$$

However, for  $n = 13$ ,  $V$  has 12 degrees of freedom and

$$\Pr(V \leq 19.5) - \Pr(V \leq 6.5) = 0.919 - 0.113 > 0.8.$$

8. If  $X$  has the  $\chi^2$  distribution with 200 degrees of freedom, then it follows from Theorem 8.2.2 that  $X$  can be represented as the sum of 200 independent and identically distributed random variables, each of which has a  $\chi^2$  distribution with one degree of freedom. Since  $E(X) = 200$  and  $\text{Var}(X) = 400$ , it follows from the central limit theorem that  $Z = (X - 200)/20$  will have approximately a standard normal distribution. Therefore,

$$\Pr(160 < X < 240) = \Pr(-2 < Z < 2) \approx 2\Phi(2) - 1 = 0.9546.$$

9. The sample mean and the sample variance are independent. Therefore, the information that the sample variance is closer to  $\sigma^2$  in one sample than it is in the other sample provides no information about which of the two sample means will be closer to  $\mu$ . In other words, in either sample, the conditional distribution of  $\bar{X}_n$ , given the observed value of the sample variance, is still the normal distribution with mean  $\mu$  and variance  $\sigma^2/n$ .

## 8.4 The $t$ Distributions

### Commentary

In this section, we derive the p.d.f. of the  $t$  distribution. That portion of the section (entitled “Derivation of the p.d.f.”) can be skipped by instructors who do not wish to focus on mathematical details. Indeed, the derivation involves the use of Jacobians (Sec. 3.9) that the instructor might have skipped earlier in the course.

If one is using the software  $R$ , then the functions `dt`, `pt`, and `qt` give the p.d.f., the c.d.f., and the quantile function of  $t$  distributions. The syntax is that the first argument is the argument of the function, and the second is the degrees of freedom. The function `rt` gives a random sample of  $t$  random variables. The first argument is how many you want, and the second is the degrees of freedom. All of the solutions that require the calculation of  $t$  probabilities or quantiles can be done using these functions instead of tables.

**Solutions to Exercises**

$$1. E(X^2) = c \int_{-\infty}^{\infty} x^2 \left(1 + \frac{x^2}{n}\right)^{-(n+1)/2} dx = 2c \int_0^{\infty} x^2 \left(1 + \frac{x^2}{n}\right)^{-(n+1)/2} dx,$$

where  $c = \frac{\Gamma[(n+1)/2]}{(n\pi)^{1/2}\Gamma(n/2)}$ . If  $y$  is defined as in the hint for this exercise, then  $x = \left(\frac{ny}{1-y}\right)^{1/2}$  and  $\frac{dx}{dy} = \frac{\sqrt{n}}{2}y^{-1/2}(1-y)^{-3/2}$ . Therefore,

$$\begin{aligned} E(X^2) &= \sqrt{n}(\text{const.}) \int_0^1 \frac{ny}{1-y} \left(1 + \frac{y}{1-y}\right)^{-(n+1)/2} y^{-1/2}(1-y)^{-3/2} dy \\ &= n^{3/2}(\text{const.}) \int_0^1 y^{1/2}(1-y)^{(n-4)/2} dy \\ &= n^{3/2}(\text{const.}) \frac{\Gamma(3/2)\Gamma[(n-2)/2]}{\Gamma[(n+1)/2]} = n\pi^{-1/2}\Gamma\left(\frac{3}{2}\right) \cdot \frac{\Gamma[(n-2)/2]}{\Gamma(n/2)} \\ &= n\pi^{-1/2} \left(\frac{1}{2}\sqrt{\pi}\right) \frac{1}{[(n-2)/2]} = \frac{n}{n-2}. \end{aligned}$$

Since  $E(X) = 0$ , it now follows that  $\text{Var}(X) = n/(n-2)$ .

2. Since  $\hat{\mu} = \bar{X}_n$  and  $\hat{\sigma}^2 = S_n^2/n$ , it follows from the definition of  $U$  in Eq. (8.4.4) that

$$\Pr(\hat{\mu} > \mu + k\hat{\sigma}) = \Pr\left(\frac{\bar{X}_n - \mu}{\hat{\sigma}} > k\right) = \Pr[U > k(n-1)^{1/2}].$$

Since  $U$  has the  $t$  distribution with  $n-1$  degrees of freedom and  $n=17$ , we must choose  $k$  such that  $\Pr(U > 4k) = 0.95$ . It is found from a table of the  $t$  distribution with 16 degrees of freedom that  $\Pr(U < 1.746) = 0.95$ . Hence, by symmetry,  $\Pr(U > -1.746) = 0.95$ . It now follows that  $4k = -1.746$  and  $k = -0.4365$ .

3.  $X_1 + X_2$  has the normal distribution with mean 0 and variance 2. Therefore,  $Y = (X_1 + X_2)/\sqrt{2}$  has a standard normal distribution. Also,  $Z = X_3^2 + X_4^2 + X_5^2$  has the  $\chi^2$  distribution with 3 degrees of freedom, and  $Y$  and  $Z$  are independent. Therefore,  $U = \frac{Y}{(Z/3)^{1/2}}$  has the  $t$  distribution with 3 degrees of freedom. Thus, if we choose  $c = \sqrt{3/2}$ , the given random variable will be equal to  $U$ .

4. Let  $y = x/2$ . Then

$$\begin{aligned} \int_{-\infty}^{2.5} \frac{dx}{(12+x^2)^2} &= \frac{1}{144} \int_{-\infty}^{2.5} \left(1 + \frac{x^2}{12}\right)^{-2} dx \\ &= \frac{1}{72} \int_{-\infty}^{1.25} \left(1 + \frac{y^2}{3}\right)^{-2} dy \\ &= \frac{\sqrt{3\pi}\Gamma(3/2)}{\Gamma(2)} \left(\frac{1}{72}\right) \int_{-\infty}^{1.25} g_3(y) dy, \end{aligned}$$

where  $g_3(y)$  is the p.d.f. of the  $t$  distribution with 3 degrees of freedom. It is found from the table of this distribution that the value of the integral is 0.85. Hence, the desired value is

$$\frac{\sqrt{3\pi}\Gamma\left(\frac{3}{2}\right)}{\Gamma(2)} \left(\frac{1}{72}\right) (0.85) = \frac{\sqrt{3\pi} \left(\frac{1}{2}\sqrt{\pi}\right) (0.85)}{72} = \frac{\sqrt{3}(0.85)\pi}{144}.$$

5. Let  $\bar{X}_2 = (X_1 + X_2)/2$  and  $S_2^2 = \sum_{i=1}^2 (X_i - \bar{X}_2)^2$ . Then

$$W = \frac{(X_1 + X_2)^2}{(X_1 - X_2)^2} = \frac{2\bar{X}_2^2}{S_2^2}.$$

It follows from Eq. (8.4.4) that  $U = \sqrt{2}\bar{X}_2/\sqrt{S_2^2}$  has the  $t$  distribution with one degree of freedom. Since  $W = U^2$ , we have

$$\Pr(W < 4) = \Pr(-2 < U < 2) = 2\Pr(U < 2) - 1.$$

It can be found from a table of the  $t$  distribution with one degree of freedom that  $\Pr(U < 2)$  is just slightly greater than 0.85. Hence,  $\Pr(W < 4) = 0.70$ .

6. The distribution of  $U = (20)^{1/2}(\bar{X}_{20} - \mu)/\sigma'$  is a  $t$  distribution with 19 degrees of freedom. Let  $v$  be the 0.95 quantile of this  $t$  distribution, namely 1.729. Then

$$0.95 = \Pr(U \leq 1.729) = \Pr(\bar{X}_{20} \leq \mu + 1.729/(20)^{1/2}\sigma').$$

It follows that we want  $c = 1.729/(20)^{1/2} = 0.3866$ .

7. According to Theorem 5.7.4,

$$\begin{aligned} \lim_{m \rightarrow \infty} \frac{(2\pi)^{1/2}(m + 1/2)^m \exp(-m - 1/2)}{\Gamma(m + 1/2)} &= 1, \\ \lim_{m \rightarrow \infty} \frac{(2\pi)^{1/2}(m)^{m-1/2} \exp(-m)}{\Gamma(m)} &= 1. \end{aligned}$$

Taking the ratio of the above and dividing by  $m^{1/2}$ , we get

$$\begin{aligned} \lim_{m \rightarrow \infty} \frac{\Gamma(m + 1/2)}{\Gamma(m)m^{1/2}} &= \lim_{m \rightarrow \infty} \frac{(2\pi)^{1/2}(m + 1/2)^m \exp(-m - 1/2)}{(2\pi)^{1/2}(m)^{m-1/2} \exp(-m)m^{1/2}} \\ &= \lim_{m \rightarrow \infty} \left( \frac{m + 1/2}{m} \right)^m \exp(-1/2) \\ &= 1, \end{aligned}$$

where the last equality follows from Theorem 5.3.3 applied to  $(1 + 1/(2m))^m$ .

8. Let  $f$  be the p.d.f. of  $X$  and let  $g$  be the p.d.f. of  $Y$ . Define

$$h(c) = \Pr(-c < X < c) - \Pr(-c < Y < c) = \int_{-c}^c [f(x) - g(x)]dx. \quad (\text{S.8.2})$$

Suppose that  $c_0$  can be chosen so that  $f(x) > g(x)$  for all  $-c_0 < x < c_0$  and  $f(x) < g(x)$  for all  $|x| > c_0$ . It should now be clear that  $h(c_0) = \max_c h(c)$ . To prove this, first let  $c > c_0$ . Then

$$h(c) = h(c_0) + \int_{-c}^{-c_0} [f(x) - g(x)]dx + \int_{c_0}^c [f(x) - g(x)]dx.$$

Since  $f(x) - g(x) < 0$  for all  $x$  in these last two integrals,  $h(c) < h(c_0)$ . Similarly, if  $0 < c < c_0$ ,

$$h(c) = h(c_0) - \int_{-c_0}^c [f(x) - g(x)]dx - \int_c^{c_0} [f(x) - g(x)]dx.$$

Since  $f(x) - g(x) > 0$  for all  $x$  in these last two integrals,  $h(c) < h(c_0)$ . Finally, notice that the standard normal p.d.f. is greater than the  $t$  p.d.f. with five degrees of freedom for all  $-c < x < c$  if  $c = 1.63$  and the normal p.d.f. is smaller than the  $t$  p.d.f. if  $|x| > 1.63$ .

## 8.5 Confidence Intervals

### Commentary

This section ends with an extended discussion of shortcomings of confidence intervals. The first paragraph on interpretation is fairly straightforward. Students at this level should be able to understand what the confidence statement is and is not saying. The long Example 8.5.11 illustrates how additional information that is available can be ignored in the confidence statement. Instructors should gauge the mathematical abilities of their students before discussing this example in detail. Although there is nothing more complicated than what has appeared earlier in the text, it does make use of multivariable calculus and some subtle reasoning.

Many instructors will recognize the statistic  $Z$  in Example 8.5.11 as an ancillary. In many examples, conditioning on an ancillary is one way of making confidence levels (and significance levels) more representative of the amount of information available. The concept of ancillarity is beyond the scope of this text, and it is not pursued in the example. The example merely raises the issue that available information like  $Z$  is not necessarily taken into account in reporting a confidence coefficient. This makes the connection between the statistical meaning of confidence and the colloquial meaning more tenuous.

If one is using the software  $R$ , remember that `qnorm` and `qt` compute quantiles of normal and  $t$  distributions. These quantiles are ubiquitous in the construction of confidence intervals.

### Solutions to Exercises

1. We need to show that

$$\Pr \left[ \overline{X}_n - \Phi^{-1} \left( \frac{1+\gamma}{2} \right) \frac{\sigma}{n^{1/2}} < \mu < \overline{X}_n + \Phi^{-1} \left( \frac{1+\gamma}{2} \right) \frac{\sigma}{n^{1/2}} \right] = \gamma. \quad (\text{S.8.3})$$

By subtracting  $\overline{X}_n$  from all three sides of the above inequalities and then dividing all three sides by  $\sigma/n^{1/2} > 0$ , we can rewrite the probability in (S.8.3) as

$$\Pr \left[ -\Phi^{-1} \left( \frac{1+\gamma}{2} \right) < \frac{\mu - \overline{X}_n}{\sigma/n^{1/2}} < \Phi^{-1} \left( \frac{1+\gamma}{2} \right) \right].$$

The random variable  $(\mu - \overline{X}_n)/(\sigma/n^{1/2})$  has a standard normal distribution no matter what  $\mu$  and  $\sigma^2$  are. And the probability that a standard normal random variable is between  $-\Phi^{-1}([1+\gamma]/2)$  and  $\Phi^{-1}([1+\gamma]/2)$  is  $(1+\gamma)/2 - [1 - (1+\gamma)/2] = \gamma$ .

2. In this exercise,  $\overline{X}_n = 3.0625$ ,  $\sigma' = \left[ \sum_{i=1}^n (X_i - \overline{X}_n)^2 / (n-1) \right]^{1/2} = 0.5125$  and  $\sigma'/n^{1/2} = 0.1812$ . Therefore, the shortest confidence interval for  $\mu$  will have the form  $3.0625 - 0.1812c < \mu < 3.0625 + 0.1812c$ .

If a confidence coefficient  $\gamma$  is to be used, then  $c$  must satisfy the relation  $\Pr(-c < U < c) = \gamma$ , where  $U$  has the  $t$  distribution with  $n - 1 = 7$  degrees of freedom. By symmetry,

$$\Pr(-c < U < c) = \Pr(U < c) - \Pr(U < -c) = \Pr(U < c) - [1 - \Pr(U < c)] = 2\Pr(U < c) - 1.$$

As in the text, we find that  $c$  must be the  $(1 + \gamma)/2$  quantile of the  $t$  distribution with 7 degrees of freedom.

- (a) Here  $\gamma = 0.90$ , so  $(1 + \gamma)/2 = 0.95$ . It is found from a table of the  $t$  distribution with 7 degrees of freedom that  $c = 1.895$ . Therefore, the confidence interval for  $\mu$  has endpoints  $3.0625 - (0.1812)(1.895) = 2.719$  and  $3.0625 + (0.1812)(1.895) = 3.406$ .
- (b) Here  $\gamma = 0.95$ ,  $(1 + \gamma)/2 = 0.975$ , and  $c = 2.365$ . Therefore, the endpoints of the confidence interval for  $\mu$  are  $3.0625 - (0.1812)(2.365) = 2.634$  and  $3.0625 + (0.1813)(2.365) = 3.491$ .
- (c) Here  $\gamma = 0.99$ ,  $(1 + \gamma)/2 = 0.995$ , and  $c = 3.499$ . Therefore, the endpoints of the interval are 2.428 and 3.697.

One obvious feature of this exercise, that should be emphasized, is that the larger the confidence coefficient  $\gamma$ , the wider the confidence interval must be.

3. The endpoints of the confidence interval are  $\bar{X}_n - c\sigma'/n^{1/2}$  and  $\bar{X}_n + c\sigma'/n^{1/2}$ . Therefore,  $L = 2\sigma'/n^{1/2}$  and  $L^2 = 4c^2\sigma'^2/n$ . Since

$$W = \frac{\sum_{i=1}^n (X_i - \bar{X}_n)^2}{\sigma^2}$$

has the  $\chi^2$  distribution with  $n - 1$  degrees of freedom,  $E(W) = n - 1$ . Therefore,  $E(\sigma'^2) = E(\sigma^2 W / [n - 1]) = \sigma^2$ . It follows that  $E(L^2) = 4c^2\sigma^2/n$ . As in the text,  $c$  must be the  $(1 + \gamma)/2$  quantile of the  $t$  distribution with  $n - 1$  degrees of freedom.

- (a) Here,  $(1 + \gamma)/2 = 0.975$ . Therefore, from a table of the  $t$  distribution with  $n - 1 = 4$  degrees of freedom it is found that  $c = 2.776$ . Hence,  $c^2 = 7.706$  and  $E(L^2) = 4(7.706)\sigma^2/5 = 6.16\sigma^2$ .
- (b) For the  $t$  distribution with 9 degrees of freedom,  $c = 2.262$ . Hence,  $E(L^2) = 2.05\sigma^2$ .
- (c) Here,  $c = 2.045$  and  $E(L^2) = 0.56\sigma^2$ .

It should be noted from parts (a), (b), and (c) that for a fixed value of  $\gamma$ ,  $E(L^2)$  decreases as the sample size  $n$  increases.

- (d) Here,  $\gamma = 0.90$ , so  $(1 + \gamma)/2 = 0.95$ . It is found that  $c = 1.895$ . Hence,  $E(L^2) = 4(1.895)^2\sigma^2/8 = 1.80\sigma^2$ .
- (e) Here,  $\gamma = 0.95$ , so  $(1 + \gamma)/2 = 0.975$  and  $c = 2.365$ . Hence,  $E(L^2) = 2.80\sigma^2$ .
- (f) Here,  $\gamma = 0.99$ , so  $(1 + \gamma)/2 = 0.995$  and  $c = 3.499$ . Hence,  $E(L^2) = 6.12\sigma^2$ .

It should be noted from parts (d), (e), and (f) that for a fixed sample size  $n$ ,  $E(L^2)$  increases as  $\gamma$  increases.

4. Since  $\sqrt{n}(\bar{X}_n - \mu)/\sigma$  has a standard normal distribution,  $\Pr\left[-1.96 < \frac{\sqrt{n}(\bar{X}_n - \mu)}{\sigma} < 1.96\right] = 0.95$ .

This relation can be rewritten in the form

$$\Pr\left(\bar{X}_n - \frac{1.96\sigma}{\sqrt{n}} < \mu < \bar{X}_n + \frac{1.96\sigma}{\sqrt{n}}\right) = 0.95.$$

Therefore, the interval with endpoints  $\bar{X}_n - 1.96\sigma/\sqrt{n}$  and  $\bar{X}_n + 1.96\sigma/\sqrt{n}$  will be a confidence interval for  $\mu$  with confidence coefficient 0.95. The length of this interval will be  $3.92\sigma/\sqrt{n}$ . It now follows that  $3.92\sigma/\sqrt{n} < 0.01\sigma$  if and only if  $\sqrt{n} > 392$ . This means that  $n > 153664$  of  $n = 153665$  or more.

5. Since  $\sum_{i=1}^n (X_i - \bar{X}_n)^2 / \sigma^2$  has a  $\chi^2$  distribution with  $n - 1$  degrees of freedom, it is possible to find constants  $c_1$  and  $c_2$  which satisfy the relation given in the hint for this exercise. (As explained in this section, there are an infinite number of different pairs of values of  $c_1$  and  $c_2$  that might be used.) The relation given in the hint can be rewritten in the form

$$\Pr \left[ \frac{1}{c_2} \sum_{i=1}^n (X_i - \bar{X}_n)^2 < \sigma^2 < \frac{1}{c_1} \sum_{i=1}^n (X_i - \bar{X}_n)^2 \right] = \gamma.$$

Therefore, the interval with endpoints equal to the observed values of  $\sum_{i=1}^n (X_i - \bar{X}_n)^2 / c_2$  and  $\sum_{i=1}^n (X_i - \bar{X}_n)^2 / c_1$  will be a confidence interval for  $\sigma^2$  with confidence coefficient  $\gamma$ .

6. The exponential distribution with mean  $\mu$  is the same as the gamma distribution with  $\alpha = 1$  and  $\beta = 1/\mu$ . Therefore, by Theorem 5.7.7,  $\sum_{i=1}^n X_i$  will have the gamma distribution with parameters  $\alpha = n$  and  $\beta = 1/\mu$ . In turn, it follows from Exercise 1 of Sec. 5.7 that  $\sum_{i=1}^n X_i / \mu$  has the gamma distribution with parameters  $\alpha = n$  and  $\beta = 1$ . It follows from Definition 8.2.1 that  $2 \sum_{i=1}^n X_i / \mu$  has the  $\chi^2$  distribution with  $2n$  degrees of freedom. Constants  $c_1$  and  $c_2$  which satisfy the relation given in the hint for this exercise will then each be  $1/2$  times some quantile of the  $\chi^2$  distribution with  $2n$  degrees of freedom. There are an infinite number of pairs of values of such quantiles, one corresponding to each pair of numbers  $q_1 \geq 0$  and  $q_2 \geq 0$  such that  $q_2 - q_1 = \gamma$ . For example, with  $q_1 = (1 - \gamma)/2$  and  $q_2 = (1 + \gamma)/2$  we can let  $c_i$  be  $1/2$  times the  $q_i$  quantile of the  $\chi^2$  distribution with  $2n$  degrees of freedom for  $i = 1, 2$ . It now follows that

$$\Pr \left( \frac{1}{c_2} \sum_{i=1}^n X_i < \mu < \frac{1}{c_1} \sum_{i=1}^n X_i \right) = \gamma.$$

Therefore, the interval with endpoints equal to the observed values of  $\sum_{i=1}^n X_i / c_2$  and  $\sum_{i=1}^n X_i / c_1$  will be a confidence interval for  $\mu$  with confidence coefficient  $\gamma$ .

7. The average of the  $n = 20$  values is  $\bar{x}_n = 156.85$ , and  $\sigma' = 22.64$ . The appropriate  $t$  distribution quantile is  $T_{19}^{-1}(0.95) = 1.729$ . The endpoints of the confidence interval are then  $156.85 \pm 22.64 \times 1.729/20^{1/2}$ . Completing the calculation, we get the interval  $(148.1, 165.6)$ .
8. According to (8.5.15),  $\Pr(|\bar{X}_2 - \theta| < 0.3 | Z = 0.9) = 1$ , because  $0.3 > (1 - 0.9)/2$ . Since  $Z = 0.9$ , we know that the interval between  $X_1$  and  $X_2$  covers a length of 0.9 in the interval  $[\theta - 1/2, \theta + 1/2]$ . Hence  $\bar{X}_2$  has to lie between

$$\frac{\theta - 1/2 + (\theta - 1/2 + .9)}{2} = \theta - 0.05 \quad \text{and} \quad \frac{\theta - 1/2 + 0.1 + \theta + 1/2}{2} = \theta + 0.05.$$

Hence  $\bar{X}_2$  must be within 0.05 of  $\theta$ , hence well within 0.3 of  $\theta$ .

9. (a) The interval between the smaller and larger values is  $(4.7, 5.3)$ .  
 (b) The values of  $\theta$  consistent with the observed data are those between  $5.3 - 0.5 = 4.8$  and  $4.7 + 0.5 = 5.2$ .  
 (c) The interval in part (a) contains the set of all possible  $\theta$  values, hence it is larger than the set of possible  $\theta$  values.  
 (d) The value of  $Z$  is  $5.3 - 4.7 = 0.6$ .  
 (e) According to (8.5.15),

$$\Pr(|\bar{X}_2 - \theta| < 0.1 | Z = 0.6) = \frac{2 \times 0.1}{1 - 0.6} = 0.5.$$

10. (a) The likelihood function is

$$f(\mathbf{x}|\theta) = \begin{cases} 1 & \text{if } 4.8 < \theta < 5.2, \\ 0 & \text{otherwise.} \end{cases}$$

(See the solution to Exercise 9(b) to see how the numbers 4.8 and 5.2 arise.) The posterior p.d.f. of  $\theta$  is proportional to this likelihood times the prior p.d.f., hence the posterior p.d.f. is

$$\begin{cases} c \exp(-0.1\theta) & \text{if } 4.8 < \theta < 5.2, \\ 0 & \text{otherwise,} \end{cases}$$

where  $c$  is a constant that makes this function into a p.d.f. The constant must satisfy

$$c \int_{4.8}^{5.2} \exp(-0.1\theta) d\theta = 1.$$

Since the integral above equals  $10[\exp(-0.48) - \exp(-0.52)] = 0.2426$ , we must have  $c = 1/0.2426 = 4.122$ .

- (b) The observed value of  $\bar{X}_2$  is  $\bar{x}_2 = 5$ . So, the posterior probability that  $|\theta - \bar{x}_2| < 0.1$  is

$$\int_{4.9}^{5.1} 4.122 \exp(-0.1\theta) d\theta = 41.22[\exp(-0.49) - \exp(-0.51)] = 0.5.$$

- (c) Since the interval in part (a) of Exercise 9 contains the entire set of possible  $\theta$  values, the posterior probability that  $\theta$  lies in that interval is 1.  
 (d) The posterior p.d.f. of  $\theta$  is almost constant over the interval  $(4.8, 5.2)$ , hence the c.d.f. will be almost linear. The function in (8.5.15) is also linear. Indeed, for  $c \leq 0.2$ , the posterior probability of  $|\theta - 5| < c$  equals

$$\begin{aligned} \int_{5-c}^{5+c} 4.122 \exp(-0.1\theta) d\theta &= 41.22 \exp(-0.5)[\exp(0.1c) - \exp(-0.1c)] \\ &\approx 25 \times 2 \times 0.1c = 5c. \end{aligned}$$

Since  $z = 0.6$  in this example,  $5c = 2c/(1-z)$ , the same as (8.5.15).

11. The variance stabilizing transformation is  $\alpha(x) = \arcsin(x^{1/2})$ , and the approximate distribution of  $\alpha(\bar{X}_n)$  is the normal distribution with mean  $\alpha(p)$  and variance  $1/n$ . So,

$$\Pr\left(\arcsin(\bar{X}_n^{1/2}) - \Phi^{-1}([1+\gamma]/2)n^{-1/2} < \arcsin p^{1/2} < \arcsin(\bar{X}_n^{1/2}) + \Phi^{-1}([1+\gamma]/2)n^{-1/2}\right) \approx \gamma.$$

This would make the interval with endpoints

$$\arcsin(\bar{x}_n^{1/2}) \pm \Phi^{-1}([1+\gamma]/2)n^{-1/2} \quad (\text{S.8.4})$$

an approximate coefficient  $\gamma$  confidence interval for  $\arcsin(p^{1/2})$ . The transformation  $\alpha(x)$  has an inverse  $\alpha^{-1}(y) = \sin^2(y)$  for  $0 \leq y \leq \pi/2$ . If the endpoints in (S.8.4) are between 0 and  $\pi/2$ , then the interval with endpoints

$$\sin^2 \left( \arcsin(\bar{x}_n^{1/2}) \pm \Phi^{-1}([1 + \gamma]/2)n^{-1/2} \right) \quad (\text{S.8.5})$$

will be an approximate coefficient  $\gamma$  confidence interval for  $p$ . If the lower endpoint in (S.8.4) is negative replace the lower endpoint in (S.8.5) by 0. If the upper endpoint in (S.8.4) is greater than  $\pi/2$ , replace the upper endpoint in (S.8.5) by 1. With these modifications, the interval with the endpoints in (S.8.5) becomes an approximate coefficient  $\gamma$  confidence interval for  $p$ .

12. For this part of the proof, we define

$$\begin{aligned} A &= r\left(G^{-1}(\gamma_2), \mathbf{X}\right), \\ B &= r\left(G^{-1}(\gamma_1), \mathbf{X}\right). \end{aligned}$$

If  $r(v, \mathbf{x})$  is strictly decreasing in  $v$  for each  $\mathbf{x}$ , we have

$$V(\mathbf{X}, \theta) < c \text{ if and only if } g(\theta) > r(c, \mathbf{X}). \quad (\text{S.8.6})$$

Let  $c = G^{-1}(\gamma_i)$  in Eq. (S.8.6) for each of  $i = 1, 2$  to obtain

$$\Pr(g(\theta) > B) = \gamma_1, \quad \Pr(g(\theta) > A) = \gamma_2. \quad (\text{S.8.7})$$

Because  $V$  has a continuous distribution and  $r$  is strictly decreasing,

$$\Pr(A = g(\theta)) = \Pr(V(\mathbf{X}, \theta) = G^{-1}(\gamma_2)) = 0,$$

and similarly  $\Pr(B = g(\theta)) = 0$ . The two equations in (S.8.7) combine to give  $\Pr(A < g(\theta) < B) = \gamma$ .

## 8.6 Bayesian Analysis of Samples from a Normal Distribution

### Commentary

Obviously, this section should only be covered by those who are treating Bayesian topics. One might find it useful to discuss the interpretation of the prior hyperparameters in terms of amount of information and prior estimates. In this sense  $\lambda_0$  and  $2\alpha_0$  represent amounts of prior information about the mean and variance respectively, while  $\mu_0$  and  $\beta_0/\alpha_0$  are prior estimates of the mean and variance respectively. The corresponding posterior estimates are then weighted averages of the prior estimates and data-based estimates with weights equal to the amounts of information. The posterior estimate of variance, namely  $\beta_1/\alpha_1$  is the weighted average of  $\beta_0/\alpha_0$  (with weight  $2\alpha_0$ ),  $\sigma'^2$  (with weight  $n - 1$ ), and  $n\lambda_0(\bar{x}_n - \mu_0)^2/(\lambda_0 + n)$  (with weight 1). This last term results from the fact that the prior distribution of the mean depends on variance (precision), hence how far  $\bar{x}_n$  is from  $\mu_0$  tells us something about the variance also.

If one is using the software *R*, the functions `qt` and `pt` respectively compute the quantile function and c.d.f. of a *t* distribution. These functions can replace the use of tables for some of the calculations done in this section and in the exercises.

## Solutions to Exercises

1. Since  $X$  has the normal distribution with mean  $\mu$  and variance  $1/\tau$ , we know that  $Y$  has the normal distribution with mean  $a\mu + b$  and variance  $a^2/\tau$ . Therefore, the precision of  $Y$  is  $\tau/a^2$ .
2. This exercise is merely a restatement of Theorem 7.3.3 with  $\theta$  replaced by  $\mu$ ,  $\sigma^2$  replaced by  $1/\tau$ ,  $\mu$  replaced by  $\mu_0$ , and  $v^2$  replaced by  $1/\lambda_0$ . The precision of the posterior distribution is the reciprocal of the variance of the posterior distribution given in that theorem.
3. The joint p.d.f.  $f_n(\mathbf{x}|\tau)$  of  $X_1, \dots, X_n$  is given shortly after Definition 8.6.1 in the text, and the prior p.d.f.  $\xi(\tau)$  is proportional to the expression  $\xi_2(\tau)$  in the proof of Theorem 8.6.1. Therefore, the posterior p.d.f. of  $\tau$  satisfies the following relation:

$$\begin{aligned}\xi(\tau | \mathbf{x}) &\propto f_n(\mathbf{x} | \tau) \xi(\tau) \propto \tau^{n/2} \exp\left\{-\frac{1}{2} \sum_{i=1}^n (x_i - \mu)^2\right\} \tau^{\alpha_0-1} \exp(-\beta_0 \tau) \\ &= \tau^{\alpha_0+(n/2)-1} \exp\left\{-\left[\beta_0 + \frac{1}{2} \sum_{i=1}^n (x_i - \mu)^2\right] \tau\right\}.\end{aligned}$$

It can now be seen that this posterior p.d.f. is, except for a constant factor, the p.d.f. of the gamma distribution specified in the exercise.

4. The posterior distribution of  $\tau$ , after using the usual improper prior, is the gamma distribution with parameters  $(n-1)/2$  and  $s_n^2/2$ . Now,  $V$  is a constant  $(n-1)\sigma'^2$  times  $\tau$ , so  $V$  has the gamma distribution with parameters  $(n-1)/2$  and  $(s_n^2/2)/[(n-1)\sigma'^2] = 1/2$ . This last gamma distribution is also known as the  $\chi^2$  distribution with  $n-1$  degrees of freedom.
5. Since  $E(\tau) = \alpha_0/\beta_0 = 1/2$  and  $\text{Var}(\tau) = \alpha_0/\beta_0^2 = 1/3$ , then  $\alpha_0 = 2$  and  $\beta_0 = 4$ . Also,  $\mu_0 = E(\mu) = -5$ . Finally,  $\text{Var}(\mu) = \beta_0/[\lambda_0(\alpha_0 - 1)] = 1$ . Therefore,  $\lambda_0 = 4$ .
6. Since  $E(\tau) = \alpha_0/\beta_0 = 1/2$  and  $\text{Var}(\tau) = \alpha_0/\beta_0^2 = 1/4$ , then  $\alpha_0 = 1$  and  $\beta_0 = 2$ . But  $\text{Var}(\mu)$  is finite only if  $\alpha_0 > -1$ .
7. Since  $E(\tau) = \alpha_0/\beta_0 = 1$  and  $\text{Var}(\tau) = \alpha_0/\beta_0^2 = 4$ , then  $\alpha_0 = \beta_0 = 1/4$ . But  $E(\mu)$  exists only if  $\alpha_0 > 1/2$ .
8. It follows from Theorem 8.6.2 that the random variable  $U = (\mu - 4)/4$  has the  $t$  distribution with  $2\alpha_0 = 2$  degrees of freedom.
  - $\Pr(\mu > 0) = \Pr(Y > -1) = \Pr(Y < 1) = 0.79$ .
  - $\Pr(0.736 < \mu < 15.680) = \Pr(-0.816 < Y < 2.920)$

$$\begin{aligned}&= \Pr(Y < 2.920) - \Pr(Y < -0.816) \\ &= \Pr(Y < 2.920) - [1 - \Pr(Y < 0.816)] \\ &= 0.95 - (1 - 0.75) = 0.70.\end{aligned}$$

9. (a) The posterior hyperparameters are computed in the example. The degrees of freedom are  $2\alpha_1 = 22$ , so the quantile from the  $t$  distribution is  $T_{22}^{-1}([1+.9]/2) = 1.717$ , and the interval is

$$\mu_1 \pm 1.717 \left( \frac{\beta_1}{\lambda_1 \alpha_1} \right)^{1/2} = 183.95 \pm 1.717 \left( \frac{50925.37}{20 \times 11} \right)^{1/2} = (157.83, 210.07).$$

- (b) This interval has endpoints  $182.17 \pm (88678.5/[17 \times 18])^{1/2} T_{17}^{-1}(0.95)$ . With  $T_{17}^{-1}(0.95) = 1.740$ , we get the interval  $(152.55, 211.79)$ .
10. Since  $E(\tau) = \alpha_0/\beta_0 = 2$  and
- $$\text{Var}(\tau) = \frac{\alpha_0}{\beta_0^2} = E(\tau^2) - [E(\tau)]^2 = 1,$$
- then  $\alpha_0 = 4$  and  $\beta_0 = 2$ . Also  $\mu_0 = E(\mu) = 0$ . Therefore, by Eq. (14),  $Y = (2\lambda_0)^{1/2}\mu$  has a t distribution with  $2\alpha_0 = 8$  degrees of freedom. It is found from a table of the t distribution that  $\Pr(|Y| < 0.706) = 0.5$ . Therefore,  $\Pr\left(|\mu| < \frac{0.706}{(2\lambda_0)^{1/2}}\right) = 0.5$ . It now follows from the condition given in the exercise that  $\frac{0.706}{(2\lambda_0)^{1/2}} = 1.412$ . Hence,  $\lambda_0 = 1/8$ .
11. It follows from Theorem 8.6.1 that  $\mu_1 = 80/81$ ,  $\lambda_1 = 81/8$ ,  $\alpha_1 = 9$ , and  $\beta_1 = 491/81$ . Therefore, if Eq. (8.6.9) is applied to this posterior distribution, it is seen that the random variable  $U = (3.877)(\mu - 0.988)$  has the t distribution with 18 degrees of freedom. Therefore, it is found from a table  $\Pr(-2.101 < Y < 2.101) = 0.95$ . An equivalent statement is  $\Pr(0.446 < \mu < 1.530) = 0.95$ . This interval will be the shortest one having probability 0.95 because the center of the interval is  $\mu_1$ , the point where the p.d.f. of  $\mu$  is a maximum. Since the p.d.f. of  $\mu$  decreases as we move away from  $\mu_1$  in either direction, it follows that an interval having given length will have the maximum probability when it is centered at  $\mu_1$ .
12. Since  $E(\tau) = \alpha_0/\beta_0 = 1$  and  $\text{Var}(\tau) = \alpha_0/\beta_0^2 = 1/3$ , it follows that  $\alpha_0 = \beta_0 = 3$ . Also, since the distribution of  $\mu$  is symmetric with respect to  $\mu_0$  and we are given that  $\Pr(\mu > 3) = 0.5$ , then  $\mu_0 = 3$ . Now, by Theorem 8.6.2,  $U = \lambda_0^{1/2}(\mu - 3)$  has the t distribution with  $2\alpha_0 = 6$  degrees of freedom. It is found from a table that  $\Pr(Y < 1.440) = 0.90$ . Therefore,  $\Pr(Y > -1.440) = 0.90$  and it follows that  $\Pr\left(\mu > 3 - \frac{1.440}{\lambda_0^{1/2}}\right) = 0.90$ . It now follows from the condition given in the exercise that  $3 - \frac{1.440}{\lambda_0^{1/2}} = 0.12$ . Hence,  $\lambda_0 = 1/4$ .
13. It follows from Theorem 8.6.1 that  $\mu_1 = 67/33$ ,  $\lambda_1 = 33/4$ ,  $\alpha_1 = 7$ , and  $\beta_1 = 367/33$ . In calculating the value of  $\beta_1$ , we have used the relation
- $$\sum_{i=1}^n (x_i - \bar{x}_n)^2 = \sum_{i=1}^n x_i^2 - n\bar{x}_n^2.$$
- If Theorem 8.6.2 is now applied to this posterior distribution, it is seen that the random variable  $U = (2.279)(\mu - 2.030)$  has the t distribution with 14 degrees of freedom. Therefore, it is found from a table that  $\Pr(-2.977 < Y < 2.977) = 0.99$ . An equivalent statement is  $\Pr(0.724 < \mu < 3.336) = 0.99$ .
14. The interval should run between the values  $\mu_1 \pm (\beta_1/[\lambda_1\alpha_1])^{1/2}T_{2\alpha_1}^{-1}(0.95)$ . The values we need are available from the example or the table of the t distribution:  $\mu_1 = 1.345$ ,  $\beta_1 = 1.0484$ ,  $\lambda_1 = 11$ ,  $\alpha_1 = 5.5$ , and  $T_{11}^{-1}(0.95) = 1.796$ . The resulting interval is  $(1.109, 1.581)$ . This interval is a bit wider than the confidence interval in Example 8.5.4. This is due mostly to the fact that  $(\beta_1/\alpha_1)^{1/2}$  is somewhat larger than  $\sigma'$ .

15. (a) The posterior hyperparameters are

$$\begin{aligned}\mu_1 &= \frac{2 \times 3.5 + 11 \times 7.2}{2 + 11} = 6.63, \\ \lambda_1 &= 2 + 11 = 13, \\ \alpha_1 &= 2 + \frac{11}{2} = 7.5, \\ \beta_1 &= 1 + \frac{1}{2} \left( 20.3 + \frac{2 \times 11}{2 + 11} (7.2 - 3.5)^2 \right) = 22.73.\end{aligned}$$

- (b) The interval should run between the values  $\mu_1 \pm (\beta_1 / [\lambda_1 \alpha_1])^{1/2} T_{2\alpha_1}^{-1}(0.975)$ . From the table of the  $t$  distribution in the book, we obtain  $T_{15}^{-1}(0.975) = 2.131$ . The interval is then  $(5.601, 7.659)$ .
16. (a) The average of all 30 observations is  $\bar{x}_{30} = 1.442$  and  $s_{30}^2 = 2.671$ . Using the prior from Example 8.6.2, we obtain

$$\begin{aligned}\mu_1 &= \frac{1 \times 1 + 30 \times 1.442}{1 + 30} = 1.428, \\ \lambda_1 &= 1 + 30 = 31, \\ \alpha_1 &= 0.5 + \frac{30}{2} = 15.5, \\ \beta_1 &= 0.5 + \frac{1}{2} \left( 2.671 + \frac{1 \times 30}{1 + 30} (1.442 - 1)^2 \right) = 1.930.\end{aligned}$$

The posterior distribution of  $\mu$  and  $\tau$  is a joint normal-gamma distribution with the above hyperparameters.

- (b) The average of the 20 new observations is  $\bar{x}_{20} = 1.474$  and  $s_{20}^2 = 1.645$ . Using the posterior in Example 8.6.2 as the prior, we obtain the hyperparameters

$$\begin{aligned}\mu_1 &= \frac{11 \times 1.345 + 20 \times 1.474}{11 + 20} = 1.428, \\ \lambda_1 &= 11 + 20 = 31, \\ \alpha_1 &= 5.5 + \frac{20}{2} = 15.5, \\ \beta_1 &= 1.0484 + \frac{1}{2} \left( 1.645 + \frac{11 \times 20}{11 + 20} (1.474 - 1.345)^2 \right) = 1.930.\end{aligned}$$

The posterior hyperparameters are the same as those found in part (a). Indeed, one can prove that they must be the same when one updates sequentially or all at once.

17. Using just the first ten observations, we have  $\bar{x}_n = 1.379$  and  $s_n^2 = 0.9663$ . This makes  $\mu_1 = 1.379$ ,  $\lambda_1 = 10$ ,  $\alpha_1 = 4.5$ , and  $\beta_1 = 0.4831$ . The posterior distribution of  $\mu$  and  $\tau$  is the normal-gamma distribution with these hyperparameters
18. Now, we use the hyperparameters found in Exercise 18 as prior hyperparameters and combine these with the last 20 observations. The average of the 20 new observations is  $\bar{x}_{20} = 1.474$  and  $s_{20}^2 = 1.645$ . We then obtain

$$\begin{aligned}\mu_1 &= \frac{10 \times 1.379 + 20 \times 1.474}{10 + 20} = 1.442, \\ \lambda_1 &= 10 + 20 = 30, \\ \alpha_1 &= 4.5 + \frac{20}{2} = 14.5, \\ \beta_1 &= 0.4831 \frac{1}{2} \left( 1.645 + \frac{10 \times 20}{10 + 20} (1.474 - 1.379)^2 \right) = 1.336.\end{aligned}$$

Comparing two sets of hyperparameters is not as informative as comparing inferences. For example, a posterior probability interval will be centered at  $\mu_1$  and have half-width proportional to  $(\beta_1/[\alpha_1 \lambda_1])^{1/2}$ . Since  $\mu_1$  is nearly the same in this case and in Exercise 16 part (b), the two intervals will be centered in about the same place. The values of  $(\beta_1/[\alpha_1 \lambda_1])^{1/2}$  for this exercise and for Exercise 16 part (b) are respectively 0.05542 and 0.06338. So we expect the intervals to be slightly shorter in this exercise than in Exercise 16. (However, the quantiles of the  $t$  distribution with 31 degrees of freedom are a bit larger in this exercise than the quantiles of the  $t$  distribution with 31 degrees of freedom in Exercise 16.)

19. (a) For the 20 observations given in Exercise 7 of Sec. 8.5, the data summaries are  $\bar{x}_n = 156.85$  and  $s_n^2 = 9740.55$ . So, the posterior hyperparameters are

$$\begin{aligned}\mu_1 &= \frac{0.5 \times 150 + 20 \times 156.85}{0.5 + 20} = 156.68, \\ \lambda_1 &= 0.5 + 20 = 20.5, \\ \alpha_1 &= 1 + \frac{20}{2} = 11, \\ \beta_1 &= 4 + \frac{1}{2} \left( 9740.55 + \frac{0.5 \times 20}{0.5 + 20} (156.85 - 150)^2 \right) = 4885.7.\end{aligned}$$

The joint posterior of  $\mu$  and  $\tau$  is the normal-gamma distribution with these hyperparameters.

- (b) The interval we want has endpoints  $\mu_1 \pm (\beta_1/[\alpha_1 \lambda_1])^{1/2} T_{2\alpha_1}^{-1}(0.95)$ . The quantile we want is  $T_{22}^{-1}(0.95) = 1.717$ . Substituting the posterior hyperparameters gives the endpoints to be  $a = 148.69$  and  $b = 164.7$ .
20. The data summaries in Example 7.3.10 are  $n = 20$ ,  $\bar{x}_{20} = 0.125$ . Combine these with  $s_{20}^2 = 2102.9$  to get the posterior hyperparameters:

$$\begin{aligned}\mu_1 &= \frac{1 \times 0 + 20 \times 0.125}{1 + 20} = 0.1190, \\ \lambda_1 &= 1 + 20 = 21, \\ \alpha_1 &= 1 + \frac{20}{2} = 11, \\ \beta_1 &= 60 + \frac{2102.9}{2} + \frac{20 \times 1 \times (0.125 - 0)^2}{2(1 + 20)} = 1111.5.\end{aligned}$$

- (a) The posterior distribution of  $(\mu, \tau)$  is the normal-gamma distribution with the posterior hyperparameters given above.
- (b) The posterior distribution of

$$\left( \frac{21 \times 11}{1111.5} \right)^{1/2} (\mu - 0.1190) = 0.4559(\mu - 0.1190) = T$$

is the  $t$  distribution with 22 degrees of freedom. So,

$$\Pr(\mu > 1 | \mathbf{x}) = \Pr[0.4559(\mu - 0.1190) > 0.4559(1 - 0.1190)] = \Pr(T > 0.4016) = 0.3459,$$

where the final probability can be found by using statistical software or interpolating in the table of the  $t$  distribution.

## 8.7 Unbiased Estimators

### Commentary

The subsection on limitations of unbiased estimators at the end of this section should be used selectively by instructors after gauging the ability of their students to understand examples with nonstandard structure.

## Solutions to Exercises

1. (a) The variance of a Poisson random variable with mean  $\theta$  is also  $\theta$ . So the variance is  $\sigma^2 = g(\theta) = \theta$ .  
 (b) The M.L.E. of  $g(\theta) = \theta$  was found in Exercise 5 of Sec. 7.5, and it equals  $\bar{X}_n$ . The mean of  $\bar{X}_n$  is the same as the mean of each  $X_i$ , namely  $\theta$ , hence the M.L.E. is unbiased.
2. Let  $E(X^k) = \beta_k$ . Then

$$E\left(\frac{1}{n} \sum_{i=1}^n X_i^k\right) = \frac{1}{n} \sum_{i=1}^n E(X_i^k) = \frac{1}{n} \cdot n\beta_k = \beta_k.$$

3. By Exercise 2,  $\delta_1 = \frac{1}{n} \sum_{i=1}^n X_i^2$  is an unbiased estimator of  $E(X^2)$ . Also, we know that  $\delta_2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X}_n)^2$  is an unbiased estimator of  $\text{Var}(X)$ . Therefore, it follows from the hint for this exercise that  $\delta_1 - \delta_2$  will be an unbiased estimator of  $[E(X)]^2$ .
4. If  $X$  has the geometric distribution with parameter  $p$ , then it follows from Eq. (5.5.7) that  $E(X) = (1-p)/p = 1/p - 1$ . Therefore,  $E(X+1) = 1/p$ , which implies that  $X+1$  is an unbiased estimator of  $1/p$ .
5. We shall follow the hint for this exercise. If  $E[\delta(X)] = \exp(\lambda)$ , then

$$\exp(\lambda) = E[\delta(X)] = \sum_{x=0}^{\infty} \delta(x) f(x \mid \lambda) = \sum_{x=0}^{\infty} \frac{\delta(x) \exp(-\lambda) \lambda^x}{x!}.$$

Therefore,

$$\sum_{x=0}^{\infty} \frac{\delta(x) \lambda^x}{x!} = \exp(2\lambda) = \sum_{x=0}^{\infty} \frac{(2\lambda)^x}{x!} = \sum_{x=0}^{\infty} \frac{2^x \lambda^x}{x!}.$$

Since two power series in  $\lambda$  can be equal only if the coefficients of  $\lambda^x$  are equal for  $x = 0, 1, 2, \dots$ , it follows that  $\delta(x) = 2^x$  for  $x = 0, 1, 2, \dots$ . This argument also shows that this estimator  $\delta(X)$  is the unique unbiased estimator of  $\exp(\lambda)$  in this problem.

6. The M.S.E. of  $\hat{\sigma}_0^2$  is given by Eq. (8.7.8) with  $c = 1/n$  and it is, therefore, equal to  $(2n-1)\sigma^4/n^2$ . The M.S.E. of  $\hat{\sigma}_1^2$  is given by Eq. (8.7.8) with  $c = 1/(n-1)$  and it is, therefore, equal to  $2\sigma^4/(n-1)$ . Since  $(2n-1)/n^2 < 2/(n-1)$  for every positive integer  $n$ , it follows that the M.S.E. of  $\hat{\sigma}_0^2$  is smaller than the M.S.E. of  $\hat{\sigma}_1^2$  for all values of  $\mu$  and  $\sigma^2$ .
7. For any possible values  $x_1, \dots, x_n$  of  $X_1, \dots, X_n$ , let  $y = \sum_{i=1}^n x_i$ . Then

$$E[\delta(X_1, \dots, X_n)] = \sum \delta(x_1, \dots, x_n) p^y (1-p)^{n-y},$$

where the summation extends over all possible values of  $x_1, \dots, x_n$ . Since  $p^y (1-p)^{n-y}$  is a polynomial in  $p$  of degree  $n$ , it follows that  $E[\delta(X_1, \dots, X_n)]$  is the sum of a finite number of terms, each of which is equal to a constant  $\delta(x_1, \dots, x_n)$  times a polynomial in  $p$  of degree  $n$ . Therefore,  $E[\delta(X_1, \dots, X_n)]$  must itself be a polynomial in  $p$  of degree  $n$  or less. The degree would actually be less than  $n$  if the sum of the terms of order  $p^n$  is 0.

8. If  $E[\delta(X)] = p$ , then

$$p = E[\delta(X)] = \sum_{x=0}^{\infty} \delta(x)p(1-p)^x.$$

Therefore,  $\sum_{x=0}^{\infty} \delta(x)(1-p)^x = 1$ . Since this relation must be satisfied for all values of  $1-p$ , it follows that the constant term  $\delta(0)$  in the power series must be equal to 1, and the coefficient  $\delta(x)$  of  $(1-p)^x$  must be equal to 0 for  $x = 1, 2, \dots$ .

9. If  $E[\delta(X)] = \exp(-2\lambda)$ , then

$$\sum_{x=0}^{\infty} \delta(x) \frac{\exp(-\lambda)\lambda^x}{x!} = \exp(-2\lambda).$$

Therefore,

$$\sum_{x=0}^{\infty} \frac{\delta(x)\lambda^x}{x!} = \exp(-\lambda) = \sum_{x=0}^{\infty} \frac{(-1)^x \lambda^x}{x!}.$$

Therefore,  $\delta(X) = (-1)^x$  or, in other world,  $\delta(X) = 1$  if  $x$  is even and  $\delta(x) = -1$  if  $x$  is odd.

10. Let  $X$  denote the number of failures that are obtained before  $k$  successes have been obtained. Then  $X$  has the negative binomial distribution with parameters  $k$  and  $p$ , and  $N = X + k$ . Therefore, by Eq. (5.5.1),

$$\begin{aligned} E\left(\frac{k-1}{N-1}\right) &= E\left(\frac{k-1}{X+k-1}\right) = \sum_{x=0}^{\infty} \frac{k-1}{x+k-1} \binom{x+k-1}{x} p^k (1-p)^x \\ &= \sum_{x=0}^{\infty} \frac{(x+k-2)!}{x!(k-2)!} p^k (1-p)^x \\ &= p \sum_{x=0}^{\infty} \binom{x+k-2}{x} p^{k-1} (1-p)^x. \end{aligned}$$

But the final summation is the sum of the probabilities for a negative binomial distribution with parameters  $k-1$  and  $p$ . Therefore, the value of this summation is 1, and  $E([k-1]/[N-1]) = p$ .

11. (a)  $E(\hat{\theta}) = \alpha E(\bar{X}_m) + (1-\alpha)E(\bar{Y}_n) = \alpha\theta + (1-\alpha)\theta = \theta$ . Hence,  $\hat{\theta}$  is an unbiased estimator of  $\theta$  for all values of  $\alpha$ ,  $m$  and  $n$ .

- (b) Since the two samples are taken independently,  $\bar{X}_m$  and  $\bar{Y}_n$  are independent. Hence,

$$\text{Var}(\hat{\theta}) = \alpha^2 \text{Var}(\bar{X}_m) + (1-\alpha)^2 \text{Var}(\bar{Y}_n) = \alpha^2 \left(\frac{\sigma_A^2}{m}\right) + (1-\alpha)^2 \left(\frac{\sigma_B^2}{n}\right).$$

Since  $\sigma_A^2 = 4\sigma_B^2$ , it follows that

$$\text{Var}(\hat{\theta}) = \left[\frac{4\alpha^2}{m} + \frac{(1-\alpha)^2}{n}\right] \sigma_B^2.$$

By differentiating the coefficient of  $\sigma_B^2$ , it is found that  $\text{Var}(\hat{\theta})$  is a minimum when  $\alpha = m/(m+4n)$ .

12. (a) Let  $X$  denote the value of the characteristic for a person chosen at random from the total population, and let  $A_i$  denote the event that the person belongs to stratum  $i$  ( $i = 1, \dots, k$ ). Then

$$\mu = E(X) = \sum_{i=1}^k E(X | A_i) \Pr(A_i) = \sum_{i=1}^k \mu_i p_i.$$

Also,

$$E(\hat{\mu}) = \sum_{i=1}^k p_i E(\bar{X}_i) = \sum_{i=1}^k p_i \mu_i = \mu.$$

- (b) Since the samples are taken independently of each other, the variables  $\bar{X}_1, \dots, \bar{X}_k$  are independent. Therefore,

$$\text{Var}(\hat{\mu}) = \sum_{i=1}^k p_i^2 \text{Var}(\bar{X}_i) = \sum_{i=1}^k \frac{p_i^2 \sigma_i^2}{n_i}.$$

Hence, the values of  $n_1, \dots, n_k$  must be chosen to minimize  $v = \sum_{i=1}^k \frac{(p_i \sigma_i)^2}{n_i}$ , subject to the constraint that  $\sum_{i=1}^k n_i = n$ . If we let  $n_k = n - \sum_{i=1}^{k-1} n_i$ , then

$$\frac{\partial v}{\partial n_i} = \frac{-(p_i \sigma_i)^2}{n_i^2} + \frac{(p_k \sigma_k)^2}{n_k^2} \quad \text{for } i = 1, \dots, k-1.$$

When each of these partial derivatives is set equal to 0, it is found that  $n_i/(p_i \sigma_i)$  has the same value for  $i = 1, \dots, k$ . Therefore,  $n_i = c p_i \sigma_i$  for some constant  $c$ . It follows that  $n = \sum_{j=1}^k n_j = c \sum_{j=1}^k p_j \sigma_j$ .

Hence,  $c = n / \sum_{j=1}^k p_j \sigma_j$  and, in turn,

$$n_i = \frac{n p_i \sigma_i}{\sum_{j=1}^k p_j \sigma_j}.$$

This analysis ignores the fact that the values of  $n_1, \dots, n_k$  must be integers. The integers  $n_1, \dots, n_k$  for which  $v$  is a minimum would presumably be near the minimizing values of  $n_1, \dots, n_k$  which have just been found.

13. (a) By Theorem 4.7.1,

$$E(\delta) = E[E(\delta|T)] = E(\delta_0).$$

Therefore,  $\delta$  and  $\delta_0$  have the same expectation. Since  $\delta$  is unbiased,  $E(\delta) = \theta$ . Hence,  $E(\delta_0) = \theta$  also. In other words,  $\delta_0$  is also unbiased.

- (b) Let  $Y = \delta(\mathbf{X})$  and  $X = T$  in Theorem 4.7.4. The result there implies that

$$\text{Var}_\theta(\delta(\mathbf{X})) = \text{Var}_\theta(\delta_0(\mathbf{X})) + E_\theta \text{Var}(\delta(\mathbf{X})|T).$$

Since  $\text{Var}(\delta(\mathbf{X})|T) \geq 0$ , so too is  $E_\theta \text{Var}(\delta(\mathbf{X})|T)$ , so  $\text{Var}_\theta(\delta(\mathbf{X})) \geq \text{Var}_\theta(\delta_0(\mathbf{X}))$ .

14. For  $0 < y < \theta$ , the c.d.f. of  $Y_n$  is

$$F(y | \theta) = \Pr(Y \leq y | \theta) = \Pr(X_1 \leq y, \dots, X_n \leq y | \theta) = \left(\frac{y}{\theta}\right)^n.$$

Therefore, for  $0 < y < \theta$ , the p.d.f. of  $Y_n$  is

$$f(y | \theta) = \frac{d}{dy} F(y | \theta) = \frac{ny^{n-1}}{\theta^n}.$$

It now follows that

$$E_\theta(Y_n) = \int_0^\theta y \frac{ny^{n-1}}{\theta^n} dy = \frac{n}{n+1} \theta.$$

Hence,  $E_\theta([n+1]Y_n/n) = \theta$ , which means that  $(n+1)Y_n/n$  is an unbiased estimator of  $\theta$ .

15. (a)  $f(1 | \theta) + f(2 | \theta) = \theta^2[\theta + (1 - \theta)] = \theta^2$ ,  
 $f(4 | \theta) + f(5 | \theta) = (1 - \theta)^2[\theta + (1 - \theta)] = (1 - \theta)^2$ ,  
 $f(3 | \theta) = 2\theta(1 - \theta)$ .

The sum of the five probabilities on the left sides of these equations is equal to the sum the right sides, which is

$$\theta^2 + (1 - \theta)^2 + 2\theta(1 - \theta) = [\theta + (1 - \theta)]^2 = 1.$$

$$(b) E_\theta[\delta_c(X)] = \sum_{x=1}^5 \delta_c(x)f(x | \theta) = 1 \cdot \theta^3 + (2 - 2c)\theta^2(1 - \theta) + (c)2\theta(1 - \theta) + (1 - 2c)\theta(1 - \theta)^2 + 0.$$

It will be found that the sum of the coefficients of  $\theta^3$  is 0, the sum of the coefficients of  $\theta^2$  is 0, the sum of the coefficients of  $\theta$  is 1, and the constant term is 0. Hence,  $E_\theta[\delta_c(X)] = \theta$ .

- (c) For every value of  $c$ ,

$$\text{Var}_{\theta_0}(\delta_c) = E_{\theta_0}(\delta_c^2) - [E_{\theta_0}(\delta_c)]^2 = E_{\theta_0}(\delta_c^2) - \theta^2.$$

Hence, the value of  $c$  for which  $\text{Var}_{\theta_0}(\delta_c)$  is a minimum will be the value of  $c$  for which  $E_{\theta_0}(\delta_c^2)$  is a minimum. Now

$$\begin{aligned} E_{\theta_0}(\delta_c^2) &= (1)^2\theta_0^3 + (2 - 2c)^2\theta_0^2(1 - \theta_0) + (c)^22\theta_0(1 - \theta_0) \\ &\quad + (1 - 2c)^2\theta_0(1 - \theta_0)^2 + 0 \\ &= 2c^2[2\theta_0^2(1 - \theta_0) + \theta_0(1 - \theta_0) + 2\theta_0(1 - \theta_0)^2] \\ &\quad - 4c[2\theta_0^2(1 - \theta_0) + \theta_0(1 - \theta_0)^2] + \text{terms not involving } c. \end{aligned}$$

After further simplification of the coefficients of  $c^2$  and  $c$ , we obtain the relation

$$E_{\theta_0}(\delta_c^2) = 6\theta_0(1 - \theta_0)c^2 + 4\theta_0(1 - \theta_0^2)c + \text{terms not involving } c.$$

By differentiating with respect to  $c$  and setting the derivative equal to 0, it is found that the value of  $c$  for which  $E_{\theta_0}(\delta_c^2)$  is a minimum is  $c = (1 + \theta_0)/3$ .

16. The unbiased estimator in Exercise 3 is

$$\frac{1}{n} \sum_{i=1}^n X_i^2 - \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X}_n)^2.$$

For the observed values  $X_1 = 2$  and  $X_2 = -1$ , we obtain the value  $-2$  for the estimate. This is unacceptable. Because  $[E(X)]^2 \geq 0$ , we should demand an estimate that is also nonnegative.

## 8.8 Fisher Information

### Commentary

Although this section is optional, it does contain the interesting theoretical result on asymptotic normality of maximum likelihood estimators. It also contains the Cramér-Rao inequality, which can be useful for finding minimum variance unbiased estimators. However, the material is really only suitable for a fairly mathematically oriented course.

### Solutions to Exercises

1.

$$\begin{aligned} f(x | \mu) &= \frac{1}{\sqrt{2\pi}\sigma} \exp\left\{-\frac{1}{2\sigma^2}(x - \mu)^2\right\}, \\ f'(x | \mu) &= \frac{1}{\sqrt{2\pi}\sigma} \frac{(x - \mu)}{\sigma^2} \exp\left\{-\frac{1}{2\sigma^2}(x - \mu)^2\right\} = \frac{x - \mu}{\sigma^2} f(x | \mu), \\ f''(x | \mu) &= \left[ \frac{(x - \mu)^2}{\sigma^4} - \frac{1}{\sigma^2} \right] f(x | \mu). \end{aligned}$$

Therefore,

$$\int_{-\infty}^{\infty} f'(x | \mu) dx = \frac{1}{\sigma^2} \int_{-\infty}^{\infty} (x - \mu) f(x | \mu) d\mu = \frac{1}{\sigma^2} E(X - \mu) = 0,$$

and

$$\int_{-\infty}^{\infty} f''(x | \mu) dx = \frac{E[(X - \mu)^2]}{\sigma^4} - \frac{1}{\sigma^2} = \frac{\sigma^2}{\sigma^4} - \frac{1}{\sigma^2} = 0.$$

2. The p.f. is

$$f(x|p) = p(1-p)^x, \text{ for } x = 0, 1, \dots$$

The logarithm of this is  $\log(p) + x \log(1-p)$ , and the derivative is

$$\frac{1}{p} - \frac{x}{1-p}.$$

According to Eq. (5.5.7) in the text, the variance of  $X$  is  $(1-p)/p^2$ , hence the Fisher information is

$$I(p) = \text{Var}\left[\frac{1}{p} - \frac{X}{1-p}\right] = \frac{\text{Var}(X)}{(1-p)^2} = \frac{1}{p^2(1-p)}.$$

3.

$$\begin{aligned} f(x | \theta) &= \frac{\exp(-\theta)\theta^x}{x!}, \\ \lambda(x | \theta) &= -\theta + x \log \theta - \log(x!), \\ \lambda'(x | \theta) &= -1 + \frac{x}{\theta}, \\ \lambda''(x | \theta) &= -\frac{x}{\theta^2}. \end{aligned}$$

Therefore, by Eq. (8.8.3),

$$I(\theta) = -E_\theta[\lambda''(X | \theta)] = \frac{E(X)}{\theta^2} = \frac{1}{\theta}.$$

4.

$$\begin{aligned} f(x | \sigma) &= \frac{1}{\sqrt{2\pi}\sigma} \exp\left\{-\frac{x^2}{2\sigma^2}\right\}, \\ \lambda(x | \sigma) &= -\log \sigma - \frac{x^2}{2\sigma^2} + \text{const.} \\ \lambda'(x | \sigma) &= -\frac{1}{\sigma} + \frac{x^2}{\sigma^3}, \\ \lambda''(x | \sigma) &= \frac{1}{\sigma^2} - \frac{3x^2}{\sigma^4}. \end{aligned}$$

Therefore,

$$I(\theta) = -E_\theta[\lambda''(X | \theta)] = -\frac{1}{\sigma^2} + \frac{3E(X^2)}{\sigma^4} = -\frac{1}{\sigma^2} + \frac{3}{\sigma^2} = \frac{2}{\sigma^2}.$$

5. Let  $\nu = \sigma^2$ . Then

$$\begin{aligned} f(x | \nu) &= \frac{1}{\sqrt{2\pi\nu}} \exp\left\{-\frac{x^2}{2\nu}\right\}, \\ \lambda(x | \nu) &= -\frac{1}{2} \log \nu - \frac{x^2}{2\nu} + \text{const.}, \\ \lambda'(x | \nu) &= -\frac{1}{2\nu} + \frac{x^2}{2\nu^2}, \\ \lambda''(x | \nu) &= \frac{1}{2\nu^2} - \frac{x^2}{\nu^3}. \end{aligned}$$

Therefore,

$$I(\sigma^2) = I(\nu) = -E_\nu[\lambda''(X | \nu)] = -\frac{1}{2\nu^2} + \frac{\nu}{\nu^3} = \frac{1}{2\nu^2} = \frac{1}{2\sigma^4}.$$

6. Let  $g(x | \mu)$  denote the p.d.f. or the p.f. of  $X$  when  $\mu$  is regarded as the parameter. Then  $g(x | \mu) = f[x | \psi(\mu)]$ . Therefore,

$$\log g(x | \mu) = \log f[x | \psi(\mu)] = \lambda[x | \psi(\mu)],$$

and

$$\frac{\partial}{\partial \mu} \log g(x | \mu) = \lambda'[x | \psi(\mu)]\psi'(\mu).$$

It now follows that

$$I_1(\mu) = E_\mu \left\{ \left[ \frac{\partial}{\partial \mu} \log g(X | \mu) \right]^2 \right\} = [\psi'(\mu)]^2 E_\mu (\{\lambda'[X | \psi(\mu)]\}^2) = [\psi'(\mu)]^2 I_0[\psi(\mu)].$$

7. We know that  $E(\bar{X}_n) = p$  and  $\text{Var}(\bar{X}_n) = p(1-p)/n$ . It was shown in Example 8.8.2 that  $I(P) = 1/[p(1-p)]$ . Therefore,  $\text{Var}(\bar{X}_n)$  is equal to the lower bound  $1/[nI(p)]$  provided by the information inequality.
8. We know that  $E(\bar{X}_n) = \mu$  and  $\text{Var}(\bar{X}_n) = \frac{\sigma^2}{n}$ . It was shown in Example 8.8.3 that  $I(\mu) = 1/\sigma^2$ . Therefore,  $\text{Var}(\bar{X}_n)$  is equal to the lower bound  $1/[nI(\mu)]$  provided by the information inequality.
9. We shall attack this exercise by trying to find an estimator of the form  $c|X|$  that is unbiased. One approach is as follows: We know that  $X^2/\sigma^2$  has the  $\chi^2$  distribution with one degree of freedom. Therefore, by Exercise 11 of Sec. 8.2,  $|X|/\sigma$  has the  $\chi$  distribution with one degree of freedom, and it was shown in that exercise that

$$E\left(\frac{|X|}{\sigma}\right) = \frac{\sqrt{2}\Gamma(1)}{\Gamma(1/2)} = \sqrt{\frac{2}{\pi}}.$$

Hence,  $E(|X|) = \sigma\sqrt{2/\pi}$ . It follows that  $E(|X|\sqrt{\pi/2}) = \sigma$ . Let  $\delta = |X|\sqrt{\pi/2}$ . Then

$$E(\delta^2) = \frac{\pi}{2}E(|X|^2) = \frac{\pi}{2}\sigma^2.$$

Hence,

$$\text{Var } \delta = E(\delta^2) - [E(\delta)]^2 = \frac{\pi}{2}\sigma^2 - \sigma^2 = \left(\frac{\pi}{2} - 1\right)\sigma^2.$$

Since  $1/I(\sigma) = \sigma^2/2$ , it follows that  $\text{Var}(\delta) > 1/I(\sigma)$ .

Another unbiased estimator is  $\delta_1(X) = \sqrt{2\pi} X$  if  $X \geq 0$  and  $\delta_1(X) = 0$  if  $X < 0$ . However, it can be shown, using advanced methods, that the estimator  $\delta$  found in this exercise is the *only* unbiased estimator of  $\sigma$  that depends on  $X$  only through  $|X|$ .

10. If  $m(\sigma) = \log \sigma$ , then  $m'(\sigma) = 1/\sigma$  and  $[m'(\sigma)]^2 = 1/\sigma^2$ . Also, it was shown in Exercise 4 that  $I(\sigma) = 2/\sigma^2$ . Therefore, if  $T$  is an unbiased estimator of  $\log \sigma$ , it follows from the relation (8.8.14) that

$$\text{Var}(T) \geq \frac{1}{\sigma^2} \cdot \frac{\sigma^2}{2n} = \frac{1}{2n}.$$

11. If  $f(x | \theta) = a(\theta)b(x)\exp[c(\theta)d(x)]$ , then

$$\lambda(x | \theta) = \log a(\theta) + \log b(x) + c(\theta)d(x)$$

and

$$\lambda'(x | \theta) = \frac{a'(\theta)}{a(\theta)} + c'(\theta)d(x).$$

Therefore,

$$\lambda'_n(\mathbf{X} | \theta) = \sum_{i=1}^n \lambda'(X_i | \theta) = n \frac{a'(\theta)}{a(\theta)} + c'(\theta) \sum_{i=1}^n d(X_i).$$

If we choose

$$u(\theta) = \frac{1}{c'(\theta)} \quad \text{and} \quad v(\theta) = -\frac{na'(\theta)}{a(\theta)c'(\theta)},$$

then Eq. (8.8.14) will be satisfied with  $T = \sum_{i=1}^n d(X_i)$ . Hence, this statistic is an efficient estimator of its expectation.

12. Let  $\theta = \sigma^2$  denote the unknown variance. Then

$$f(x | \theta) = \frac{1}{\sqrt{2\pi\theta}} \exp\left\{-\frac{1}{2\theta}(x - \mu)^2\right\}.$$

This p.d.f.  $f(x | \theta)$  has the form of an exponential family, as given in Exercise 12, with  $d(x) = (x - \mu)^2$ . Therefore,  $T = \sum_{i=1}^n (X_i - \mu)^2$  will be an efficient estimator. Since  $E[(X_i - \mu)^2] = \sigma^2$  for  $i = 1, \dots, n$ , then  $E(T) = n\sigma^2$ . Also, by Exercise 17 of Sec. 5.7,  $E[(X_i - \mu)^4] = 3\sigma^4$  for  $i = 1, \dots, n$ . Therefore,  $\text{Var}[(X_i - \mu)^2] = 3\sigma^4 - \sigma^4 = 2\sigma^4$ , and it follows that  $\text{Var}(T) = 2n\sigma^4$ .

It should be emphasized that any linear function of  $T$  will also be an efficient estimator. In particular,  $T/n$  will be an efficient estimator of  $\sigma^2$ .

13. The incorrect part of the argument is at the beginning, because the information inequality cannot be applied to the uniform distribution. For each different value of  $\theta$ , there is a different set of values of  $x$  for which  $f(x | \theta) \geq 0$ .

- 14.

$$\begin{aligned} f(x | \alpha) &= \frac{\beta^\alpha}{\Gamma(\alpha)} x^{\alpha-1} \exp(-\beta x), \\ \lambda(x | \alpha) &= \alpha \log \beta - \log \Gamma(\alpha) + (\alpha - 1) \log x - \beta x, \\ \lambda'(x | \alpha) &= \log \beta - \frac{\Gamma'(\alpha)}{\Gamma(\alpha)} + \log x, \\ \lambda''(x | \alpha) &= -\frac{\Gamma(\alpha)\Gamma''(\alpha) - [\Gamma'(\alpha)]^2}{[\Gamma(\alpha)]^2} \end{aligned}$$

Therefore,

$$I(\alpha) = \frac{\Gamma(\alpha)\Gamma''(\alpha) - [\Gamma'(\alpha)]^2}{[\Gamma(\alpha)]^2}$$

The distribution of the M.L.E. of  $\alpha$  will be approximately the normal distribution with mean  $\alpha$  and variance  $1/[nI(\alpha)]$ .

It should be noted that we have determined this distribution without actually determining the M.L.E. itself.

15. We know that the M.L.E. of  $\mu$  is  $\hat{\mu} = \bar{x}_n$  and, from Example 8.8.3, that  $I(\mu) = 1/\sigma^2$ . The posterior distribution of  $\mu$  will be approximately a normal distribution with mean  $\hat{\mu}$  and variance  $1/[nI(\hat{\mu})] = \sigma^2/n$ .
16. We know that the M.L.E. of  $p$  is  $\hat{p} = \bar{x}_n$  and, from Example 8.8.2, that  $I(p) = 1/[p(1 - p)]$ . The posterior distribution of  $p$  will be approximately a normal distribution with mean  $\hat{p}$  and variance  $1/[nI(\hat{p})] = \bar{x}_n(1 - \bar{x}_n)/n$ .

17. The derivative of the log-likelihood with respect to  $p$  is

$$\lambda'(x|p) = \frac{\partial}{\partial p} \left[ \log \binom{n}{x} + x \log(p) + (n-x) \log(1-p) \right] = \frac{x}{p} - \frac{n-x}{1-p} = \frac{x-np}{p(1-p)}.$$

The mean of  $\lambda'(X|p)$  is clearly 0, so its variance is

$$I(p) = \frac{\text{Var}(X)}{p^2(1-p)^2} = \frac{n}{p(1-p)}.$$

18. The derivative of the log-likelihood with respect to  $p$  is

$$\lambda'(x|p) = \frac{\partial}{\partial p} \left[ \log \binom{r+x-1}{x} + r \log(p) + x \log(1-p) \right] = \frac{r}{p} - \frac{x}{1-p} = \frac{r-rp-xp}{p(1-p)}.$$

The mean of  $\lambda'(X|p)$  is clearly 0, so its variance is

$$I(p) = \frac{p^2 \text{Var}(X)}{p^2(1-p)^2} = \frac{r}{p^2(1-p)}.$$

## 8.9 Supplementary Exercises

### Solutions to Exercises

- According to Exercise 5 in Sec. 8.8, the Fisher information  $I(\sigma^2)$  based on a sample of size 1 is  $1/[2\sigma^4]$ . According to the information inequality, the variance of an unbiased estimator of  $\sigma^2$  must be at least  $2\sigma^4/n$ . The variance of  $V = \sum_{i=1}^n X_i^2/n$  is  $\text{Var}(X_1^2)/n$ . Since  $X_1^2/\sigma^2$  has a  $\chi^2$  distribution with 1 degree of freedom, its variance is 2. Hence  $\text{Var}(X_1^2) = 2\sigma^4$  and  $\text{Var}(V)$  equals the lower bound from the information inequality.  $E(V) = E(X_1^2) = \sigma^2$ , so  $V$  is unbiased.
- The  $t$  distribution with one degree of freedom is the Cauchy distribution. Therefore, by Exercise 18 of Sec. 5.6, we can represent the random variable  $X$  in the form  $X = U/V$ , where  $U$  and  $V$  are independent and each has a standard normal distribution. But  $1/X$  can then be represented as  $1/X = V/U$ . Since  $V/U$  is again the ratio of independent, standard normal variables, it follows that  $1/X$  again has the Cauchy distribution.
- It is known from Exercise 18 of Sec. 5.6 that  $U/V$  has a Cauchy distribution, which is the  $t$  distribution with one degree of freedom. Next, since  $|V| = (V^2)^{1/2}$ , it follows from Definition 8.4.1 that  $U/|V|$  has the required  $t$  distribution. Hence, by the previous exercise in this section,  $|V|/U$  will also have this  $t$  distribution. Since  $U$  and  $V$  are i.i.d., it now follows that  $|U|/V$  must have the same distribution as  $|V|/U$ .
- It is known from Exercise 5 of Sec. 8.3 that  $X_1 + X_2$  and  $X_1 - X_2$  are independent. Further, if we let

$$Y_1 = \frac{1}{\sqrt{2}\sigma}(X_1 + X_2) \quad \text{and} \quad Y_2 = \frac{1}{\sqrt{2}\sigma}(X_1 - X_2),$$

then  $Y_1$  and  $Y_2$  have standard normal distributions. It follows, therefore, from Exercise 18 of Sec. 5.6 that  $Y_1/Y_2$  has a Cauchy distribution, which is the same as the  $t$  distribution with one degree of freedom. But

$$\frac{Y_1}{Y_2} = \frac{X_1 + X_2}{X_1 - X_2},$$

so the desired result has been established. This result could also have been established by a direct calculation of the required p.d.f.

5. Since  $X_i$  has the exponential distribution with parameter  $\beta$ , it follows that  $2\beta X_i$  has the exponential distribution with parameter  $1/2$ . But this exponential distribution is the  $\chi^2$  distribution with 2 degrees of freedom. Therefore, the sum of the i.i.d. random variables  $2\beta X_i$  ( $i = 1, \dots, n$ ) will have a  $\chi^2$  distribution with  $2n$  degrees of freedom.
6. Let  $\hat{\theta}_n$  be the proportion of the  $n$  observations that lie in the set  $A$ . Since each observation has probability  $\theta$  of lying in  $A$ , the observations can be thought of as forming  $n$  Bernoulli trials, each with probability  $\theta$  of success. Hence,  $E(\hat{\theta}_n) = \theta$  and  $\text{Var}(\hat{\theta}_n) = \theta(1 - \theta)/n$ .
7. (a)  $E(\alpha S_X^2 + \beta S_Y^2) = \alpha(m - 1)\sigma^2 + \beta(n - 1)2\sigma^2$ .  
Hence, this estimator will be unbiased if  $\alpha(m - 1) + 2\beta(n - 1) = 1$ .
- (b) Since  $S_X^2$  and  $S_Y^2$  are independent,

$$\begin{aligned}\text{Var}(\alpha S_X^2 + \beta S_Y^2) &= \alpha^2 \text{Var}(S_X^2) + \beta^2 \text{Var}(S_Y^2) \\ &= \alpha^2[2(m - 1)\sigma^4] + \beta^2[2(n - 1) \cdot 4\sigma^4] \\ &= 2\sigma^4[(m - 1)\alpha^2 + 4(n - 1)\beta^2].\end{aligned}$$

Therefore, we must minimize

$$A = (m - 1)\alpha^2 + 4(n - 1)\beta^2$$

subject to the constraint  $(m - 1)\alpha + 2(n - 1)\beta = 1$ . If we solve this constraint for  $\beta$  in terms of  $\alpha$ , and make this substitution for  $\beta$  in  $A$ , we can then minimize  $A$  over all values of  $\alpha$ . The result is  $\alpha = \frac{1}{m + n - 2}$  and, hence,  $\beta = \frac{1}{2(m + n - 2)}$ .

8.  $X_{n+1} - \bar{X}_n$  has the normal distribution with mean 0 and variance  $(1 + 1/n)\sigma^2$ . Hence, the distribution of  $(n/[n + 1])^{1/2}(X_{n+1} - \bar{X}_n)/\sigma$  is a standard normal distribution. Also,  $nT_n^2/\sigma^2$  has an independent  $\chi^2$  distribution with  $n - 1$  degrees of freedom. Thus, the following ratio will have the  $t$  distribution with  $n - 1$  degrees of freedom:

$$\frac{\left(\frac{n}{n+1}\right)^{1/2} (X_{n+1} - \bar{X}_n)/\sigma}{\left[\frac{nT_n^2}{(n-1)\sigma^2}\right]^{1/2}} = \left(\frac{n-1}{n+1}\right)^{1/2} \frac{X_{n+1} - \bar{X}_n}{T_n}.$$

It can now be seen that  $k = ([n - 1]/[n + 1])^{1/2}$ .

9. Under the given conditions,  $Y/(2\sigma)$  has a standard normal distribution and  $S_n^2/\sigma^2$  has an independent  $\chi^2$  distribution with  $n - 1$  degrees of freedom. Thus, the following random variable will have a  $t$  distribution with  $n - 1$  degrees of freedom:

$$\frac{Y/(2\sigma)}{\{S_n^2/[\sigma^2(n - 1)]\}^{1/2}} = \frac{Y/2}{\sigma'},$$

where  $\sigma' = [S_n^2/(n - 1)]^{1/2}$ .

10. As found in Exercise 3 of Sec. 8.5, the expected squared length of the confidence interval is  $E(L^2) = 4c^2\sigma^2/n$ , where  $c$  is found from the table of the  $t$  distribution with  $n - 1$  degrees of freedom in the back of the book under the .95 column (to give probability .90 between  $-c$  and  $c$ ). We must compute the value of  $4c^2/n$  for various values of  $n$  and see when it is less than  $1/2$ . For  $n = 23$ , it is found that  $c_{22} = 1.717$  and the coefficient of  $\sigma^2$  in  $E(L^2)$  is  $4(1.717)^2/23 = .512$ . For  $n = 24$ ,  $c_{23} = 1.714$  and the coefficient of  $\sigma^2$  is  $4(1.714)^2/24 = .490$ . Hence,  $n = 24$  is the required value.
11. Let  $c$  denote the .99 quantile of the  $t$  distribution with  $n - 1$  degrees of freedom; i.e.,  $\Pr(U < c) = .99$  if  $U$  has the specified  $t$  distribution. Therefore,  $\Pr\left[\frac{n^{1/2}(\bar{X}_n - \mu)}{\sigma'} < c\right] = .99$  or, equivalently,
- $$\Pr\left[\mu > \bar{X}_n - \frac{c\sigma'}{n^{1/2}}\right] = .99. \text{ Hence, } L = \bar{X}_n - c\sigma'/n^{1/2}.$$
12. Let  $c$  denote the .01 quantile of the  $\chi^2$  distribution with  $n - 1$  degrees of freedom; i.e.,  $\Pr(V < c) = .01$  if  $V$  has the specified  $\chi^2$  distribution. Therefore,

$$\Pr\left(\frac{S_n^2}{\sigma^2} > c\right) = .99$$

or, equivalently,

$$\Pr(\sigma^2 < S_n^2/c) = .99.$$

Hence,  $U = S_n^2/c$ .

13. (a) The posterior distribution of  $\theta$  is the normal distribution with mean  $\mu_1$  and variance  $\nu_1^2$ , as given by (7.3.1) and (7.3.2). Therefore, under this distribution,

$$\Pr(\mu_1 - 1.96\nu_1 < \theta < \mu_1 + 1.96\nu_1) = .95.$$

This interval  $I$  is the shortest one that has the required probability because it is symmetrically placed around the mean  $\mu_1$  of the normal distribution.

- (b) It follows from (7.3.1) that  $\mu_1 \rightarrow \bar{x}_n$  as  $\nu^2 \rightarrow \infty$  and from (7.3.2) that  $\nu_1^2 \rightarrow \sigma^2/n$ . Hence, the interval  $I$  converges to the interval

$$\bar{x}_n - \frac{1.96\sigma}{n^{1/2}} < \theta < \bar{x}_n + \frac{1.96\sigma}{n^{1/2}}.$$

It was shown in Exercise 4 of Sec. 8.5 that this interval is a confidence interval for  $\theta$  with confidence coefficient .95.

14. (a) Since  $Y$  has a Poisson distribution with mean  $n\theta$ , it follows that

$$\begin{aligned} E(\exp(-cY)) &= \sum_{y=0}^{\infty} \frac{\exp(-cy) \exp(-n\theta)(n\theta)^y}{y!} = \exp(-n\theta) \sum_{y=0}^{\infty} \frac{(n\theta \exp(-c))^y}{y!} \\ &= \exp(-n\theta) \exp[n\theta \exp(-c)] = \exp(n\theta[\exp(-c) - 1]). \end{aligned}$$

Since this expectation must be  $\exp(-\theta)$ , it follows that  $n(\exp(-c) - 1) = -1$  or  $c = \log[n/(n-1)]$ .

- (b) It was shown in Exercise 3 of Sec. 8.8 that  $I(\theta) = 1/\theta$  in this problem. Since  $m(\theta) = \exp(-\theta)$ ,  $[m'(\theta)]^2 = \exp(-2\theta)$ . Hence, from Eq. (8.8.14),

$$\text{Var}(\exp(-cY)) \geq \frac{\theta \exp(-2\theta)}{n}.$$

15. In the notation of Sec. 8.8,

$$\begin{aligned}\lambda(x | \theta) &= \log \theta + (\theta - 1) \log x, \\ \lambda'(x | \theta) &= \frac{1}{\theta} + \log x, \\ \lambda''(x | \theta) &= -1/\theta^2.\end{aligned}$$

Hence, by Eq. (8.8.3),  $I(\theta) = 1/\theta^2$  and it follows that the asymptotic distribution of

$$\frac{n^{1/2}}{\theta}(\hat{\theta}_n - \theta)$$

is standard normal.

- 16.

$$\begin{aligned}f(x | \theta) &= \theta^{-1} \exp(-x/\theta), \\ \lambda(x | \theta) &= -\log \theta - x/\theta, \\ \lambda'(x | \theta) &= -\frac{1}{\theta} + \frac{x}{\theta^2}, \\ \lambda''(x | \theta) &= \frac{1}{\theta^2} - \frac{2x}{\theta^3},\end{aligned}$$

Therefore,

$$I(\theta) = -E_\theta[\lambda''(X|\theta)] = \frac{1}{\theta^2}.$$

17. If  $m(p) = (1-p)^2$ , then  $m'(p) = -2(1-p)$  and  $[m'(p)]^2 = 4(1-p)^2$ . It was shown in Example 8.8.2 that  $I(p) = 1/[p(1-p)]$ . Therefore, if  $T$  is an unbiased estimator of  $m(p)$ , it follows from the relation (8.8.14) that

$$\text{Var}(T) \geq \frac{4(1-p)^2 p(1-p)}{n} = \frac{4p(1-p)^3}{n}.$$

18.  $f(x|\beta) = \beta \exp(-\beta x)$ . This p.d.f. has the form of an exponential family, as given in Exercise 11 of Sec. 8.8, with  $d(x) = x$ . Therefore,  $T = \sum_{i=1}^n X_i$  will be an efficient estimator. We know that  $E(X_i) = 1/\beta$  and  $\text{Var}(X_i) = 1/\beta^2$ . Hence,  $E(T) = n/\beta$  and  $\text{Var}(T) = n/\beta^2$ .

Since any linear function of  $T$  will also be an efficient estimator, it follows that  $\bar{X}_n = T/n$  will be an efficient estimator of  $1/\beta$ . As a check of this result, it can be verified directly that  $\text{Var}(\bar{X}_n) = 1/[n\beta^2] = [m'(\beta)]^2/[nI(\beta)]$ , where  $m(\beta) = 1/\beta$  and  $I(\beta)$  was obtained in Example 8.8.6.

19. It was shown in Example 8.8.6 that  $I(\beta) = 1/\beta^2$ . The distribution of the M.L.E. of  $\beta$  will be approximately the normal distribution with mean  $\beta$  and variance  $1/[nI(\beta)]$ .
20. (a) Let  $\alpha(\beta) = 1/\beta$ . Then  $\alpha'(\beta) = -1/\beta^2$ . By Exercise 19, it is known that  $\hat{\beta}_n$  is approximately normal with mean  $\beta$  and variance  $\beta^2/n$ . Therefore,  $1/\hat{\beta}_n$  will be approximately normal with mean  $1/\beta$  and variance  $[\alpha'(\beta)]^2(\beta^2/n) = 1/(n\beta^2)$ . Equivalently, the asymptotic distribution of  $(n\beta^2)^{1/2}(1/\hat{\beta}_n - 1/\beta)$  is standard normal.

- (b) Since the mean of the exponential distribution is  $1/\beta$  and the variance is  $1/\beta^2$ , it follows directly from the central limit theorem that the asymptotic distribution of  $\bar{X}_n = 1/\hat{\beta}_n$  is exactly that found in part (a).
21. (a) The distribution of  $Y$  is the Poisson distribution with mean  $n\theta$ . In order for  $r(Y)$  to be an unbiased estimator of  $1/\theta$ , we need

$$\frac{1}{\theta} = E_\theta(r(Y)) = \sum_{y=0}^{\infty} r(y) \exp(-n\theta) \frac{(n\theta)^y}{y!}.$$

This equation can be rewritten as

$$\exp(n\theta) = \sum_{y=0}^{\infty} \frac{r(y)n^y}{y!} \theta^{y+1}. \quad (\text{S.8.8})$$

The function on the left side of (S.8.8) has a unique power series representation, hence the right side of (S.8.8) must equal that power series. However, the limit as  $\theta \rightarrow 0$  of the left side of (S.8.8) is 1, while the limit of the right side is 0, hence the power series on the right cannot represent the function on the left.

- (b)  $E(n/[Y + 1]) = \sum_{y=0}^{\infty} n \exp(-n\theta)[n\theta]^y/(y + 1)!$ . By letting  $u = y + 1$  in this sum, we get  $n[1 - \exp(-n\theta)]/[n\theta] = 1/\theta - \exp(-n\theta)/\theta$ . So the bias is  $\exp(-n\theta)/\theta$ . Clearly  $\exp(-n\theta)$  goes to 0 as  $n \rightarrow \infty$ .
- (c)  $n/(1 + Y) = 1/(\bar{X}_n + 1/n)$ . We know that  $\bar{X}_n + 1/n$  has approximately the normal distribution with mean  $\theta + 1/n$  and variance  $\theta/n$ . We can ignore the  $1/n$  added to  $\theta$  in the mean since this will eventually be small relative to  $\theta$ . Using the delta method, we find that  $1/(\bar{X}_n + 1/n)$  has approximately the normal distribution with mean  $1/\theta$  and variance  $(1/\theta^2)^2\theta/n = (n\theta^3)^{-1}$ .

22. (a) The p.d.f. of  $Y_n$  is

$$f(y|\theta) = \begin{cases} ny^{n-1}/\theta^n & \text{if } 0 \leq y \leq \theta, \\ 0 & \text{otherwise.} \end{cases}$$

This can be found using the method of Example 3.9.6. If  $X = Y_n/\theta$ , then the p.d.f. of  $X$  is

$$g(x|\theta) = f(x\theta|\theta)\theta = \begin{cases} nx^{n-1} & \text{if } 0 \leq x \leq 1, \\ 0 & \text{otherwise.} \end{cases}$$

Notice that this does not depend on  $\theta$ . The c.d.f. is then  $G(x) = x^n$  for  $0 < x < 1$ . The quantile function is  $G^{-1}(p) = p^{1/n}$ .

- (b) The bias of  $Y_n$  as an estimator of  $\theta$  is

$$E_\theta(Y_n) - \theta = \int_0^\theta y \frac{ny^{n-1}}{\theta^n} dy - \theta = -\frac{\theta}{n+1}.$$

- (c) The distribution of  $Z = Y_n/\theta$  has p.d.f.

$$g(z) = \theta f(z\theta|\theta) = \begin{cases} nz^{n-1} & \text{for } 0 \leq z \leq 1, \\ 0 & \text{otherwise,} \end{cases}$$

where  $f(\cdot|\theta)$  comes from part (a). One can see that  $g(z)$  does not depend on  $\theta$ , hence the distribution of  $Z$  is the same for all  $\theta$ .

(d) We would like to find two random variables  $A(Y_n)$  and  $B(Y_n)$  such that

$$\Pr(A(Y_n) \leq \theta \leq B(Y_n)) = \gamma, \text{ for all } \theta. \quad (\text{S.8.9})$$

This can be arranged by using the fact that  $Y_n/\theta$  has the c.d.f.  $G(x) = x^n$  for all  $\theta$ . This means that

$$\Pr\left(a \leq \frac{Y_n}{\theta} \leq b\right) = b^n - a^n,$$

for all  $\theta$ . Let  $a$  and  $b$  be constants such that  $b^n - a^n = \gamma$  (e.g.,  $b = ([1 + \gamma]/2)^{1/n}$  and  $a = ([1 - \gamma]/2)^{1/n}$ ). Then set  $A(Y_n) = Y_n/b$  and  $B(Y_n) = Y_n/a$ . It follows that (S.8.9) holds.

# Chapter 9

## Testing Hypotheses

### 9.1 Problems of Testing Hypotheses

#### Commentary

This section was augmented in the fourth edition. It now includes a general introduction to likelihood ratio tests and some foundational discussion of the terminology of hypothesis testing. After covering this section, one could skip directly to Sec. 9.5 and discuss the  $t$  test without using any of the material in Sec. 9.2–9.4. Indeed, unless your course is a rigorous mathematical statistics course, it might be highly advisable to skip ahead.

#### Solutions to Exercises

1. (a) Let  $\delta$  be the test that rejects  $H_0$  when  $X \geq 1$ . The power function of  $\delta$  is

$$\pi(\beta|\delta) = \Pr(X \geq 1|\beta) = \exp(-\beta),$$

for  $\beta > 0$ .

1. (b) The size of the test  $\delta$  is  $\sup_{\beta \geq 1} \pi(\beta|\delta)$ . Using the answer to part (a), we see that  $\pi(\beta|\delta)$  is a decreasing function of  $\beta$ , hence the size of the test is  $\pi(1|\delta) = \exp(-1)$ .
2. (a) We know that if  $0 < y < \theta$ , then  $\Pr(Y_n \leq y) = (y/\theta)^n$ . Also, if  $y \geq \theta$ , then  $\Pr(Y_n \leq y) = 1$ . Therefore, if  $\theta \leq 1.5$ , then  $\pi(\theta) = \Pr(Y_n \leq 1.5) = 1$ . If  $\theta > 1.5$ , then  $\pi(\theta) = \Pr(Y_n \leq 1.5) = (1.5/\theta)^n$ .
2. (b) The size of the test is

$$\alpha = \sup_{\theta \geq 2} \pi(\theta) = \sup_{\theta \geq 2} \left(\frac{1.5}{\theta}\right)^n = \left(\frac{1.5}{2}\right)^n = \left(\frac{3}{4}\right)^n.$$

3. (a) For any given value of  $p$ ,  $\pi(p) = \Pr(Y \geq 7) + \Pr(Y \leq 1)$ , where  $Y$  has a binomial distribution with parameters  $n = 20$  and  $p$ . For  $p = 0$ ,  $\Pr(Y \geq 7) = 0$  and  $\Pr(Y \leq 1) = 1$ . Therefore,  $\pi(0) = 1$ . For  $p = 0.1$ , it is found from the table of the binomial distribution that

$$\Pr(Y \geq 7) = .0020 + .0003 + .0001 + .0000 = .0024$$

and  $\Pr(Y \leq 1) = .1216 + .2701 = .3917$ . Hence,  $\pi(0.1) = 0.3941$ . Similarly, for  $p = 0.2$ , it is found that

$$\Pr(Y \geq 7) = .0545 + .0222 + .0074 + .0020 + .0005 + .0001 = .0867$$

and  $\Pr(Y \leq 1) = .0115 + .0576 = .0691$ . Hence,  $\pi(0.2) = 0.1558$ . By continuing to use the tables in this way, we can find the values of  $\pi(0.3)$ ,  $\pi(0.4)$ , and  $\pi(0.5)$ . For  $p = 0.6$ , we must use the fact that if  $Y$  has a binomial distribution with parameters 20 and 0.6, then  $Z = 20 - Y$  has a binomial distribution with parameters 20 and 0.4. Also,  $\Pr(Y \geq 7) = \Pr(Z \leq 13)$  and  $\Pr(Y \leq 1) = \Pr(Z \geq 19)$ . It is found from the tables that  $\Pr(Z \leq 13) = .9935$  and  $\Pr(Z \geq 19) = .0000$ . Hence,  $\pi(0.6) = .9935$ . Similarly, if  $p = 0.7$ , then  $Z = 20 - Y$  will have a binomial distribution with parameters 20 and 0.3. In this case it is found that  $\Pr(Z \leq 13) = .9998$  and  $\Pr(Z \geq 19) = .0000$ . Hence,  $\pi(0.7) = 0.9998$ . By continuing in this way, the values of  $\pi(0.8)$ ,  $\pi(0.9)$ , and  $\pi(1.0) = 1$  can be obtained.

- (b) Since  $H_0$  is a simple hypothesis, the size  $\alpha$  of the test is just the value of the power function at the point specified by  $H_0$ . Thus,  $\alpha = \pi(0.2) = 0.1558$ .
- 4. The null hypothesis  $H_0$  is simple. Therefore, the size  $\alpha$  of the test is  $\alpha = \Pr(\text{Rejecting } H_0 | \mu = \mu_0)$ . When  $\mu = \mu_0$ , the random variable  $Z = n^{1/2}(\bar{X}_n - \mu_0)$  will have the standard normal distribution. Hence, since  $n = 25$ ,

$$\alpha = \Pr(|\bar{X}_n - \mu_0| \geq c) = \Pr(|Z| \geq 5c) = 2[1 - \Phi(5c)].$$

Thus,  $\alpha = 0.05$  if and only if  $\Phi(5c) = 0.975$ . It is found from a table of the standard normal distribution that  $5c = 1.96$  and  $c = 0.392$ .

- 5. A hypothesis is simple if and only if it specifies a single value of both  $\mu$  and  $\sigma$ . Therefore, only the hypothesis in (a) is simple. All the others are composite. In particular, although the hypothesis in (d) specifies the value of  $\mu$ , it leaves the value of  $\sigma$  arbitrary.
- 6. If  $H_0$  is true, then  $X$  will surely be smaller than 3.5. If  $H_1$  is true, then  $X$  will surely be greater than 3.5. Therefore, the test procedure which rejects  $H_0$  if and only if  $X > 3.5$  will have probability 0 of leading to a wrong decision, no matter what the true value of  $\theta$  is.
- 7. Let  $C$  be the critical region of  $Y_n$  values for the test  $\delta$ , and let  $C^*$  be the critical region for  $\delta^*$ . It is easy to see that  $C^* \subset C$ . Hence

$$\pi(\theta|\delta) - \pi(\theta|\delta^*) = \Pr\left(Y_n \in C \cap (C^*)^C \mid \theta\right).$$

Here  $C \cap (C^*)^C = [4, 4.5]$ , so

$$\pi(\theta|\delta) - \pi(\theta|\delta^*) = \Pr(4 \leq Y_n \leq 4.5|\theta). \quad (\text{S.9.1})$$

- (a) For  $\theta \leq 4$   $\Pr(4 \leq Y_n|\theta) = 0$ , so the two power functions must be equal by (S.9.1).
- (b) For  $\theta > 4$ ,

$$\Pr(4 \leq Y_n \leq 4.5|\theta) = \frac{(\min\{\theta, 4.5\})^n - 4^n}{\theta^n} > 0.$$

Hence,  $\pi(\theta|\delta) > \pi(\theta|\delta^*)$  by (S.9.1).

- (c) The only places where the power functions differ are for  $\theta > 4$ . Since these values are all in  $\Omega_1$ , it is better for a test to have higher power function for these values. Since  $\delta$  has higher power function than  $\delta^*$  for all of these values,  $\delta$  is the better test.

8. (a) The distribution of  $Z$  given  $\mu$  is the normal distribution with mean  $n^{1/2}(\mu - \mu_0)$  and variance 1. We can write

$$\Pr(Z \geq c|\mu) = 1 - \Phi([c - n^{1/2}(\mu - \mu_0)]) = \Phi(n^{1/2}\mu - n^{1/2}\mu_0 - c).$$

Since  $\Phi$  is an increasing function and  $n^{1/2}\mu - n^{1/2}\mu_0 - c$  is an increasing function of  $\mu$ , the power function is an increasing function of  $\mu$ .

- (b) The size of the test will be the power function at  $\mu = \mu_0$ , since  $\mu_0$  is the largest value in  $\Omega_0$  and the power function is increasing. Hence, the size is  $\Phi(-c)$ . If we set this equal to  $\alpha_0$ , we can solve for  $c = -\Phi^{-1}(\alpha_0)$ .
9. A sensible test would be to reject  $H_0$  if  $\bar{X}_n < c'$ . So, let  $T = \mu_0 - \bar{X}_n$ . Then the power function of the test  $\delta$  that rejects  $H_0$  when  $T \geq c$  is

$$\begin{aligned}\pi(\mu|\delta) &= \Pr(T \geq c|\mu) \\ &= \Pr(\bar{X}_n \leq \mu_0 - c|\mu) \\ &= \Phi(\sqrt{n}[\mu_0 - c - \mu]).\end{aligned}$$

Since  $\Phi$  is an increasing function and  $\sqrt{n}[\mu_0 - c - \mu]$  is a decreasing function of  $\mu$ , it follows that  $\Phi(\sqrt{n}[\mu_0 - c - \mu])$  is a decreasing function of  $\mu$ .

10. When  $Z = z$  is observed, the  $p$ -value is  $\Pr(Z \geq z|\mu_0) = \Phi(n^{1/2}[\mu_0 - z])$ .
11. (a) For  $c_1 \geq 2$ ,  $\Pr(Y \leq c_1|p = 0.4) \geq 0.23$ , hence  $c_1 \leq 1$ . Also, for  $c_2 \leq 5$ ,  $\Pr(Y \geq c_2|p = 0.4) \geq 0.26$ , hence  $c_2 \geq 6$ . Here are some values of the desired probability for various  $(c_1, c_2)$  pairs

$c_1$	$c_2$	$\Pr(Y \leq c_1 p = 0.4) + \Pr(Y \geq c_2 p = 0.4)$
1	6	0.1699
1	7	0.0956
0	6	0.1094
-1	6	0.0994

So, the closest we can get to 0.1 without going over is 0.0994, which is achieved when  $c_1 < 0$  and  $c_2 = 6$ .

- (b) The size of the test is 0.0994, as we calculated in part (a).  
(c) The power function is plotted in Fig. S.9.1. Notice that the power function is too low for values of  $p < 0.4$ . This is due to the fact that the test only rejects  $H_0$  when  $Y \geq 6$ . A better test might be one with  $c_1 = 1$  and  $c_2 = 7$ . Even though the size is slightly smaller (as is the power for  $p > 0.4$ ), its power is much greater for  $p < 0.4$ .

12. (a) The power function of  $\delta_c$  is

$$\pi(\theta|\delta_c) = \Pr(X \geq c|\theta) = \int_c^\infty \frac{dx}{\pi[1 + (x - \theta)^2]} = \frac{1}{\pi} \left[ \frac{\pi}{2} - \arctan(c - \theta) \right].$$

Since  $\arctan$  is an increasing function and  $c - \theta$  is a decreasing function of  $\theta$ , the power function is increasing in  $\theta$ .

- (b) To make the size of the test 0.05, we need to solve

$$0.05 = \frac{1}{\pi} \left[ \frac{\pi}{2} - \arctan(c - \theta_0) \right],$$

for  $c$ . We get

$$c = \theta_0 + \tan(0.45\pi) = \theta_0 + 6.314.$$

Figure S.9.1: Power function of test in Exercise 11c of Sec. 9.1.

(c) The  $p$ -value when  $X = x$  is observed is

$$\Pr(X \geq x | \theta = \theta_0) = \frac{1}{\pi} \left[ \frac{\pi}{2} - \arctan(x - \theta_0) \right].$$

13. For  $c = 3$ ,  $\Pr(X \geq c|\theta = 1) = 0.0803$ , while for  $c = 2$ , the probability is 0.2642. Hence, we must use  $c = 3$ .

14. (a) The distribution of  $X$  is a gamma distribution with parameters  $n$  and  $\theta$  and  $Y = X\theta$  has a gamma distribution with parameters  $n$  and 1. Let  $G_n$  be the c.d.f. of the gamma distribution with parameters  $n$  and 1. The power function of  $\delta_c$  is then

$$\pi(\theta|\delta_c) = \Pr(X \geq c|\theta) = \Pr(Y \geq c\theta|\theta) = 1 - G_n(c\theta).$$

Since  $1 - G_n$  is a decreasing function and  $c\theta$  is an increasing function of  $\theta$ ,  $1 - G_n(c\theta)$  is a decreasing function of  $\theta$ .

(b) We need  $1 - G_n(c\theta_0) = \alpha_0$ . This means that  $c = G_n^{-1}(1 - \alpha_0)/\theta_0$ .

(c) With  $\alpha_0 = 0.1$ ,  $n = 1$  and  $\theta_0 = 2$ , we find that  $G_n(y) = 1 - \exp(-y)$  and  $G_n^{-1}(p) = -\log(1 - p)$ . So,  $c = -\log(0.1)/2 = 1.151$ . The power function is plotted in Fig. S.9.2.

15. The  $p$ -value when  $X = x$  is observed is the size of the test that rejects  $H_0$  when  $X \geq x$ , namely

$$\Pr(X \geq x | \theta = 1) = \begin{cases} 0 & \text{if } x \geq 1, \\ 1 - x & \text{if } 0 < x < 1. \end{cases}$$

16. The confidence interval is  $(s_n^2/c_2, s_n^2/c_1)$ , where  $s_n^2 = \sum_{i=1}^n (x_i - \bar{x}_n)^2$  and  $c_1, c_2$  are the  $(1 - \gamma)/2$  and  $(1 + \gamma)/2$  quantiles of the  $\chi^2$  distribution with  $n - 1$  degrees of freedom. We create the test  $\delta_c$  of  $H_0 : \sigma^2 = c$  by rejecting  $H_0$  if  $c$  is not in the interval. Let  $T(\mathbf{x}) = s_n^2$  and notice that  $c$  is outside of the interval if and only if  $T(\mathbf{x})$  is not in the interval  $(c_1 c, c_2 c)$ .

17. We need  $q(y)$  to have the property that  $\Pr(q(Y) < p|p) \geq \gamma$  for all  $p$ . We shall prove that  $q(y)$  equal to the smallest  $p_0$  such that  $\Pr(Y \geq y|p = p_0) \geq 1 - \gamma$  satisfies this property. For each  $p$ , let  $A_p = \{y : q(y) < p\}$ . We need to show that  $\Pr(Y \in A_p|p) \geq \gamma$ . First, notice that  $q(y)$  is an increasing

Figure S.9.2: Power function of test in Exercise 14c of Sec. 9.1.

function of  $y$ . This means that for each  $p$  there is  $y_p$  such that  $A_p = \{0, \dots, y_p\}$ . So, we need to show that  $\Pr(Y \leq y_p | p) \geq \gamma$  for all  $p$ . Equivalently, we need to show that  $\Pr(Y > y_p | p) \leq 1 - \gamma$ . Notice that  $y_p$  is the largest value of  $y$  such that  $q(y) < p$ . That is,  $y_p$  is the largest value of  $y$  such that there exists  $p_0 < p$  with  $\Pr(Y \geq y | p_0) \geq 1 - \gamma$ . For each  $y$ ,  $\Pr(Y > y | p)$  is a continuous nondecreasing function of  $p$ . If  $\Pr(Y > y_p | p) > 1 - \gamma$ , then there exists  $p_0 < p$  such that

$$1 - \gamma < \Pr(Y > y_p | p_0) = \Pr(Y \geq y_p + 1 | p_0).$$

This contradicts the fact that  $y_p$  is the largest  $y$  such that there is  $p_0 < p$  with  $\Pr(Y \geq y | p_0) \geq 1 - \gamma$ . Hence  $\Pr(Y > y_p | p) \leq 1 - \gamma$  and the proof is complete.

18. Our tests are all of the form “Reject  $H_0$  if  $T \geq c$ .” Let  $\delta_c$  be this test, and define

$$\alpha(c) = \sup_{\theta \in \Omega_0} \Pr(T \geq c | \theta),$$

the size of the test  $\delta_c$ . Then  $\delta_c$  has level of significance  $\alpha_0$  if and only if  $\alpha(c) \leq \alpha_0$ . Notice that  $\alpha(c)$  is a decreasing function of  $c$ . When  $T = t$  is observed, we reject  $H_0$  at level of significance  $\alpha_0$  using  $\delta_c$  if and only if  $t \geq c$ , which is equivalent to  $\alpha(t) \leq \alpha_0$ . Hence  $\alpha(t)$  is the smallest level of significance at which we can reject  $H_0$  if  $T = t$  is observed. Notice that  $\alpha(t)$  is the expression in Eq. (9.1.12).

19. We want our test to reject  $H_0$  if  $\bar{X}_n \leq Y$ , where  $Y$  might be a random variable. We can write this as not rejecting  $H_0$  if  $\bar{X}_n > Y$ . We want  $\bar{X}_n > Y$  to be equivalent to  $\mu_0$  being inside of our interval. We need the test to have level  $\alpha_0$ , so

$$\Pr(\bar{X}_n \leq Y | \mu = \mu_0, \sigma^2) = \alpha_0 \tag{S.9.2}$$

is necessary. We know that  $n^{1/2}(\bar{X}_n - \mu_0)/\sigma'$  has the  $t$  distribution with  $n - 1$  degrees of freedom if  $\mu = \mu_0$ , hence Eq. (S.9.2) will hold if  $Y = \mu_0 - n^{-1/2}\sigma' T_{n-1}^{-1}(1 - \alpha_0)$ . Now,  $\bar{X}_n > Y$  if and only if  $\mu_0 < \bar{X}_n + n^{-1/2}\sigma' T_{n-1}^{-1}(1 - \alpha_0)$ . This is equivalent to  $\mu_0$  in our interval if our interval is

$$(-\infty, \bar{X}_n + n^{-1/2}\sigma' T_{n-1}^{-1}(1 - \alpha_0)).$$

20. Let  $\theta_0 \in \Omega$ , and let  $g_0 = g(\theta_0)$ . By construction,  $g(\theta_0) \in \omega(\mathbf{X})$  if and only if  $\delta_{g_0}$  does not reject  $H_{0,g_0} : g(\theta) \leq g_0$ . Given  $\theta = \theta_0$ , the probability that  $\delta_{g_0}$  does not reject  $H_{0,g_0}$  is at least  $\gamma$  because the null hypothesis is true and the level of the test is  $\alpha_0 = 1 - \gamma$ . Hence, (9.1.15) holds.

21. Let  $U = n^{1/2}(\bar{X}_n - \mu_0)/\sigma'$ .

(a) We reject the null hypothesis in (9.1.22) if and only if

$$U \geq T_{n-1}^{-1}(1 - \alpha_0). \quad (\text{S.9.3})$$

We reject the null hypothesis in (9.1.27) if and only if

$$U \leq -T_{n-1}^{-1}(1 - \alpha_0). \quad (\text{S.9.4})$$

With  $\alpha_0 < 0.5$ ,  $T_{n-1}^{-1}(1 - \alpha_0) > 0$ . So, (S.9.3) requires  $U > 0$  while (S.9.4) requires  $U < 0$ . These cannot both occur.

- (b) Both (S.9.3) and (S.9.4) fail if and only if  $U$  is strictly between  $-T_{n-1}^{-1}(1 - \alpha_0)$  and  $T_{n-1}^{-1}(1 - \alpha_0)$ . This can happen if  $\bar{X}_n$  is sufficiently close to  $\mu_0$ . This has probability  $1 - 2\alpha_0 > 0$ .
- (c) If  $\alpha_0 > 0.5$ , then  $T_{n-1}^{-1}(1 - \alpha_0) < 0$ , and both null hypotheses would be rejected if  $U$  is between the numbers  $T_{n-1}^{-1}(1 - \alpha_0) < 0$  and  $-T_{n-1}^{-1}(1 - \alpha_0) > 0$ . This has probability  $2\alpha_0 - 1 > 0$ .

## 9.2 Testing Simple Hypotheses

### Commentary

This section, and the two following, contain some traditional optimality results concerning tests of hypotheses about one-dimensional parameters. In this section, we present the Neyman-Pearson lemma which gives optimal tests for simple null hypotheses against simple alternative hypotheses. It is recommended that one skip this section, and the two that follow, unless one is teaching a rigorous mathematical statistics course. This section ends with a brief discussion of randomized tests. Randomized tests are mainly of theoretical interest. They only show up in one additional place in the text, namely the proof of Theorem 9.3.1.

### Solutions to Exercises

1. According to Theorem 9.2.1, we should reject  $H_0$  if  $f_1(x) > f_0(x)$ , not reject  $H_0$  if  $f_1(x) < f_0(x)$  and do whatever we wish if  $f_1(x) = f_0(x)$ . Here

$$\begin{aligned} f_0(x) &= \begin{cases} 0.3 & \text{if } x = 1, \\ 0.7 & \text{if } x = 0, \end{cases} \\ f_1(x) &= \begin{cases} 0.6 & \text{if } x = 1, \\ 0.4 & \text{if } x = 0. \end{cases} \end{aligned}$$

We have  $f_1(x) > f_0(x)$  if  $x = 1$  and  $f_1(x) < f_0(x)$  if  $x = 0$ . We never have  $f_1(x) = f_0(x)$ . So, the test is to reject  $H_0$  if  $X = 1$  and not reject  $H_0$  if  $X = 0$ .

2. (a) Theorem 9.2.1 can be applied with  $a = 1$  and  $b = 2$ . Therefore,  $H_0$  should not be rejected if  $f_1(x)/f_0(x) < 1/2$ . Since  $f_1(x)/f_0(x) = 2x$ , the procedure is to not reject  $H_0$  if  $x < 1/4$  and to reject  $H_0$  if  $x > 1/4$ .

(b) For this procedure,

$$\alpha(\delta) = \Pr(\text{Rej. } H_0 | f_0) = \int_{1/4}^1 f_0(x) dx = \frac{3}{4}$$

and

$$\beta(\delta) = \Pr(\text{Acc. } H_0 | f_1) = \int_0^{1/4} 2x dx = \frac{1}{16}.$$

Therefore,  $\alpha(\delta) + 2\beta(\delta) = 7/8$ .

3. (a) Theorem 9.2.1 can be applied with  $a = 3$  and  $b = 1$ . Therefore,  $H_0$  should not be rejected if  $f_1(x)/f_0(x) = 2x < 3$ . Since all possible values of  $X$  lie in the interval  $(0,1)$ , and since  $2x < 3$  for all values in this interval, the optimal procedure is to not reject  $H_0$  for every possible observed value.
- (b) Since  $H_0$  is never rejected,  $\alpha(\delta) = 0$  and  $\beta(\delta) = 1$ . Therefore,  $3\alpha(\delta) + \beta(\delta) = 1$ .
4. (a) By the Neyman-Pearson lemma,  $H_0$  should be rejected if  $f_1(x)/f_0(x) = 2x > k$ , where  $k$  is chosen so that  $\Pr(2x > k | f_0) = 0.1$ . For  $0 < k < 2$ ,

$$\Pr(2X > k | f_0) = \Pr\left(X > \frac{k}{2} \middle| f_0\right) = 1 - \frac{k}{2}.$$

If this value is to be equal to 0.1, then  $k = 1.8$ . Therefore, the optimal procedure is to reject  $H_0$  if  $2x > 1.8$  or, equivalently, if  $x > 0.9$ .

(b) For this procedure,

$$\beta(\delta) = \Pr(\text{Acc. } H_0 | f_1) = \int_0^{0.9} f_1(x) dx = 0.81.$$

5. (a) The conditions here are different from those of the Neyman-Pearson lemma. Rather than fixing the value of  $\alpha(\delta)$  and minimizing  $\beta(\delta)$ , we must here fix the value of  $\beta(\delta)$  and minimize  $\alpha(\delta)$ . Nevertheless, the same proof as that given for the Neyman-Pearson lemma shows that the optimal procedure is again to reject  $H_0$  if  $f_1(\mathbf{X})/f_0(\mathbf{X}) > k$ , where  $k$  is now chosen so that

$$\beta(\delta) = \Pr(\text{Acc. } H_0 | H_1) = \Pr\left[\frac{f_1(\mathbf{X})}{f_0(\mathbf{X})} < k | H_1\right] = 0.05.$$

In this exercise,

$$f_0(\mathbf{X}) = \frac{1}{(2\pi)^{n/2}} \exp\left[-\frac{1}{2} \sum_{i=1}^n (x_i - 3.5)^2\right]$$

and

$$f_1(\mathbf{X}) = \frac{1}{(2\pi)^{n/2}} \exp\left[-\frac{1}{2} \sum_{i=1}^n (x_i - 5.0)^2\right].$$

Therefore,

$$\begin{aligned} \log \frac{f_1(\mathbf{X})}{f_0(\mathbf{X})} &= \frac{1}{2} \left[ \sum_{i=1}^n (x_i - 3.5)^2 - \sum_{i=1}^n (x_i - 5.0)^2 \right] \\ &= \frac{1}{2} \left[ \sum_{i=1}^n x_i^2 - 7 \sum_{i=1}^n x_i + 12.25n - \sum_{i=1}^n x_i^2 + 10 \sum_{i=1}^n x_i - 25n \right] \\ &= \frac{3}{2} n \bar{x}_n - (\text{const.}). \end{aligned}$$

It follows that the likelihood ratio  $f_1(\mathbf{X})/f_0(\mathbf{X})$  will be greater than some specified constant  $k$  if and only if  $\bar{x}_n$  is greater than some other constant  $k'$ . Therefore, the optimal procedure is to reject  $H_0$  if  $\bar{x}_n > k'$ , where  $k'$  is chosen so that

$$\Pr(\bar{X}_n < k' | H_1) = 0.05.$$

We shall now determine the value of  $k'$ . If  $H_1$  is true, then  $\bar{X}_n$  will have a normal distribution with mean 5.0 and variance  $1/n$ . Therefore,  $Z = \sqrt{n}(\bar{X}_n - 5.0)$  will have the standard normal distribution, and it follows that

$$\Pr(\bar{X}_n < k' | H_1) = \Pr[Z < \sqrt{n}(k' - 5.0)] = \Phi[\sqrt{n}(k' - 5.0)].$$

If this probability is to be equal to 0.05, then it can be found from a table of values of  $\Phi$  that  $\sqrt{n}(k' - 5.0) = -1.645$ . Hence,  $k' = 5.0 - 1.645n^{-1/2}$ .

- (b) For  $n = 4$ , the test procedure is to reject  $H_0$  if  $\bar{X}_n > 5.0 - 1.645/2 = 4.1775$ . Therefore,

$$\alpha(\delta) = \Pr(\text{Rej. } H_0 | H_0) = \Pr(\bar{X}_n > 4.1775 | H_0).$$

When  $H_0$  is true,  $\bar{X}_n$  has a normal distribution with mean 3.5 and variance  $1/n = 1/4$ . Therefore,  $Z = 2(\bar{X}_n - 3.5)$  will have the standard normal distribution, and

$$\begin{aligned}\alpha(\delta) &= \Pr[Z > 2(4.1775 - 3.5)] = \Pr(Z > 1.355) \\ &= 1 - \Phi(1.355) = 0.0877.\end{aligned}$$

6. Theorem 9.2.1 can be applied with  $a = b = 1$ . Therefore,  $H_0$  should be rejected if  $f_1(\mathbf{X})/f_0(\mathbf{X}) > 1$ .

If we let  $y = \sum_{i=1}^n x_i$ , then

$$f_1(\mathbf{X}) = p_1^y (1-p_1)^{n-y}$$

and

$$f_0(\mathbf{X}) = p_0^y (1-p_0)^{n-y}.$$

Hence,

$$\frac{f_1(\mathbf{X})}{f_0(\mathbf{X})} = \left[ \frac{p_1(1-p_0)}{p_0(1-p_1)} \right]^y \left( \frac{1-p_1}{1-p_0} \right)^n.$$

But  $f_1(\mathbf{X})/f_0(\mathbf{X}) > 1$  if and only if  $\log[f_1(\mathbf{X})/f_0(\mathbf{X})] > 0$ , and this inequality will be satisfied if and only if

$$y \log \left[ \frac{p_1(1-p_0)}{p_0(1-p_1)} \right] + n \log \left( \frac{1-p_1}{1-p_0} \right) > 0.$$

Since  $p_1 < p_0$  and  $1-p_0 < 1-p_1$ , the first logarithm on the left side of this relation is negative. Finally, if we let  $\bar{x}_n = y/n$ , then this relation can be rewritten as follows:

$$\bar{x}_n < \frac{\log \left( \frac{1-p_1}{1-p_0} \right)}{\log \left[ \frac{p_0(1-p_1)}{p_1(1-p_0)} \right]}.$$

The optimal procedure is to reject  $H_0$  when this inequality is satisfied.

7. (a) By the Neyman-Pearson lemma,  $H_0$  should be rejected if  $f_1(\mathbf{X})/f_0(\mathbf{X}) > k$ . Here,

$$f_0(\mathbf{X}) = \frac{1}{(2\pi)^{n/2} 2^{n/2}} \exp \left[ -\frac{1}{4} \sum_{i=1}^n (x_i - \mu)^2 \right]$$

and

$$f_1(\mathbf{X}) = \frac{1}{(2\pi)^{n/2} 3^{n/2}} \exp \left[ -\frac{1}{6} \sum_{i=1}^n (x_i - \mu)^2 \right].$$

Therefore,

$$\log \frac{f_1(\mathbf{X})}{f_0(\mathbf{X})} = \frac{1}{12} \sum_{i=1}^n (x_i - \mu)^2 + (\text{const.}).$$

It follows that the likelihood ratio will be greater than a specified constant  $k$  if and only if  $\sum_{i=1}^n (x_i - \mu)^2$  is greater than some other constant  $c$ . The constant  $c$  is to be chosen so that

$$\Pr \left[ \sum_{i=1}^n (X_i - \mu)^2 > c \mid H_0 \right] = 0.05.$$

The value of  $c$  can be determined as follows. When  $H_0$  is true,  $W = \sum_{i=1}^n (X_i - \mu)^2 / 2$  will have  $\chi^2$  distribution with  $n$  degrees of freedom. Therefore,

$$\Pr \left[ \sum_{i=1}^n (X_i - \mu)^2 > c \mid H_0 \right] = \Pr \left( W > \frac{c}{2} \right).$$

If this probability is to be equal to 0.05, then the value of  $c/2$  can be determined from a table of the  $\chi^2$  distribution.

- (b) For  $n = 8$ , it is found from a table of the  $\chi^2$  distribution with 8 degrees of freedom that  $c/2 = 15.51$  and  $c = 31.02$ .
8. (a) The p.d.f.'s  $f_0(x)$  and  $f_1(x)$  are as sketched in Fig. S.9.3. Under  $H_0$  it is impossible to obtain a value of  $X$  greater than 1, but such values are possible under  $H_1$ . Therefore, if a test procedure rejects  $H_0$  only if  $x > 1$ , then it is impossible to make an error of type 1, and  $\alpha(\delta) = 0$ . Also,

$$\beta(\delta) = \Pr(X < 1 \mid H_1) = \frac{1}{2}.$$

Figure S.9.3: Figure for Exercise 8a of Sec. 9.2.

- (b) To have  $\alpha(\delta) = 0$ , we can include in the critical region only a set of points having probability 0 under  $H_0$ . Therefore, only points  $x > 1$  can be considered. To minimize  $\beta(\delta)$  we should choose this set to have maximum probability under  $H_1$ . Therefore, all points  $x > 1$  should be used in the critical region.
9. As in Exercise 8, we should reject  $H_0$  if at least one of the  $n$  observations is greater than 1. For this test,  $\alpha(\delta) = 0$  and

$$\beta(\delta) = \Pr(\text{Acc. } H_0 | H_1) = \Pr(X_1 < 1, \dots, X_n < 1 | H_1) = \left(\frac{1}{2}\right)^n.$$

10. (a) and (b). Theorem 9.2.1 can be applied with  $a = b = 1$ . The optimal procedure is to reject  $H_0$  if  $f_1(\mathbf{X})/f_0(\mathbf{X}) > 1$ . If we let  $y = \sum_{i=1}^n x_i$ , then for  $i = 0, 1$ ,

$$f_i(\mathbf{X}) = \frac{\exp(-n\lambda_i)\lambda_i^y}{\prod_{i=1}^n (x_i!)}$$

Therefore,

$$\log \frac{f_1(\mathbf{X})}{f_0(\mathbf{X})} = y \log \left( \frac{\lambda_1}{\lambda_0} \right) - n(\lambda_1 - \lambda_0).$$

Since  $\lambda_1 > \lambda_0$ , it follows that  $f_1(\mathbf{X})/f_0(\mathbf{X}) > 1$  if and only if  $\bar{x}_n = y/n > (\lambda_1 - \lambda_0)/(\log \lambda_1 - \log \lambda_0)$ .

- (c) If  $H_i$  is true, then  $Y$  will have a Poisson distribution with mean  $n\lambda_i$ . For  $\lambda_0 = 1/4$ ,  $\lambda_1 = 1/2$ , and  $n = 20$ ,

$$\frac{n(\lambda_1 - \lambda_0)}{\log \lambda_1 - \log \lambda_0} = \frac{20(0.25)}{0.69314} = 7.214.$$

Therefore, it is found from a table of the Poisson distribution with mean  $20(1/4) = 5$  that

$$\alpha(\delta) = \Pr(Y > 7.214 | H_0) = \Pr(Y \geq 8 | H_0) = 0.1333.$$

Also, it is found from a table with mean  $20(1/2) = 10$  that

$$\beta(\delta) = \Pr(Y \leq 7.214 | H_1) = \Pr(Y \leq 7 | H_1) = 0.2203.$$

Therefore,  $\alpha(\delta) + \beta(\delta) = 0.3536$ .

11. Theorem 9.2.1 can be applied with  $a = b = 1$ . The optimal procedure is to reject  $H_0$  if  $f_1(\mathbf{X})/f_0(\mathbf{X}) > 1$ . Here,

$$f_0(\mathbf{X}) = \frac{1}{(2\pi)^{n/2} 2^n} \exp \left[ -\frac{1}{8} \sum_{i=1}^n (x_i + 1)^2 \right]$$

and

$$f_1(\mathbf{X}) = \frac{1}{(2\pi)^{n/2} 2^n} \exp \left[ -\frac{1}{8} \sum_{i=1}^n (x_i - 1)^2 \right].$$

After some algebraic reduction, it can be shown that  $f_1(\mathbf{X})/f_0(\mathbf{X}) > 1$  if and only if  $\bar{x}_n > 0$ . If  $H_0$  is true,  $\bar{X}_n$  will have the normal distribution with mean  $-1$  and variance  $4/n$ . Therefore,  $Z = \sqrt{n}(\bar{X}_n + 1)/2$  will have the standard normal distribution, and

$$\alpha(\delta) = \Pr(\bar{X}_n > 0 | H_0) = \Pr \left( Z > \frac{1}{2}\sqrt{n} \right) = 1 - \Phi \left( \frac{1}{2}\sqrt{n} \right).$$

Similarly, if  $H_1$  is true,  $\bar{X}_n$  will have the normal distribution with mean 1 and variance  $4/n$ . Therefore,  $Z' = \sqrt{n}(\bar{X}_n - 1)/2$  will have the standard normal distribution, and

$$\beta(\delta) = \Pr(\bar{X}_n < 0 | H_1) = \Pr\left(Z' < -\frac{1}{2}\sqrt{n}\right) = 1 - \Phi\left(\frac{1}{2}\sqrt{n}\right).$$

Hence,  $\alpha(\delta) + \beta(\delta) = 2[1 - \Phi(\sqrt{n}/2)]$ . We can now use a program that computes  $\Phi$  to obtain the following results:

- (a) If  $n = 1$ ,  $\alpha(\delta) + \beta(\delta) = 2(0.3085) = 0.6170$ .
- (b) If  $n = 4$ ,  $\alpha(\delta) + \beta(\delta) = 2(0.1587) = 0.3173$ .
- (c) If  $n = 16$ ,  $\alpha(\delta) + \beta(\delta) = 2(0.0228) = 0.0455$ .
- (d) If  $n = 36$ ,  $\alpha(\delta) + \beta(\delta) = 2(0.0013) = 0.0027$ .

Slight discrepancies appear above due to rounding *after* multiplying by 2 rather than before.

12. In the notation of this section,  $f_i(\mathbf{x}) = \theta_i^n \exp(-\theta_i \sum_{j=1}^n x_j)$  for  $i = 0, 1$ . The desired test has the following form: reject  $H_0$  if  $f_1(\mathbf{x})/f_0(\mathbf{x}) > k$  where  $k$  is chosen so that the probability of rejecting  $H_0$  is  $\alpha_0$  given  $\theta = \theta_0$ . The ratio of  $f_1$  to  $f_0$  is

$$\frac{f_1(\mathbf{x})}{f_0(\mathbf{x})} = \frac{\theta_1^n}{\theta_0^n} \exp\left([\theta_0 - \theta_1] \sum_{i=1}^n x_i\right).$$

Since  $\theta_0 < \theta_1$ , the above ratio will be greater than  $k$  if and only if  $\sum_{i=1}^n x_i$  is less than some other constant,  $c$ . That  $c$  is chosen so that  $\Pr(\sum_{i=1}^n X_i < c | \theta = \theta_0) = \alpha_0$ . The distribution of  $\sum_{i=1}^n X_i$  given  $\theta = \theta_0$  is the gamma distribution with parameters  $n$  and  $\theta_0$ . Hence,  $c$  must be the  $\alpha_0$  quantile of that distribution.

13. (a) The test rejects  $H_0$  if  $f_0(\mathbf{X}) < f_1(\mathbf{X})$ . In this case,  $f_0(\mathbf{x}) = \exp(-[x_1 + x_2]/2)/4$ , and  $f_1(\mathbf{x}) = 4/(2 + x_1 + x_2)^3$  for both  $x_1 > 0$  and  $x_2 > 0$ . Let  $T = X_1 + X_2$ . Then we reject  $H_0$  if

$$\exp(-T/2)/4 < 4/(2 + T)^3. \quad (\text{S.9.5})$$

- (b) If  $X_1 = 4$  and  $X_2 = 3$  are observed, then  $T = 7$ . The inequality in (S.9.5) is  $\exp(-7/2)/4 < 4/9^3$  or  $0.007549 < 0.00549$ , which is false, so we do not reject  $H_0$ .
- (c) If  $H_0$  is true, then  $T$  is the sum of two independent exponential random variables with parameter  $1/2$ . Hence, it has the gamma distribution with parameters 2 and  $1/2$  by Theorem 5.7.7.
- (d) The test is to reject  $H_0$  if  $f_1(\mathbf{X})/f_0(\mathbf{X}) > c$ , where  $c$  is chosen so that the probability is 0.1 that we reject  $H_0$  given  $\theta = \theta_0$ . We can write

$$\frac{f_1(\mathbf{X})}{f_0(\mathbf{X})} = \frac{16 \exp(T/2)}{(2 + T)^3}. \quad (\text{S.9.6})$$

The function on the right side of (S.9.6) takes the value 2 at  $T = 0$ , decreases to the value 0.5473 at  $T = 4$ , and increases for  $T > 4$ . Let  $G$  be the c.d.f. of the gamma distribution with parameters 2 and  $1/2$  (also the  $\chi^2$  distribution with 4 degrees of freedom). The level 0.01 test will reject  $H_0$  if  $T < c_1$  or  $T > c_2$  where  $c_1$  and  $c_2$  satisfy  $G(c_1) + 1 - G(c_2) = 0.01$ , and either  $16 \exp(c_1/2)/(2 + c_1)^3 = 16 \exp(c_2/2)/(2 + c_2)^3$  or  $c_1 = 0$  and  $16 \exp(c_2/2)/(2 + c_2)^3 > 2$ . It follows that  $1 - G(c_2) \leq 0.01$ , that is,  $c_2 \geq G^{-1}(0.99) = 13.28$ . But

$$16 \exp(13.28)/(2 + 13.28)^3 = 3.4 > 2.$$

It follows that  $c_1 = 0$  and the test is to reject  $H_0$  if  $T > 13.28$ .

- (e) If  $X_1 = 4$  and  $X_2 = 3$ , then  $T = 7$  and we do not reject  $H_0$ .

### 9.3 Uniformly Most Powerful Tests

#### Commentary

This section introduces the concept of monotone likelihood ratio, which is used to provide conditions under which uniformly most powerful tests exist for one-sided hypotheses. One may safely skip this section if one is not teaching a rigorous mathematical statistics course. One step in the proof of Theorem 9.3.1 relies on randomized tests (Sec. 9.2), which the instructor might have skipped earlier.

#### Solutions to Exercises

- Let  $y = \sum_{i=1}^n x_i$ . Then the joint p.f. is

$$f_n(\mathbf{X} | \lambda) = \frac{\exp(-n\lambda)\lambda^y}{\prod_{i=1}^n (x_i!)}$$

Therefore, for  $0 < \lambda_1 < \lambda_2$ ,

$$\frac{f_n(\mathbf{X} | \lambda_2)}{f_n(\mathbf{X} | \lambda_1)} = \exp(-n(\lambda_2 - \lambda_1)) \left( \frac{\lambda_2}{\lambda_1} \right)^y,$$

which is an increasing function of  $y$ .

- Let  $y = \sum_{i=1}^n (x_i - \mu)^2$ . Then the joint p.d.f. is

$$f_n(\mathbf{X} | \sigma^2) = \frac{1}{(2\pi)^{\frac{n}{2}} \sigma^n} \exp\left(-\frac{y}{2\sigma^2}\right).$$

Therefore, for  $0 < \sigma_1^2 < \sigma_2^2$ ,

$$\frac{f_n(\mathbf{X} | \sigma_2^2)}{f_n(\mathbf{X} | \sigma_1^2)} = \frac{\sigma_1^n}{\sigma_2^n} \exp\left\{\frac{1}{2} \left( \frac{1}{\sigma_1^2} - \frac{1}{\sigma_2^2} \right) y\right\},$$

which is an increasing function of  $y$ .

- Let  $y = \prod_{i=1}^n x_i$  and let  $z = \sum_{i=1}^n x_i$ . Then the joint p.d.f. is

$$f_n(\mathbf{X} | \alpha) = \frac{\beta^{n\alpha}}{[\Gamma(\alpha)]^n} y^{\alpha-1} \exp(-\beta z).$$

Therefore, for  $0 < \alpha_1 < \alpha_2$ ,

$$\frac{f_n(\mathbf{X} | \alpha_2)}{f_n(\mathbf{X} | \alpha_1)} = (\text{const.}) y^{\alpha_2 - \alpha_1},$$

which is an increasing function of  $y$ .

4. The joint p.d.f.  $f_n(\mathbf{X} | \beta)$  in this exercise is the same as the joint p.d.f.  $f_n(\mathbf{X} | \alpha)$  given in Exercise 3, except that the value of  $\beta$  is now unknown and the value of  $\alpha$  is known. Since  $z = n\bar{x}_n$ , it follows that for  $0 < \beta_1 < \beta_2$ ,

$$\frac{f_n(\mathbf{X} | \beta_2)}{f_n(\mathbf{X} | \beta_1)} = (\text{const.}) \exp([\beta_1 - \beta_2]n\bar{x}_n).$$

The expression on the right side of this relation is a decreasing function of  $\bar{x}_n$ , because  $\beta_1 - \beta_2 < 0$ . Therefore, this expression is an increasing function of  $-\bar{x}_n$ .

5. Let  $y = \sum_{i=1}^n d(x_i)$ . Then the joint p.d.f. or the joint p.f. is

$$f_n(\mathbf{X} | \theta) = [a(\theta)]^n \left[ \prod_{i=1}^n b(x_i) \right] \exp[c(\theta)y].$$

Therefore, for  $\theta_1 < \theta_2$ ,

$$\frac{f_n(\mathbf{X} | \theta_2)}{f_n(\mathbf{X} | \theta_1)} = \left[ \frac{a(\theta_2)}{a(\theta_1)} \right]^n \exp\{[c(\theta_2) - c(\theta_1)]y\}.$$

Since  $c(\theta_2) - c(\theta_1) > 0$ , this expression is an increasing function of  $y$ .

6. Let  $\theta_1 < \theta_2$ . The range of possible values of  $r(\mathbf{X}) = \max\{X_1, \dots, X_n\}$  is the interval  $[0, \theta_2]$  when comparing  $\theta_1$  and  $\theta_2$ . The likelihood ratio for values of  $r(\mathbf{x})$  in this interval is

$$\begin{cases} \frac{\theta_1^n}{\theta_2^n} & \text{if } 0 \leq r(\mathbf{x}) \leq \theta_1, \\ \infty & \text{if } \theta_1 < r(\mathbf{x}) \leq \theta_2. \end{cases}$$

This is monotone increasing, even though it takes only two values. It does take the larger value  $\infty$  when  $r(\mathbf{x})$  is large and it takes the smaller value  $\theta_1^n/\theta_2^n$  when  $r(\mathbf{x})$  is small.

7. No matter what the true value of  $\theta$  is, the probability that  $H_0$  will be rejected is 0.05. Therefore, the value of the power function at every value of  $\theta$  is 0.05.
8. We know from Exercise 2 that the joint p.d.f. of  $X_1, \dots, X_n$  has a monotone likelihood ratio in the statistic  $\sum_{i=1}^n X_i^2$ . Therefore, by Theorem 9.3.1, a test which rejects  $H_0$  when  $\sum_{i=1}^n X_i^2 \geq c$  will be a UMP test. To achieve a specified level of significance  $\alpha_0$ , the constant  $c$  should be chosen so that  $\Pr\left(\sum_{i=1}^n X_i^2 \geq c | \sigma^2 = 2\right) = \alpha_0$ . Since  $\sum_{i=1}^n X_i^2$  has a continuous distribution and not a discrete distribution, there will be a value of  $c$  which satisfies this equation for any specified value of  $\alpha_0$  ( $0 < \alpha_0 < 1$ ).
9. The first part of this exercise was answered in Exercise 8. When  $n = 10$  and  $\sigma^2 = 2$ , the distribution of  $Y = \sum_{i=1}^n X_i^2/2$  will be the  $\chi^2$  distribution with 10 degrees of freedom, and it is found from a table of this distribution that  $\Pr(Y \geq 18.31) = 0.05$ . Also,

$$\Pr\left(\sum_{i=1}^n X_i^2 \geq c | \sigma^2 = 2\right) = \Pr\left(Y \geq \frac{c}{2}\right).$$

Therefore, if this probability is to be equal to 0.05, then  $c/2 = 18.31$  or  $c = 36.62$ .

10. Let  $Y = \sum_{i=1}^n X_i$ . As in Example 9.3.7, a test which specifies rejecting  $H_0$  if  $Y \geq c$  is a UMP test. When  $n = 20$  and  $p = 1/2$ , it is found from the table of the binomial distribution given at the end of the book that

$$\Pr(Y \geq 14) = .0370 + .0148 + .0046 + .0011 + .0002 = .0577.$$

Therefore, the level of significance of the UMP test which rejects  $H_0$  when  $Y \geq 14$  will be 0.0577. Similarly, the UMP test that rejects  $H_0$  when  $Y \geq 15$  has level of significance 0.0207.

11. It is known from Exercise 1 that the joint p.f. of  $X_1, \dots, X_n$  has a monotone likelihood ratio in the statistic  $Y = \sum_{i=1}^n X_i$ . Therefore, by Theorem 9.3.1, a test which rejects  $H_0$  when  $Y \geq c$  will be a UMP test. When  $\lambda = 1$  and  $n = 10$ ,  $Y$  will have a Poisson distribution with mean 10, and it is found from the table of the Poisson distribution given at the end of this book that

$$\Pr(Y \geq 18) = .0071 + .0037 + .0019 + .0009 + .0004 + .0002 + .0001 = .0143.$$

Therefore, the level of significance of the UMP test which rejects  $H_0$  when  $Y \geq 18$  will be 0.0143.

12. Change the parameter from  $\theta$  to  $\zeta = -\theta$ . In terms of the new parameter  $\zeta$ , the hypotheses to be tested are:

$$\begin{aligned} H_0 &: \zeta \leq -\theta_0, \\ H_1 &: \zeta > -\theta_0. \end{aligned}$$

Let  $g_n(\mathbf{X} | \zeta) = f_n(\mathbf{X} | -\zeta)$  denote the joint p.d.f. or the joint p.f. of  $X_1, \dots, X_n$  when  $\zeta$  is regarded as the parameter. If  $\zeta_1 < \zeta_2$ , then  $\theta_1 = -\zeta_1 > -\zeta_2 = \theta_2$ . Therefore, the ratio  $g_n(\mathbf{X} | \zeta_2)/g_n(\mathbf{X} | \zeta_1)$  will be a decreasing function of  $r(\mathbf{X})$ . It follows that this ratio will be an increasing function of the statistic  $s(\mathbf{X}) = -r(\mathbf{X})$ .

Thus, in terms of  $\zeta$ , the hypotheses have the same form as the hypotheses (9.3.8) and  $g_n(\mathbf{x} | \zeta)$  has a monotone likelihood ratio in the statistic  $s(\mathbf{X})$ . Therefore, by Theorem 9.3.1, a test which rejects  $H_0$  when  $s(\mathbf{X}) \geq c'$ , for some constant  $c'$ , will be a UMP test. But  $s(\mathbf{X}) \geq c'$  if and only if  $T = r(\mathbf{X}) \leq c$ , where  $c = -c'$ . Therefore, the test which rejects  $H_0$  when  $T \leq c$  will be a UMP test. If  $c$  is chosen to satisfy the relation given in the exercise, then it follows from Theorem 9.3.1 that level of significance of this test will be  $\alpha_0$ .

13. (a) By Exercise 12, the test which rejects  $H_0$  when  $\bar{X}_n \leq c$  will be a UMP test. For the level of significance to be 0.1,  $c$  should be chosen so that  $\Pr(\bar{X}_n \leq c | \mu = 10) = 0.1$ . In this exercise,  $n = 4$ . When  $\mu = 10$ , the random variable  $z = 2(\bar{X}_n - 10)$  has a standard normal distribution and  $\Pr(\bar{X}_n \leq c | \mu = 10) = \Pr[Z \leq 2(c - 10)]$ . It is found from a table of the standard normal distribution that  $\Pr(Z \leq -1.282) = 0.1$ . Therefore,  $2(c - 10) = -1.282$  or  $c = 9.359$ .
- (b) When  $\mu = 9$ , the random variable  $2(\bar{X}_n - 9)$  has the standard normal distribution. Therefore, the power of the test is

$$\Pr(\bar{X}_n \leq 9.359 | \mu = 9) = \Pr(Z \leq 0.718) = \Phi(0.718) = 0.7636,$$

where we have interpolated in the table of the normal distribution between 0.71 and 0.72.

- (c) When  $\mu = 11$ , the random variable  $Z = 2(\bar{X}_n - 11)$  has the standard normal distribution. Therefore, the probability of rejecting  $H_0$  is

$$\Pr(\bar{X}_n \geq 93359 | \mu = 11) = \Pr(Z \geq -3.282) = \Pr(Z \leq 3.282) = \Phi(3.282) = 0.9995.$$

14. By Exercise 12, a test which rejects  $H_0$  when  $\sum_{i=1}^n X_i \leq c$  will be a UMP test. When  $n = 10$  and  $\lambda = 1$ ,  $\sum_{i=1}^n X_i$  will have a Poisson distribution with mean 10 and  $\alpha_0 = \Pr\left(\sum_{i=1}^n X_i \leq c | \lambda = 1\right)$ . From a table of the Poisson distribution, the following values of  $\alpha_0$  are obtained.

$$\begin{aligned} c &= 0, \alpha_0 = .0000; \\ c &= 1, \alpha_0 = .0000 + .0005 = .0005; \\ c &= 2, \alpha_0 = .0000 + .0005 + .0023 = .0028; \\ c &= 3, \alpha_0 = .0000 + .0005 + .0023 + .0076 = .0104; \\ c &= 4, \alpha_0 = .0000 + .0005 + .0023 + .0076 + .0189 = .0293. \end{aligned}$$

For larger values of  $c$ ,  $\alpha_0 > 0.03$ .

15. By Exercise 4, the joint p.d.f. of  $X_1, \dots, X_n$  has a monotone likelihood ratio in the statistic  $-\bar{X}_n$ . Therefore, by Exercise 12, a test which rejects  $H_0$  when  $-\bar{X}_n \leq c'$ , for some constant  $c'$ , will be a UMP test. But this test is equivalent to a test which rejects  $H_0$  when  $\bar{X}_n \geq c$ , where  $c = -c'$ . Since  $\bar{X}_n$  has a continuous distribution, for any specified value of  $\alpha_0$  ( $0 < \alpha_0 < 1$ ) there exists a value of  $c$  such that  $\Pr(\bar{X}_n \geq c | \beta = 1/2) = \alpha_0$ .
16. We must find a constant  $c$  such that when  $n = 10$ ,  $\Pr(\bar{X}_n \geq c | \beta = 1/2) = 0.05$ . When  $\beta = 1/2$ , each observation  $X_i$  has an exponential distribution with  $\beta = 1/2$ , which is a gamma distribution with parameters  $\alpha = 1$  and  $\beta = 1/2$ . Therefore,  $\sum_{i=1}^n X_i$  has a gamma distribution with parameters  $\alpha = n = 10$  and  $\beta = 1/2$ , which is a  $\chi^2$  distribution with  $2n = 20$  degrees of freedom. But

$$\Pr\left(\bar{X}_n \geq c | \beta = \frac{1}{2}\right) = \Pr\left(\sum_{i=1}^n X_i \geq 10c | \beta = \frac{1}{2}\right).$$

It is found from a table of the  $\chi^2$  distribution with 20 degrees of freedom that  $\Pr(\sum_{i=1}^n X_i \geq 31.41) = 0.05$ . Therefore,  $10c = 31.41$  and  $c = 3.141$ .

17. In this exercise,  $H_0$  is a simple hypothesis. By the Neyman-Pearson lemma, the test which has maximum power at a particular alternative value  $\theta_1 > 0$  will reject  $H_0$  if  $f(x | \theta = \theta_1)/f(x | \theta = 0) > c$ , where  $c$  is chosen so that the probability that this inequality will be satisfied when  $\theta = 0$  is  $\alpha_0$ . Here,

$$\frac{f(x | \theta = \theta_1)}{f(x | \theta = 0)} > c$$

if and only if  $(1 - c)x^2 + 2c\theta_1 x > c\theta_1^2 - (1 - c)$ . For each value of  $\theta_1$ , the value of  $c$  is to be chosen so that the set of points satisfying this inequality has probability  $\alpha_0$  when  $\theta = 0$ . For two different values of  $\theta_1$ , these two sets will be different. Therefore, different test procedures will maximize the power at the two different values of  $\theta_1$ . Hence, no single test is a UMP test.

18. The UMP test will reject  $H_0$  when  $\bar{X}_n \geq c$ , where  $\Pr(\bar{X}_n \geq c | \mu = 0) = \Pr(\sqrt{n}\bar{X}_n \geq \sqrt{nc} | \mu = 0) = 0.025$ . However, when  $\mu = 0$ ,  $\sqrt{n}\bar{X}_n$  has the standard normal distribution. Therefore,  $\Pr(\sqrt{n}\bar{X}_n \geq 1.96 | \mu = 0) = 0.025$ . It follows that  $\sqrt{nc} = 1.96$  and  $c = 1.96n^{-1/2}$ .

- (a) When  $\mu = 0.5$ , the random variable  $Z = \sqrt{n}(\bar{X}_n - 0.5)$  has the standard normal distribution. Therefore,

$$\begin{aligned}\pi(0.5 | \delta^*) &= \Pr(\bar{X}_n \geq 1.96n^{-1/2} | \mu = 0.5) = \Pr(Z \geq 1.96 - 0.5n^{1/2}) \\ &= \Pr(Z \leq 0.5n^{1/2} - 1.96) = \Phi(0.5n^{1/2} - 1.96).\end{aligned}$$

But  $\Phi(1.282) = 0.9$ . Therefore,  $\pi(0.5 | \delta^*) \geq 0.9$  if and only if  $0.5n^{1/2} - 1.96 \geq 1.282$ , or, equivalently, if and only if  $n \geq 42.042$ . Thus, a sample of size  $n = 43$  is required in order to have  $\pi(0.5 | \delta^*) \geq 0.9$ . Since the power function is a strictly increasing function of  $\mu$ , it will then also be true that  $\pi(0.5 | \delta^*) \geq 0.9$  for  $\mu > 0.5$ .

- (b) When  $\mu = -0.1$ , the random variable  $Z = \sqrt{n}(\bar{X}_n + 0.1)$  has the standard normal distribution. Therefore,

$$\begin{aligned}\pi(-0.1 | \delta^*) &= \Pr(\bar{X}_n \geq 1.96n^{-1/2} | \mu = -0.1) = \Pr(Z \geq 1.96 + 0.1n^{1/2}) \\ &= 1 - \Phi(1.96 + 0.1n^{1/2}).\end{aligned}$$

But  $\Phi(3.10) = 0.999$ . Therefore,  $\pi(-0.1 | \delta^*) \leq 0.001$  if and only if  $1.96 + 0.1n^{1/2} \geq 3.10$  or, equivalently, if and only if  $n \geq 129.96$ . Thus, a sample of size  $n = 130$  is required in order to have  $\pi(-0.1 | \delta^*) \leq 0.001$ . Since the power function is a strictly increasing function of  $\mu$ , it will then also be true that  $\pi(\mu | \delta^*) \leq 0.001$  for  $\mu < -0.1$ .

19. (a) Let  $f(\mathbf{x}|\mu)$  be the joint p.d.f. of  $\mathbf{X}$  given  $\mu$ . For each set  $A$  and  $i = 0, 1$ ,

$$\Pr(\mathbf{X} \in A | \mu = \mu_i) = \int \cdots \int_A f(\mathbf{x}|\mu_i) d\mathbf{x}. \quad (\text{S.9.7})$$

It is clear that  $f(\mathbf{x}|\mu_0) > 0$  for all  $\mathbf{x}$  and so is  $f(\mathbf{x}|\mu_1) > 0$  for all  $\mathbf{x}$ . Hence (S.9.7) is strictly positive for  $i = 0$  if and only if it is strictly positive for  $i = 1$ .

- (b) Both  $\delta$  and  $\delta_1$  are size  $\alpha_0$  tests of  $H'_0 : \mu = \mu_0$  versus  $H'_1 : \mu > \mu_0$ . Let

$$\begin{aligned}A &= \{\mathbf{x} : \delta \text{ rejects but } \delta_1 \text{ does not reject}\}, \\ B &= \{\mathbf{x} : \delta \text{ does not reject but } \delta_1 \text{ rejects}\}, \\ C &= \{\mathbf{x} : \text{both tests reject}\}.\end{aligned}$$

Because both tests have the same size, it must be the case that

$$\Pr(\mathbf{X} \in A | \mu = \mu_0) + \Pr(\mathbf{X} \in B | \mu = \mu_0) = \alpha_0 = \Pr(\mathbf{X} \in C | \mu = \mu_0) + \Pr(\mathbf{X} \in D | \mu = \mu_0).$$

Hence,

$$\Pr(\mathbf{X} \in A | \mu = \mu_0) = \Pr(\mathbf{X} \in B | \mu = \mu_0). \quad (\text{S.9.8})$$

Because of the MLR and the form of the test  $\delta_1$ , we know that there is a constant  $c$  such that for every  $\mu > \mu_0$  and every  $\mathbf{x} \in B$  and every  $\mathbf{y} \in A$ ,

$$\frac{f(\mathbf{x}|\mu)}{f(\mathbf{x}|\mu_0)} > c > \frac{f(\mathbf{y}|\mu)}{f(\mathbf{y}|\mu_0)}. \quad (\text{S.9.9})$$

Now,

$$\pi(\mu | \delta) = \int \cdots \int_A f(\mathbf{x}|\mu) d\mathbf{x} + \int \cdots \int_C f(\mathbf{x}|\mu) d\mathbf{x}.$$

Also,

$$\pi(\mu|\delta_1) = \int \cdots \int_B f(\mathbf{x}|\mu) d\mathbf{x} + \int \cdots \int_C f(\mathbf{x}|\mu) d\mathbf{x}.$$

It follows that, for  $\mu > \mu_0$ ,

$$\begin{aligned} \pi(\mu|\delta_1) - \pi(\mu|\delta) &= \int \cdots \int_B f(\mathbf{x}|\mu) d\mathbf{x} - \int \cdots \int_A f(\mathbf{x}|\mu) d\mathbf{x} \\ &= \int \cdots \int_B \frac{f(\mathbf{x}|\mu)}{f(\mathbf{x}|\mu_0)} f(\mathbf{x}|\mu_0) d\mathbf{x} - \int \cdots \int_A \frac{f(\mathbf{x}|\mu)}{f(\mathbf{x}|\mu_0)} f(\mathbf{x}|\mu_0) d\mathbf{x} \\ &> \int \cdots \int_B c f(\mathbf{x}|\mu_0) d\mathbf{x} - \int \cdots \int_A c f(\mathbf{x}|\mu_0) d\mathbf{x} = 0, \end{aligned}$$

where the inequality follows from (S.9.9), and the final equality follows from (S.9.8).

## 9.4 Two-Sided Alternatives

### Commentary

This section considers tests for simple (and interval) null hypotheses against two-sided alternative hypotheses. The concept of unbiased tests is introduced in a subsection at the end. Even students in a mathematical statistics course may have trouble with the concept of unbiased test.

### Solutions to Exercises

- If  $\pi(\mu|\delta)$  is to be symmetric with respect to the point  $\mu = \mu_0$ , then the constants  $c_1$  and  $c_2$  must be chosen to be symmetric with respect to the value  $\mu_0$ . Let  $c_1 = \mu_0 - k$  and  $c_2 = \mu_0 + k$ . When  $\mu = \mu_0$ , the random variable  $Z = n^{1/2}(\bar{X}_n - \mu_0)$  has the standard normal distribution. Therefore,

$$\begin{aligned} \pi(\mu_0|\delta) &= \Pr(\bar{X}_n \leq \mu_0 - k | \mu_0) + \Pr(\bar{X}_n \geq \mu_0 + k | \mu_0) \\ &= \Pr(Z \leq -n^{1/2}k) + \Pr(Z \geq n^{1/2}k) \\ &= 2\Pr(Z \geq n^{1/2}k) = 2[1 - \Phi(n^{1/2}k)]. \end{aligned}$$

Since  $k$  must be chosen so that  $\pi(\mu_0|\delta) = 0.10$ , it follows that  $\Phi(n^{1/2}k) = 0.95$ . Therefore,  $n^{1/2}k = 1.645$  and  $k = 1.645n^{-1/2}$ .

- When  $\mu = \mu_0$ , the random variable  $Z = n^{1/2}(\bar{X}_n - \mu_0)$  has the standard normal distribution. Therefore,

$$\begin{aligned} \pi(\mu_0|\delta) &= \Pr(\bar{X}_n \leq c_1 | \mu_0) + \Pr(\bar{X}_n \geq c_2 | \mu_0) \\ &= \Pr(Z \leq -1.96) + \Pr[Z \geq n^{1/2}(c_2 - \mu_0)] \\ &= \Phi(-1.96) + 1 - \Phi[n^{1/2}(c_2 - \mu_0)] \\ &= 1.025 - \Phi[n^{1/2}(c_2 - \mu_0)]. \end{aligned}$$

If we are to have  $\pi(\mu_0|\delta) = 0.10$ , then we must have  $\Phi[n^{1/2}(c_2 - \mu_0)] = 0.925$ . Therefore,  $n^{1/2}(c_2 - \mu_0) = 1.439$  and  $c_2 = \mu_0 + 1.439n^{-1/2}$ .

- From Exercise 1, we know that if  $c_1 = \mu_0 - 1.645n^{-1/2}$  and  $c_2 = \mu_0 + 1.645n^{-1/2}$ , then  $\pi(\mu_0|\delta) = 0.10$  and, by symmetry,  $\pi(\mu_0 + 1|\delta) = \pi(\mu_0 - 1|\delta)$ . Also, when  $\mu = \mu_0 + 1$ , the random variable

$n^{1/2}(\bar{X}_n - \mu_0 - 1)$  has the standard normal distribution. Therefore,

$$\begin{aligned}\pi(\mu_0 + 1 | \delta) &= \Pr(\bar{X}_n \leq c_1 | \mu_0 + 1) + \Pr(\bar{X}_n \geq c_2 | \mu_0 + 1) \\ &= \Pr(Z \leq -1.645 - n^{1/2}) + \Pr(Z \geq 1.645 - n^{1/2}) \\ &= \Phi(-1.645 - n^{1/2}) + \Phi(n^{1/2} - 1.645).\end{aligned}$$

$$\text{For } n = 9, \quad \pi(\mu_0 + 1 | \delta) = \Phi(-4.645) + \Phi(1.355) < 0.95.$$

$$\text{For } n = 10, \quad \pi(\mu_0 + 1 | \delta) = \Phi(-4.807) + \Phi(1.517) < 0.95.$$

$$\text{For } n = 11, \quad \pi(\mu_0 + 1 | \delta) = \Phi(-4.962) + \Phi(1.672) > 0.95.$$

4. If we choose  $c_1$  and  $c_2$  to be symmetric with respect to the value 0.15, then it will be true that  $\pi(0.1 | \delta) = \pi(0.2 | \delta)$ . Accordingly, let  $c_1 = 0.15 - k$  and  $c_2 = 0.15 + k$ . When  $\mu = 0.1$ , the random variable  $Z = 5(\bar{X}_n - 0.1)$  has a standard normal distribution. Therefore,

$$\begin{aligned}\pi(0.1 | \delta) &= \Pr(\bar{X}_n \leq c_1 | 0.1) + \Pr(\bar{X}_n \geq c_2 | 0.1) \\ &= \Pr(Z \leq 0.25 - 5k) + \Pr(Z \geq 0.25 + 5k) \\ &= \Phi(0.25 - 5k) + \Phi(-0.25 - 5k).\end{aligned}$$

We must choose  $k$  so that  $\pi(0.1 | \delta) = 0.07$ . By trial and error, using the table of the standard normal distribution, we find that when  $5k = 1.867$ ,

$$\pi(0.1 | \delta) = \Phi(-1.617) + \Phi(-2.117) = 0.0529 + 0.0171 = 0.07.$$

Hence,  $k = 0.3734$ .

5. As in Exercise 4,

$$\pi(0.1 | \delta) = \Pr[Z \leq 5(c_1 - 0.1)] + \Pr[Z \geq 5(c_2 - 0.1)] = \Phi(5c_1 - 0.5) + \Phi(0.5 - 5c_2).$$

Similarly,

$$\pi(0.2 | \delta) = \Pr[Z \leq 5(c_1 - 0.2)] + \Pr[Z \geq 5(c_2 - 0.2)] = \Phi(5c_1 - 1) + \Phi(1 - 5c_2).$$

Hence, the following two equations must be solved simultaneously:

$$\Phi(5c_1 - 0.5) + \Phi(0.5 - 5c_2) = 0.02,$$

$$\Phi(5c_1 - 1) + \Phi(1 - 5c_2) = 0.05.$$

By trial and error, using the table of the standard normal distribution, it is found ultimately that if  $5c_1 = -2.12$  and  $5c_2 = 2.655$ , then

$$\Phi(5c_1 - 0.5) + \Phi(0.5 - 5c_2) = \Phi(-2.62) + \Phi(-2.155) = 0.0044 + 0.0155 = 0.02.$$

and

$$\Phi(5c_1 - 1) + \Phi(1 - 5c_2) = \Phi(-3.12) + \Phi(-1.655) = 0.0009 + 0.0490 = 0.05.$$

6. Let  $T = \max(X_1, \dots, X_n)$ . Then

$$f_n(\mathbf{X} | \theta) = \begin{cases} \frac{1}{\theta^n} & \text{for } 0 \leq t \leq \theta, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore, for  $\theta_1 < \theta_2$ ,

$$\frac{f_n(\mathbf{X} | \theta_2)}{f_n(\mathbf{X} | \theta_1)} = \begin{cases} \left(\frac{\theta_1}{\theta_2}\right)^n & \text{for } 0 \leq t \leq \theta_1, \\ \infty & \text{for } \theta_1 < t \leq \theta_2. \end{cases}$$

It can be seen from this relationship that  $f_n(\mathbf{X} | \theta)$  has a monotone likelihood ratio in the statistic  $T$  (although we are being somewhat nonrigorous by treating  $\infty$  as a number).

For any constant  $c$  ( $0 < c \leq 3$ ),  $\Pr(T \geq c | \theta = 3) = 1 - (c/3)^n$ . Therefore, to achieve a given level of significance  $\alpha_0$ , we should choose  $c = 3(1 - \alpha_0)^{1/n}$ . It follows from Theorem 9.3.1 that the corresponding test will be a UMP test.

7. For  $\theta > 0$ , the power function is  $\pi(\theta | \delta) = \Pr(T \geq c | \theta)$ . Hence,

$$\pi(\theta | \delta) = \begin{cases} 0 & \text{for } \theta \leq c, \\ 1 - \left(\frac{c}{\theta}\right)^n & \text{for } \theta > c. \end{cases}$$

The plot is in Fig. S.9.4.

Figure S.9.4: Figure for Exercise 7 of Sec. 9.4.

8. (a) It follows from Exercise 8 of Sec. 9.3 that the specified test will be a UMP test.  
 (b) For any given value of  $c$  ( $0 < c < 3$ ),  $\Pr(T \leq c | \theta = 3) = (c/3)^n$ . Therefore, to achieve a given level of significance  $\alpha_0$ , we should choose  $c = 3\alpha_0^{1/n}$ .
9. A sketch is given in Fig. S.9.5.

10. (a) Let  $\alpha_0 = 0.05$  and let  $c_1 = 3\alpha_0^{1/n}$  as in Exercise 8. Also, let  $c_2 = 3$ . Then

$$\pi(\theta | \delta) = \Pr(T \leq 3\alpha_0^{1/n} | \theta) + \Pr(T \geq 3 | \theta).$$

Since  $\Pr(T \geq 3 | \theta) = 0$  for  $\theta \leq 3$ , the function  $\pi(\theta | \delta)$  is as sketched in Exercise 10 for  $\theta \leq 3$ . For  $\theta > 3$ ,

$$\pi(\theta | \delta) = \left[ \frac{3\alpha_0^{1/n}}{\theta} \right]^n + \left[ 1 - \left( \frac{3}{\theta} \right)^n \right] > \alpha_0. \quad (\text{S.9.10})$$

Figure S.9.5: Figure for Exercise 9 of Sec. 9.4.

- (b) In order for a test  $\delta$  to be UMP level  $\alpha_0$ , for (9.4.15), it necessary and sufficient that the following three things happen:

- $\delta$  has the same power function as the test in Exercise 6 for  $\theta > 3$ .
- $\delta$  has the same power function as the test in Exercise 8 for  $\theta < 3$ .
- $\pi(3|\delta) \leq \alpha_0$ .

Because  $c_2 = 3$ , we saw in part (a) that  $\pi(\theta|\delta)$  is the same as the power function of the test in Exercise 8 for  $\theta < 3$ . We also saw in part (a) that  $\pi(3|\delta) = 0.05 = \alpha_0$ . For  $\theta > 3$ , the power function of the test in Exercise 6 is

$$\Pr(T \geq 3(1 - \alpha_0)^{1/n} | \theta) = 1 - \left( \frac{3(1 - \alpha_0)^{1/n}}{\theta} \right)^n = 1 - \left( \frac{3}{\theta} \right)^n (1 - \alpha_0).$$

It is straightforward to see that this is the same as (S.9.10).

11. It can be verified that if  $c_1$  and  $c_2$  are chosen to be symmetric with respect to the value  $\mu_0$ , then the power function  $\pi(\mu|\delta)$  will be symmetric with respect to the point  $\mu = \mu_0$  and will attain its minimum value at  $\mu = \mu_0$ . Therefore, if  $c_1$  and  $c_2$  are chosen as in Exercise 1, the required conditions will be satisfied.
12. The power function of the test  $\delta$  described in this exercise is

$$\pi(\beta|\delta) = 1 - \exp(-c_1\beta) + \exp(-c_2\beta).$$

- (a) In order for  $\delta$  to have level of significance  $\alpha_0$ , we must have  $\pi(1|\delta) \leq \alpha_0$ . Indeed, the test will have size  $\alpha_0$  exactly if
- $$\alpha_0 = 1 - \exp(-c_1) + \exp(-c_2).$$
- (b) We can let  $c_1 = -\log(1 - \alpha_0/2)$  and  $c_2 = -\log(\alpha_0/2)$  to solve this equation.
13. The first term on the right of (9.4.13) is

$$\frac{n}{\theta} \int_0^x \frac{\theta^n}{\Gamma(n)} t^{n-1} \exp(-t\theta) dt = \frac{n}{\theta} G(x; n, \theta).$$

The second term on the right of (9.4.13) is the negative of

$$\frac{n}{\theta} \int_0^x \frac{\theta^{n+1}}{\Gamma(n+1)} t^n \exp(-t\theta) dt = \frac{n}{\theta} G(x; n+1, \theta).$$

## 9.5 The $t$ Test

### Commentary

This section provides a natural continuation to Sec. 9.1 in a modern statistics course. We introduce the  $t$  test and its power function, defined in terms of the noncentral  $t$  distribution. The theoretical derivation of the  $t$  test as a likelihood ratio test is isolated at the end of the section and could easily be skipped without interrupting the flow of material. Indeed, that derivation should only be of interest in a fairly mathematical statistics course.

As with confidence intervals, computer software can replace tables for obtaining quantiles of the  $t$  distributions that are used in tests. The  $R$  function `qt` can compute these. For computing  $p$ -values, one can use `pt`. The precise use of `pt` depends on whether the alternative hypothesis is one-sided or two-sided. For testing  $H_0 : \mu \leq \mu_0$  versus  $H_1 : \mu > \mu_0$  using the statistic  $U$  in Eq. (9.5.2), the  $p$ -value would be `1-pt(u,n-1)`, where  $u$  is the observed value of  $U$ . For the opposite one-sided hypotheses, the  $p$ -value would be `pt(u,n-1)`. For testing  $H_0 : \mu = \mu_0$  versus  $H_1 : \mu \neq \mu_0$ , the  $p$ -value is `2*(1-pt(abs(u),n-1))`. The power function of a  $t$  test can be computed using the optional third parameter with `pt`, which is the noncentrality parameter (whose default value is 0). Similar considerations apply to the comparison of two means in Sec. 9.6.

### Solutions to Exercises

1. We computed the summary statistics  $\bar{x}_n = 1.379$  and  $\sigma' = 0.3277$  in Example 8.5.4.
  - (a) The test statistic is  $U$  from (9.5.2)
 
$$U = 10^{1/2} \frac{1.379 - 1.2}{0.3277} = 1.727.$$

We reject  $H_0$  at level  $\alpha_0 = 0.05$  if  $U \geq 1.833$ , the 0.95 quantile of the  $t$  distribution with 9 degrees of freedom. Since  $1.727 \not\geq 1.833$ , we do not reject  $H_0$  at level 0.05.
  - (b) We need to compute the probability that a  $t$  random variable with 9 degrees of freedom exceeds 1.727. This probability can be computed by most statistical software, and it equals 0.0591. Without a computer, one could interpolate in the table of the  $t$  distribution in the back of the book. That would yield 0.0618.
2. When  $\mu_0 = 20$ , the statistic  $U$  given by Eq. (9.5.2) has a  $t$  distribution with 8 degrees of freedom. The value of  $U$  in this exercise is 2.
  - (a) We would reject  $H_0$  if  $U \geq 1.860$ . Therefore, we reject  $H_0$ .
  - (b) We would reject  $H_0$  if  $U \leq -2.306$  or  $U \geq 2.306$ . Therefore, we don't reject  $H_0$ .
  - (c) We should include in the confidence interval, all values of  $\mu_0$  for which the value of  $U$  given by Eq. (9.5.2) will lie between  $-2.306$  and  $2.306$ . These values form the interval  $19.694 < \mu_0 < 24.306$ .
3. It must be assumed that the miles per gallon obtained from the different tankfuls are independent and identically distributed, and that each has a normal distribution. When  $\mu_0 = 20$ , the statistic  $U$  given by Eq. (9.5.2) has the  $t$  distribution with 8 degrees of freedom. Here, we are testing the following hypotheses:

$$\begin{aligned} H_0 : \mu &\geq 20, \\ H_1 : \mu &< 20. \end{aligned}$$

We would reject  $H_0$  if  $U \leq -1.860$ . From the given value, it is found that  $\bar{X}_n = 19$  and  $S_n^2 = 22$ . Hence,  $U = -1.809$  and we do not reject  $H_0$ .

4. When  $\mu_0 = 0$ , the statistic  $U$  given by Eq. (9.5.2) has the  $t$  distribution with 7 degrees of freedom. Here

$$\bar{X}_n = \frac{-11.2}{8} = -1.4$$

and

$$\sum_{i=1}^n (X_i - \bar{X}_n)^2 = 43.7 - 8(1.4)^2 = 28.02.$$

The value of  $U$  can now be found to be  $-1.979$ . We should reject  $H_0$  if  $U \leq -1.895$  or  $U \geq 1.895$ . Therefore, we reject  $H_0$ .

5. It is found from the table of the  $t$  distribution with 7 degrees of freedom that  $c_1 = -2.998$  and  $c_2$  lies between 1.415 and 1.895. Since  $U = -1.979$ , we do not reject  $H_0$ .
6. Let  $U$  be given by Eq. (9.5.2) and suppose that  $c$  is chosen so that the level of significance of the test is  $\alpha_0$ . Then

$$\pi(\mu, \sigma^2 | \delta) = \Pr(U \geq c | \mu, \sigma^2).$$

If we let  $Y = n^{1/2}(\bar{X}_n - \mu)/\sigma$  and  $Z = \sum_{i=1}^n (X_i - \bar{X}_n)^2/\sigma^2$ , then  $Y$  will have a standard normal distribution,  $Z$  will have a  $\chi^2$  distribution with  $n - 1$  degrees of freedom, and  $Y$  and  $Z$  will be independent. Also,

$$U = \frac{Y + n^{1/2} \left( \frac{\mu - \mu_0}{\sigma} \right)}{[Z/(n-1)]^{1/2}}.$$

It follows that all pairs  $(\mu, \sigma^2)$  which yield the same value of  $(\mu - \mu_0)/\sigma$  will yield the same value of  $\pi(\mu, \sigma^2 | \delta)$ .

7. The random variable  $T = (X - \mu)/\sigma$  will have the standard normal distribution, the random variable  $Z = \sum_{i=1}^n Y_i^2/\sigma^2$  will have a  $\chi^2$  distribution with  $n$  degrees of freedom, and  $T$  and  $Z$  will be independent. Therefore, when  $\mu = \mu_0$ , the following random variable  $U$  will have the  $t$  distribution with  $n$  degrees of freedom:

$$U = \frac{T}{[Z/n]^{1/2}} = \frac{n^{1/2}(X - \mu_0)}{\left[ \sum_{i=1}^n Y_i^2 \right]^{1/2}}.$$

The hypothesis  $H_0$  would be rejected if  $U \geq c$ .

8. When  $\sigma^2 = \sigma_0^2$ ,  $S_n^2/\sigma_0^2$  has a  $\chi^2$  distribution with  $n - 1$  degrees of freedom. Choose  $c$  so that, when  $\sigma^2 = \sigma_0^2$ ,  $\Pr(S_n^2/\sigma_0^2 \geq c) = \alpha_0$ , and reject  $H_0$  if  $S_n^2/\sigma_0^2 \geq c$ . Then  $\pi(\mu, \sigma^2 | \delta) = \alpha_0$  if  $\sigma^2 = \sigma_0^2$ . If  $\sigma^2 \neq \sigma_0^2$ , then  $Z = S_n^2/\sigma^2$  has the  $\chi^2$  distribution with  $n - 1$  degrees for freedom, and  $S_n^2/\sigma_0^2 = (\sigma^2/\sigma_0^2)T$ . Therefore,

$$\pi(\mu, \sigma^2 | \delta) = \Pr(S_n^2/\sigma_0^2 \geq c | \mu, \sigma^2) = \Pr(T \geq c\sigma_0^2/\sigma^2).$$

If  $\sigma_0^2/\sigma^2 > 1$ , then  $\pi(\mu, \sigma^2 | \delta) < \Pr(T \geq c) = \alpha_0$ . If  $\sigma_0^2/\sigma^2 < 1$ , then  $\pi(\mu, \sigma^2 | \delta) > \Pr(T \geq c) = \alpha_0$ .

9. When  $\sigma^2 = 4$ ,  $S_n^2/4$  has the  $\chi^2$  distribution with 9 degrees of freedom. We would reject  $H_0$  if  $S_n^2/4 \geq 16.92$ . Since  $S_n^2/4 = 60/4 = 15$ , we do not reject  $H_0$ .
10. When  $\sigma^2 = 4$ ,  $S_n^2/4$  has the  $\chi^2$  distribution with 9 degrees of freedom. Therefore,  $\Pr(S_n^2/4 < 2.700) = \Pr(S_n^2/4 > 19.02) = 0.025$ . It follows that  $c_1 = 4(2.700) = 10.80$  and  $c_2 = 4(19.02) = 76.08$ .
11.  $U_1$  has the distribution of  $X/Y$  where  $X$  has a normal distribution with mean  $\psi$  and variance 1, and  $Y$  is independent of  $X$  such that  $mY^2$  has the  $\chi^2$  distribution with  $m$  degrees of freedom. Notice that  $-X$  has a normal distribution with mean  $-\psi$  and variance 1 and is independent of  $Y$ . So  $U_2$  has the distribution of  $-X/Y = -U_1$ . So

$$\Pr(U_2 \leq -c) = \Pr(-U_1 \leq -c) = \Pr(U_1 \geq c).$$

12. The statistic  $U$  has the  $t$  distribution with 16 degrees of freedom. The calculated value is

$$U = \frac{\sqrt{17}(\bar{X}_n - 3)}{[S_n^2/16]^{1/2}} = \frac{0.2}{(0.09/16)^{1/2}} = \frac{8}{3}$$

and the corresponding tail area is  $\Pr(U > 8/3)$ .

13. The test statistic is  $U = 169^{1/2}(3.2 - 3)/(0.09)^{1/2} = 8.667$ . The  $p$ -value can be calculated using statistical software as  $1 - T_{169}(8.667) = 1.776 \times 10^{-15}$ .
14. The statistic  $U$  has the  $t$  distribution with 16 degrees of freedom. The calculated value of  $U$  is

$$U = \frac{0.1}{(0.09/16)^{1/2}} = \frac{4}{3}.$$

Because the alternative hypothesis is two-sided, the corresponding tail area is

$$\Pr\left(U \geq \frac{4}{3}\right) + \Pr\left(U \leq -\frac{4}{3}\right) = 2\Pr\left(U \geq \frac{4}{3}\right).$$

15. The test statistic is  $U = 169^{1/2}(3.2 - 3.1)/(0.09)^{1/2} = 4.333$ . The  $p$ -value can be calculated using statistical software as  $2[1 - T_{169}(4.333)] = 2.512 \times 10^{-5}$ .
16. The calculated value of  $U$  is

$$U = \frac{-0.1}{(0.09/16)^{1/2}} = -\frac{4}{3}.$$

Since this value is the negative of the value found in Exercise 14, the corresponding tail area will be the same as in Exercise 14.

17. The denominator of  $\Lambda(\mathbf{x})$  is still (9.5.11). The M.L.E.  $(\hat{\mu}_0, \hat{\sigma}_0^2)$  is easier to calculate in this exercise, namely  $\hat{\mu}_0 = \mu_0$  (the only possible value) and

$$\hat{\sigma}_0^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \mu_0)^2.$$

These are the same values that lead to Eq. (9.5.12) in the text. Hence,  $\Lambda(\mathbf{x})$  has the value given in Eq. (9.5.14). For  $k < 1$ ,  $\Lambda(\mathbf{x}) \leq k$  if and only if

$$|U| \geq ((n-1)[k^{2/n} - 1])^{1/2} = c.$$

18. In this case  $\Omega_0 = \{(\mu, \sigma^2) : \mu \geq \mu_0\}$ , and  $\Lambda(\mathbf{x}) = 1$  if  $\bar{x}_n \geq \mu_0$ . If  $\bar{x}_n < \mu_0$ , then the numerator of  $\Lambda(\mathbf{x})$  is (9.5.12), and the formula for  $\Lambda(\mathbf{x})$  is the same as (9.5.13) with the branch labels switched. This time,  $\Lambda(\mathbf{x})$  is a non-decreasing function of  $U$ , the observed value of  $U$ . So for  $k < 1$ ,  $\Lambda(\mathbf{x}) \leq k$  if and only if  $U \leq c$ , for the same  $c$  as in Example 9.5.12.

## 9.6 Comparing the Means of Two Normal Distributions

### Commentary

The two-sample  $t$  test is introduced for the case of equal variances. There is some material near the end of the section about the case of unequal variances. This is useful material, but is not traditionally covered and can be skipped. Also, the derivation of the two-sample  $t$  test as a likelihood ratio test is provided for mathematical interest at the end of the section.

### Solutions to Exercises

1. In this example,  $n = 5$ ,  $m = 5$ ,  $\bar{X}_m = 18.18$ ,  $\bar{Y}_n = 17.32$ ,  $S_X^2 = 12.61$ , and  $S_Y^2 = 11.01$ . Then

$$U = \frac{(5+5-2)^{1/2}(18.18 - 17.32)}{\left(\frac{1}{5} + \frac{1}{5}\right)^{1/2}(11.01 + 12.61)^{1/2}} = 0.7913.$$

We see that  $|U| = 0.7913$  is much smaller than the 0.975 quantile of the  $t$  distribution with 8 degrees of freedom.

2. In this exercise,  $m = 8$ ,  $n = 6$ ,  $\bar{x}_m = 1.5125$ ,  $\bar{y}_n = 1.6683$ ,  $S_X^2 = 0.18075$ , and  $S_Y^2 = 0.16768$ . When  $\mu_1 = \mu_2$ , the statistic  $U$  defined by Eq. (9.6.3) will have the  $t$  distribution with 12 degrees of freedom. The hypotheses are as follows:

$$\begin{aligned} H_0 : \quad & \mu_1 \geq \mu_2, \\ H_1 : \quad & \mu_1 < \mu_2. \end{aligned}$$

Since the inequalities are reversed from those in (9.6.1), the hypothesis  $H_0$  should be rejected if  $U < c$ . It is found from a table that  $c = -1.356$ . The calculated value of  $U$  is  $-1.692$ . Therefore,  $H_0$  is rejected.

3. The value  $c = 1.782$  can be found from a table of the  $t$  distribution with 12 degrees of freedom. Since  $U = -1.692$ ,  $H_0$  is not rejected.
4. The random variable  $\bar{X}_m - \bar{Y}_n$  has a normal distribution with mean 0 and variance  $(\sigma_1^2/m) + (k\sigma_1^2/n)$ . Therefore, the following random variable has the standard normal distribution:

$$Z_1 = \frac{\bar{X}_m - \bar{Y}_n}{\left(\frac{1}{m} + \frac{k}{n}\right)^{1/2} \sigma_1}.$$

The random variable  $S_X^2/\sigma_1^2$  has a  $\chi^2$  distribution with  $m-1$  degrees of freedom. The random variable  $S_Y^2/(k\sigma_1^2)$  has a  $\chi^2$  distribution with  $n-1$  degrees of freedom. These two random variables are independent. Therefore,  $Z_2 = (1/\sigma_1^2)(S_X^2 + S_Y^2/k)$  has a  $\chi^2$  distribution with  $m+n-2$  degrees of freedom. Since  $Z_1$  and  $Z_2$  are independent, it follows that  $U = (m+n-2)^{1/2} Z_1 / Z_2^{1/2}$  has the  $t$  distribution with  $m+n-2$  degrees of freedom.

5. Again,  $H_0$  should be rejected if  $U < -1.356$ . Since  $U = -1.672$ ,  $H_0$  is rejected.
6. If  $\mu_1 - \mu_2 = \lambda$ , the following statistic  $U$  will have the  $t$  distribution with  $m + n - 2$  degrees of freedom:

$$U = \frac{(m+n-2)^{1/2}(\bar{X}_m - \bar{Y}_n - \lambda)}{\left(\frac{1}{m} + \frac{1}{n}\right)^{1/2}(S_X^2 + S_Y^2)^{1/2}}$$

The hypothesis  $H_0$  should be rejected if either  $U < c_1$  or  $U > c_2$ .

7. To test the hypotheses in Exercise 6,  $H_0$  would not be rejected if  $-1.782 < U < 1.782$ . The set of all values of  $\lambda$  for which  $H_0$  would not be rejected will form a confidence interval for  $\mu_1 - \mu_2$  with confidence coefficient 0.90. The value of  $U$ , for an arbitrary value of  $\lambda$ , is found to be

$$U = \frac{\sqrt{12}(-0.1558 - \lambda)}{0.3188}.$$

It is found that  $-1.782 < U < 1.782$  if and only if  $-0.320 < \lambda < 0.008$ .

8. The noncentrality parameter when  $|\mu_1 - \mu_2| = \sigma$  is

$$\psi = \frac{1}{\left(\frac{1}{8} + \frac{1}{10}\right)^{1/2}} = 2.108.$$

The degrees of freedom are 16. Figure 9.14 in the text makes it look like the power is about 0.23. Using computer software, we can compute the noncentral  $t$  probability to be 0.248.

9. The  $p$ -value can be computed as the size of the test that rejects  $H_0$  when  $|U| \geq |u|$ , where  $u$  is the observed value of the test statistic. Since  $U$  has the  $t$  distribution with  $m + n - 2$  degrees of freedom when  $H_0$  is true, the size of the test that rejects  $H_0$  when  $|U| \geq |u|$  is the probability that a  $t$  random variable with  $m + n - 2$  degrees of freedom is either less than  $-|u|$  or greater than  $|u|$ . This probability is

$$T_{m+n-2}(-|u|) + 1 - T_{m+n-2}(|u|) = 2[1 - T_{m+n-2}(|u|)],$$

by the symmetry of  $t$  distributions.

10. Let  $X_i$  stand for an observation in the calcium supplement group and let  $Y_j$  stand for an observation in the placebo group. The summary statistics are

$$\begin{aligned} m &= 10, \\ n &= 11, \\ \bar{x}_m &= 109.9, \\ \bar{y}_n &= 113.9, \\ s_x^2 &= 546.9, \\ s_y^2 &= 1282.9. \end{aligned}$$

We would reject the null hypothesis if  $U > T_{19}^{-1}(0.9) = 1.328$ . The test statistic has the observed value  $u = -0.9350$ . Since  $u < 1.328$ , we do not reject the null hypothesis.

11. (a) The observed value of the test statistic  $U$  is

$$u = \frac{(43 + 35 - 2)^{1/2}(8.560 - 5.551)}{\left(\frac{1}{43} + \frac{1}{35}\right)^{1/2}(2745.7 + 783.9)^{1/2}} = 1.939.$$

We would reject the null hypothesis at level  $\alpha_0 = 0.01$  if  $U > 2.376$ , the 0.99 quantile of the  $t$  distribution with 76 degrees of freedom. Since  $u < 2.376$ , we do not reject  $H_0$  at level 0.01. (The answer in the back of the book is incorrect in early printings.)

- (b) For Welch's test, the approximate degrees of freedom is

$$\nu = \frac{\left(\frac{2745.7}{43 \times 42} + \frac{783.9}{35 \times 34}\right)^2}{\frac{1}{42^3} \left(\frac{2745.7}{43}\right)^2 + \frac{1}{34^3} \left(\frac{783.9}{35}\right)^2} = 70.04.$$

The corresponding  $t$  quantile is 2.381. The test statistic is

$$\frac{8.560 - 5.551}{\left(\frac{2745.7}{43 \times 42} + \frac{783.9}{35 \times 34}\right)^{1/2}} = 2.038.$$

Once again, we do not reject  $H_0$ . (The answer in the back of the book is incorrect in early printings.) book is incorrect.)

12. The  $W$  in (9.6.15) is the sum of two independent random variables, one having a gamma distribution with parameters  $(m - 1)/2$  and  $m(m - 1)/(2\sigma_1^2)$  and the other having a gamma distribution with parameters  $(n - 1)/2$  and  $n(n - 1)/(2\sigma_2^2)$ . So, the mean and variance of  $W$  are

$$\begin{aligned} E(W) &= \frac{(m - 1)/2}{m(m - 1)/(2\sigma_1^2)} + \frac{(n - 1)/2}{n(n - 1)/(2\sigma_2^2)} = \frac{\sigma_1^2}{m} + \frac{\sigma_2^2}{n}, \\ \text{Var}(W) &= \frac{(m - 1)/2}{m^2(m - 1)^2/(4\sigma_1^4)} + \frac{(n - 1)/2}{n^2(n - 1)^2/(4\sigma_2^4)} = \frac{2\sigma_1^4}{m^2(m - 1)} + \frac{2\sigma_2^4}{n^2(n - 1)}. \end{aligned}$$

The gamma distribution with parameters  $\alpha$  and  $\beta$  has the above mean and variance if  $\alpha/\beta = E(W)$  and  $\alpha/\beta^2 = \text{Var}(W)$ . In particular,  $\alpha = E(W)^2/\text{Var}(W)$ , so

$$2\alpha = \frac{\left(\frac{\sigma_1^2}{m} + \frac{\sigma_2^2}{n}\right)^2}{\frac{\sigma_1^4}{m^2(m - 1)} + \frac{\sigma_2^4}{n^2(n - 1)}}.$$

This is easily seen to be the same as the expression in (9.6.16).

13. The likelihood ratio statistic for this case is

$$\Lambda(\mathbf{x}, \mathbf{y}) = \frac{\sup_{\{(\mu_1, \mu_2, \sigma^2): \mu_1 \neq \mu_2\}} g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma^2)}{\sup_{\{(\mu_1, \mu_2, \sigma^2): \mu_1 = \mu_2\}} g(\mathbf{x}, \mathbf{y} | \mu_1, \mu_2, \sigma^2)}. \quad (\text{S.9.11})$$

Maximizing the numerator of (S.9.11) is identical to maximizing the numerator of (9.6.10) when  $\bar{x}_m \leq \bar{y}_n$  because we need  $\mu_1 = \mu_2$  in both cases. So the M.L.E.'s are

$$\begin{aligned} \hat{\mu}_1 &= \hat{\mu}_2 = \frac{m\bar{x}_m + n\bar{y}_n}{m + n}, \\ \hat{\sigma}^2 &= \frac{mn(\bar{x}_m - \bar{y}_n)^2 / (m + n) + s_x^2 + s_y^2}{m + n}. \end{aligned}$$

Maximizing the denominator of (S.9.11) is identical to the maximization of the denominator of (9.6.10) when  $\bar{x}_m \leq \bar{y}_n$ . We use the overall M.L.E.'s

$$\hat{\mu}_1 = \bar{x}_m, \quad \hat{\mu}_2 = \bar{y}_n, \quad \text{and} \quad \hat{\sigma}^2 = \frac{1}{m+n}(s_x^2 + s_y^2).$$

This makes  $\Lambda(\mathbf{x}, \mathbf{y})$  equal to  $(1+v^2)^{-(m+n)/2}$  where  $v$  is defined in (9.6.12). So  $\Lambda(\mathbf{x}, \mathbf{y}) \geq k$  if and only if  $v^2 \leq k'$  for some other constant  $k'$ . This translates easily to  $|U| \geq c$ .

## 9.7 The $F$ Distributions

### Commentary

The  $F$  distributions are introduced along with the  $F$  test for equality of variances from normal samples. The power function of the  $F$  test is derived also. The derivation of the  $F$  test as a likelihood ratio test is provided for mathematical interest.

Those using the software  $R$  can make use of the functions `df`, `pf`, and `qf` which compute respectively the p.d.f., c.d.f., and quantile function of an arbitrary  $F$  distribution. The first argument is the argument of the function and the next two are the degrees of freedom. The function `rf` produces a random sample of  $F$  random variables.

### Solutions to Exercises

1. The test statistic is  $V = [2745.7/42]/[783.9/34] = 2.835$ . We reject the null hypothesis if  $V$  is greater than the 0.95 quantile of the  $F$  distribution with 42 and 34 degrees of freedom, which is 1.737. So, we reject the null hypothesis at level 0.05.
2. Let  $Y = 1/X$ . Then  $Y$  has the  $F$  distribution with 8 and 3 degrees of freedom. Also

$$\Pr(X > c) = \Pr\left(Y < \frac{1}{c}\right) = 0.975.$$

It can be found from the table given at the end of the book that  $\Pr(Y < 14.54) = 0.975$ . Therefore,  $1/c = 14.54$  and  $c = 0.069$ .

3. If  $Y$  has the  $t$  distribution with 8 degrees of freedom, then  $X = Y^2$  will have the  $F$  distribution with 1 and 8 degrees of freedom. Also,

$$0.3 = \Pr(X > c) = \Pr(Y > \sqrt{c}) + \Pr(Y < -\sqrt{c}) = 2\Pr(Y > \sqrt{c}).$$

Therefore,  $\Pr(Y > \sqrt{c}) = 0.15$ . It can be found from the table given at the end of the book that  $\Pr(Y > 1.108) = 0.15$ . Hence,  $\sqrt{c} = 1.108$  and  $c = 1.228$ .

4. Suppose that  $X$  is represented as in Eq. (9.7.1). Since  $Y$  and  $Z$  are independent,

$$E(X) = \frac{n}{m}E\left(\frac{Y}{Z}\right) = \frac{n}{m}E(Y)E\left(\frac{1}{z}\right).$$

Since  $Y$  has the  $\chi^2$  distribution with  $m$  degrees of freedom,  $E(Y) = m$ . Since  $Z$  has the  $\chi^2$  distribution with  $n$  degrees of freedom,

$$\begin{aligned} E\left(\frac{1}{Z}\right) &= \int_0^\infty \frac{1}{z} f(z) dz = \frac{1}{2^{n/2}\Gamma(n/2)} \int_0^\infty z^{(n/2)-2} \exp(-z/2) dz \\ &= \frac{2^{(n/2)-1}\Gamma[(n/2)-1]}{2^{n/2}\Gamma(n/2)} = \frac{1}{2[(n/2)-1]} = \frac{1}{n-2}. \end{aligned}$$

Hence,  $E(X) = n/(n-2)$ .

5. By Eq. (9.7.1),  $X$  can be represented in the form  $X = Y/Z$ , where  $Y$  and  $Z$  are independent and have identical  $\chi^2$  distributions. Therefore,  $\Pr(Y > Z) = \Pr(Y < Z) = 1/2$ . Equivalently,  $\Pr(X > 1) = \Pr(X < 1) = 1/2$ . Therefore, the median of the distribution of  $X$  is 1.
6. Let  $f(x)$  denote the p.d.f. of  $X$ , let  $W = mX/(mX + n)$ , and let  $g(w)$  denote the p.d.f. of  $W$ . Then  $X = nW/[m(1 - W)]$  and  $\frac{dx}{dw} = \frac{n}{m} \cdot \frac{1}{(1-w)^2}$ . For  $0 < w < 1$ ,

$$\begin{aligned} g(w) &= f\left[\frac{nw}{m(1-w)}\right] \cdot \left|\frac{dx}{dw}\right| \\ &= k \left(\frac{n}{m}\right)^{(m/2)-1} \frac{w^{(m/2)-1}}{(1-w)^{(m/2)-1}} \cdot \frac{(1-w)^{(m+n)/2}}{n^{(m+n)/2}} \left(\frac{n}{m}\right) \frac{1}{(1-w)^2} \\ &= k \frac{1}{m^{m/2} n^{n/2}} w^{(m/2)-1} (1-w)^{(n/2)-1}, \end{aligned}$$

where

$$k = \frac{\Gamma[(m+n)/2] m^{m/2} n^{n/2}}{\Gamma(m/2)\Gamma(n/2)}.$$

It can be seen  $g(w)$  is the p.d.f. of the required beta distribution.

7. (a) Here,  $\bar{X}_m = 84/16 = 5.25$  and  $\bar{Y}_n = 18/10 = 1.8$ . Therefore,  $S_1^2 = \sum_{i=1}^{16} X_i^2 - 16(\bar{X}_m^2) = 122$  and  $S_2^2 = \sum_{i=1}^{10} Y_i^2 - 10(\bar{Y}_n^2) = 39.6$ . It follows that

$$\hat{\sigma}_1^2 = \frac{1}{16} S_1^2 = 7.625 \quad \text{and} \quad \hat{\sigma}_2^2 = \frac{1}{10} S_2^2 = 3.96.$$

If  $\sigma_1^2 = \sigma_2^2$ , the following statistic  $V$  will have the  $F$  distribution with 15 and 9 degrees of freedom:

$$V = \frac{S_1^2/15}{S_2^2/9}.$$

- (b) If the test is to be carried out at the level of significance 0.05, then  $H_0$  should be rejected if  $V > 3.01$ . It is found that  $V = 1.848$ . Therefore, we do not reject  $H_0$ .
8. For any values of  $\sigma_1^2$  and  $\sigma_2^2$ , the random variable

$$\frac{S_1^2/(15\sigma_1^2)}{S_2^2/(9\sigma_2^2)}$$

has the  $F$  distribution with 15 and 9 degrees of freedom. Therefore, if  $\sigma_1^2 = 3\sigma_2^2$ , the following statistic  $V$  will have that  $F$  distribution:

$$V = \frac{S_1^2/45}{S_2^2/9}.$$

As before,  $H_0$  should be rejected if  $V > c$ , where  $c = 3.01$  if the desired level of significance is 0.05.

9. When  $\sigma_1^2 = \sigma_2^2$ ,  $V$  has an  $F$  distribution with 15 and 9 degrees of freedom. Therefore,  $\Pr(V > 3.77) = 0.025$ , which implies that  $c_2 = 3.77$ . Also,  $1/V$  has an  $F$  distribution with 9 and 15 degrees of freedom. Therefore,  $\Pr(1/V > 3.12) = 0.025$ . It follows that  $\Pr(V < 1/(3.12)) = 0.025$ , which means that  $c_1 = 1/(3.12) = 0.321$ .
10. Let  $V$  be as defined in Exercise 9. If  $\sigma_1^2 = r\sigma_2^2$ , then  $V/r$  has the  $F$  distribution with 15 and 9 degrees of freedom. Therefore,  $H_0$  would be rejected if  $V/r < c_1$  or  $V/r > c_2$ , where  $c_1$  and  $c_2$  have the values found in Exercise 9.
11. For any positive number  $r$ , the hypothesis  $H_0$  in Exercise 9 will not be rejected if  $c_1 < V/r < c_2$ . The set of all values of  $r$  for which  $H_0$  would not be rejected will form a confidence interval with confidence coefficient 0.95. But  $c_1 < V/r < c_2$  if and only if  $V/c_2 < r < V/c_1$ . Therefore, the confidence interval will contain all values of  $r$  between  $V/3.77 = 0.265V$  and  $V/0.321 = 3.12V$ .
12. If a random variable  $Z$  has the  $\chi^2$  distribution with  $n$  degrees of freedom,  $Z$  can be represented as the sum of  $n$  independent and identically distributed random variables  $Z_1, \dots, Z_n$ , each of which has a  $\chi^2$  distribution with 1 degree of freedom. Therefore,  $Z/n = \sum_{i=1}^n Z_i/n = \bar{Z}_n$ . As  $n \rightarrow \infty$ , it follows from the law of large numbers that  $\bar{Z}_n$  will converge in probability to the mean of each  $Z_i$ , which is 1. Therefore  $Z/n \xrightarrow{P} 1$ . It follows from Eq. (9.7.1) that if  $X$  has the  $F$  distribution with  $m_0$  and  $n$  degrees of freedom, then as  $n \rightarrow \infty$ , the distribution of  $X$  will become the same as the distribution of  $Y/m_0$ .
13. Suppose that  $X$  has the  $F$  distribution with  $m$  and  $n$  degrees of freedom, and consider the representation of  $X$  in Eq. (9.7.1). Then  $Y/m \xrightarrow{P} 1$ . Therefore, as  $m \rightarrow \infty$ , the distribution of  $X$  will become the same as the distribution of  $n/Z$ , where  $Z$  has a  $\chi^2$  distribution with  $n$  degrees of freedom. Suppose that  $c$  is the 0.05 quantile of the  $\chi^2$  distribution with  $n$  degrees of freedom. Then  $\Pr(n/Z < n/c) = 0.95$ . Hence,  $\Pr(X < n/c) = 0.95$ , and the value  $n/c$  should be entered in the column of the  $F$  distribution with  $m = \infty$ .
14. The test rejects the null hypothesis if the  $F$  statistic is greater than the 0.95 quantile of the  $F$  distribution with 15 and 9 degrees of freedom, which is 3.01. The power of the test when  $\sigma_1^2 = 2\sigma_2^2$  is  $1 - G_{15,9}(3.01/2) = 0.2724$ . This can be computed using a computer program that evaluates the c.d.f. of an arbitrary  $F$  distribution.
15. The  $p$ -value will be the value of  $\alpha_0$  such that the observed  $v$  is exactly equal to either  $c_1$  or  $c_2$ . The problem is deciding whether  $v = c_1$  or  $v = c_2$  since, we haven't constructed a specific test. Since  $c_1$  and  $c_2$  are assumed to be the  $\alpha_0/2$  and  $1 - \alpha_0/2$  quantiles of the  $F$  distribution with  $m - 1$  and  $n - 1$  degrees of freedom, we must have  $c_1 < c_2$  and  $G_{m-1,n-1}(c_1) < 1/2$  and  $G_{m-1,n-1}(c_2) > 1/2$ . These inequalities allow us to choose whether  $v = c_1$  or  $v = c_2$ . Every  $v > 0$  is some quantile of each  $F$  distribution, indeed the  $G_{m-1,n-1}^{-1}(v)$  quantile. If  $G_{m-1,n-1}(v) < 1/2$ , then  $v = c_1$  and  $\alpha_0 = 2G_{m-1,n-1}(v)$ . If  $G_{m-1,n-1}(v) > 1/2$ , then  $v = c_2$ , and  $\alpha_0 = 2[1 - G_{m-1,n-1}(v)]$ . (There is 0 probability that  $G_{m-1,n-1}(v) = 1/2$ .) Hence,  $\alpha_0$  is the smaller of the two numbers  $2G_{m-1,n-1}(v)$  and  $2[1 - G_{m-1,n-1}(v)]$ .

In Example 9.7.4,  $v = 0.9491$  was the observed value and  $2G_{25,25}(0.9491) = 0.8971$ , so this would be the  $p$ -value.

16. The denominator of the likelihood ratio is maximized when all parameters equal their M.L.E.'s. The numerator is maximized when  $\sigma_1^2 = \sigma_2^2$ . As in the text, the likelihood ratio then equals

$$\Lambda(\mathbf{x}, \mathbf{y}) = dw^{m/2}(1-w)^{n/2},$$

where  $w$  and  $d$  are defined in the text. In particular,  $w$  is a strictly increasing function of the observed value of  $V$ . Notice that  $\Lambda(\mathbf{x}, \mathbf{y}) \leq k$  when  $w \leq k_1$  or  $w \geq k_2$ . This corresponds to  $V \leq c_1$  or  $V \geq c_2$ . In order for the test to have level  $\alpha_0$ , the values  $c_1$  and  $c_2$  have to satisfy  $\Pr(V \leq c_1) + \Pr(V \geq c_2) = \alpha_0$  when  $\sigma_1^2 = \sigma_2^2$ .

17. The test found in Exercise 9 uses the values  $c_1 = 0.321$  and  $c_2 = 3.77$ . The likelihood ratio test rejects  $H_0$  when  $dw^8(1-w)^5 \leq k$ , which is equivalent to  $w^8(1-w)^5 \leq k/d$ . If  $V = v$ , then  $w = 15v/(15v+9)$ . In order for a test to be a likelihood ratio test, the two values  $c_1$  and  $c_2$  must lead to the same value of the likelihood ratio. In particular, we must have

$$\left(\frac{15c_1}{15c_1+9}\right)^8 \left(1 - \frac{15c_1}{15c_1+9}\right)^5 = \left(\frac{15c_2}{15c_2+9}\right)^8 \left(1 - \frac{15c_2}{15c_2+9}\right)^5.$$

Plugging the values of  $c_1$  and  $c_2$  from Exercise 9 into this formula we get  $2.555 \times 10^{-5}$  on the left and  $1.497 \times 10^{-5}$  on the right.

18. Let  $V^*$  be defined as in (9.7.5) so that  $V^*$  has the  $F$  distribution with  $m - 1$  and  $n - 1$  degrees of freedom and The distribution of  $V = (\sigma_1^2/\sigma_2^2)V^*$ . It is straightforward to compute

$$\Pr(V \leq c_1) = \Pr\left(\frac{\sigma_1^2}{\sigma_2^2}V^* \leq c_1\right) = \Pr\left(V^* \leq \frac{\sigma_2^2}{\sigma_1^2}c_1\right) = G_{m-1,n-1}\left(\frac{\sigma_2^2}{\sigma_1^2}c_1\right),$$

and similarly,

$$\Pr(V \geq c_2) = 1 - G_{m-1,n-1}\left(\frac{\sigma_2^2}{\sigma_1^2}c_2\right).$$

19. (a) Apply the result of Exercise 18 with  $c_1 = G_{10,20}^{-1}(0.025) = 0.2952$  and  $c_2 = G_{10,20}^{-1}(0.975) = 2.774$  and  $\sigma_2^2/\sigma_1^2 = 1/1.01$ . The result is

$$G_{10,20}(c_1/1.01) + 1 - G_{10,20}(c_2/1.01) = G_{10,20}(0.289625) + 1 - G_{10,20}(2.746209) = 0.0503.$$

- (b) Apply the result of Exercise 18 with  $c_1 = G_{10,20}^{-1}(0.025) = 0.2952$  and  $c_2 = G_{10,20}^{-1}(0.975) = 2.774$  and  $\sigma_2^2/\sigma_1^2 = 1.01$ . The result is

$$G_{10,20}(1.01 \times c_1) + 1 - G_{10,20}(1.01 \times c_2) = G_{10,20}(0.2954475) + 1 - G_{10,20}(2.80148) = 0.0498.$$

- (c) Since the answer to part (b) is less than 0.05 (the value of the power function for all parameters in the null hypothesis set), the test is not unbiased.

## 9.8 Bayes Test Procedures

### Commentary

This section introduces Bayes tests for the situations described in the earlier sections of the chapter. It derives Bayes tests as solutions to decision problems in which the loss function takes only three values: 0 for correct decision, and one positive value for each type of error. The cases of simple and one-sided hypotheses are covered as are the various situations involving samples from normal distributions. The calculations are done with improper prior distributions so that attention can focus on the methodology and similarity with the non-Bayesian results.

### Solutions to Exercises

1. In this exercise,  $\xi_0 = 0.9$ ,  $\xi_1 = 0.1$ ,  $w_0 = 1000$ , and  $w_1 = 18,000$ . Also,

$$f_0(x) = \frac{1}{(2\pi)^{1/2}} \exp\left[-\frac{1}{2}(x - 50)^2\right]$$

and

$$f_1(x) = \frac{1}{(2\pi)^{1/2}} \exp\left[-\frac{1}{2}(x - 52)^2\right].$$

By the results of this section, it should be decided that the process is out of control if

$$\frac{f_1(x)}{f_0(x)} > \frac{\xi_0 w_0}{\xi_1 w_1} = \frac{1}{2}.$$

This inequality can be reduced to the inequality  $2x - 102 > -\log 2$  or, equivalently,  $x > 50.653$ .

2. In this exercise,  $\xi_0 = 2/3$ ,  $\xi_1 = 1/3$ ,  $w_0 = 1$ , and  $w_1 = 4$ . Therefore, by the results of this section, it should be decided that  $f_0$  is correct if

$$\frac{f_1(x)}{f_0(x)} < \frac{\xi_0 w_0}{\xi_1 w_1} = \frac{1}{2}.$$

Since  $f_1(x)/f_0(x) = 4x^3$ , it should be decided that  $f_0$  is correct if  $4x^3 < 1/2$  or, equivalently, if  $x < 1/2$ .

3. In this exercise,  $\xi_0 = 0.8$ ,  $\xi_1 = 0.2$ ,  $w_0 = 400$ , and  $w_1 = 2500$ . Also, if we let  $y = \sum_{i=1}^n x_i$ , then

$$f_0(\mathbf{X}) = \frac{\exp(-3n) 3^y}{\prod_{i=1}^n (x_i!)}$$

and

$$f_1(\mathbf{X}) = \frac{\exp(-7n) 7^y}{\prod_{i=1}^n (x_i!)}$$

By the results of this section, it should be decided that the failure was caused by a major defect if

$$\frac{f_1(\mathbf{X})}{f_0(\mathbf{X})} = \exp(-4n) \left(\frac{7}{3}\right)^y > \frac{\xi_0 w_0}{\xi_1 w_1} = 0.64$$

or, equivalently, if

$$y > \frac{4n + \log(0.64)}{\log\left(\frac{7}{3}\right)}.$$

4. In this exercise,  $\xi_0 = 1/4$ ,  $\xi_1 = 3/4$ , and  $w_0 = w_1 = 1$ . Let  $x_1, \dots, x_n$  denote the observed values in the sample, and let  $y = \sum_{i=1}^n x_i$ . Then

$$f_0(\mathbf{X}) = (0.3)^y (0.7)^{n-y}$$

and

$$f_1(\mathbf{X}) = (0.4)^y (0.6)^{n-y}.$$

By the results of this section,  $H_0$  should be rejected if

$$\frac{f_1(\mathbf{X})}{f_0(\mathbf{X})} > \frac{\xi_0 w_0}{\xi_1 w_1} = \frac{1}{3}.$$

But

$$\frac{f_1(\mathbf{X})}{f_0(\mathbf{X})} = \left(\frac{4}{3} \cdot \frac{7}{6}\right)^y \left(\frac{6}{7}\right)^n > \frac{1}{3}$$

if and only if

$$y \log \frac{14}{9} + n \log \frac{6}{7} > \log \frac{1}{3}$$

or, equivalently, if and only if

$$\bar{x}_n = \frac{y}{n} > \frac{\log \frac{7}{6} + \frac{1}{n} \log \frac{1}{3}}{\log \frac{14}{9}}.$$

5. (a) In the notation of this section  $\xi_0 = \Pr(\theta = \theta_0)$  and  $f_i$  is the p.f. or p.d.f. of  $\mathbf{X}$  given  $\theta = \theta_i$ . By the law of total probability, the marginal p.f. or p.d.f. of  $\mathbf{X}$  is  $\xi_0 f_0(\mathbf{x}) + \xi_1 f_1(\mathbf{x})$ . Applying Bayes' theorem for random variables gives us that

$$\Pr(\theta = \theta_0 | \mathbf{x}) = \frac{\xi_0 f_0(\mathbf{x})}{\xi_0 f_0(\mathbf{x}) + \xi_1 f_1(\mathbf{x})}.$$

- (b) The posterior expected value of the loss given  $\mathbf{X} = \mathbf{x}$  is

$$\begin{aligned} \frac{w_0 \xi_0 f_0(\mathbf{x})}{\xi_0 f_0(\mathbf{x}) + \xi_1 f_1(\mathbf{x})} &\quad \text{if } \text{reject } H_0, \\ \frac{w_1 \xi_1 f_1(\mathbf{x})}{\xi_0 f_0(\mathbf{x}) + \xi_1 f_1(\mathbf{x})} &\quad \text{if } \text{don't reject } H_0. \end{aligned}$$

The tests  $\delta$  that minimize  $r(\delta)$  have the form

$$\begin{aligned} \text{Don't Reject } H_0 & \text{ if } \xi_0 w_0 f_0(\mathbf{x}) > \xi_1 w_1 f_1(\mathbf{x}), \\ \text{Reject } H_0 & \text{ if } \xi_0 w_0 f_0(\mathbf{x}) < \xi_1 w_1 f_1(\mathbf{x}), \\ \text{Do either} & \text{ if } \xi_0 w_0 f_0(\mathbf{x}) = \xi_1 w_1 f_1(\mathbf{x}). \end{aligned}$$

Notice that these tests choose the action that has smaller posterior expected loss. If neither action has smaller posterior expected loss, these tests can do either, but either would then minimize the posterior expected loss.

- (c) The “reject  $H_0$ ” condition in part (b) is  $\xi_0 w_0 f_0(\mathbf{x}) < \xi_1 w_1 f_1(\mathbf{x})$ . This is equivalent to  $w_0 \Pr(\theta = \theta_0 | \mathbf{x}) < w_1 [1 - \Pr(\theta = \theta_0 | \mathbf{x})]$ . Simplifying this inequality yields  $\Pr(\theta = \theta_0 | \mathbf{x}) < w_1 / (w_0 + w_1)$ . Since we can do whatever we want when equality holds, and since “ $H_0$  true” means  $\theta = \theta_0$ , we see that the test described in part (c) is one of the tests from part (b).
- 6. The proof is just as described in the hint. For example, (9.8.12) becomes

$$\int_{\theta_0}^{\infty} \int_{-\infty}^{\theta_0} w_1(\theta) w_0(\psi) \xi(\theta) \xi(\psi) [f_n(\mathbf{x}_1 | \theta) f_n(\mathbf{x}_2 | \psi) - f_n(\mathbf{x}_2 | \theta) f_n(\mathbf{x}_1 | \psi)] d\psi d\theta.$$

The steps after (9.8.12) are unchanged.

- 7. We shall argue indirectly. Suppose that there is  $\mathbf{x}$  such that the  $p$ -value is not equal to the posterior probability that  $H_0$  is true. First, suppose that the  $p$ -value is greater. Let  $\alpha_0$  be greater than the posterior probability and less than the  $p$ -value. Then the test that rejects  $H_0$  when  $\Pr(H_0 \text{ true} | \mathbf{x}) \leq \alpha_0$  will reject  $H_0$ , but the level  $\alpha_0$  test will not reject  $H_0$  because the  $p$ -value is greater than  $\alpha_0$ . This contradicts the fact that the two tests are the same. The case in which the  $p$ -value is smaller is very similar.
- 8. (a) The joint p.d.f. of the data given the parameters is

$$(2\pi)^{-(m+n)/2} \tau^{(m+n)/2} \exp\left(-\frac{\tau}{2} \left[ \sum_{i=1}^m (x_i - \mu_1)^2 + \sum_{j=1}^n (y_j - \mu_2)^2 \right]\right).$$

Use the following two identities to complete the proof of this part:

$$\begin{aligned} \sum_{i=1}^m (x_i - \mu_1)^2 &= \sum_{i=1}^m (x_i - \bar{x}_m)^2 + m(\bar{x}_m - \mu_1)^2, \\ \sum_{j=1}^n (y_j - \mu_2)^2 &= \sum_{j=1}^n (y_j - \bar{y}_n)^2 + n(\bar{y}_n - \mu_2)^2. \end{aligned}$$

- (b) The prior p.d.f. is just  $1/\tau$ .

- i. As a function of  $\mu_1$ , the posterior p.d.f. is a constant times  $\exp(-m\tau(\bar{x}_m - \mu_1)^2/2)$ , which is just like the p.d.f. of a normal distribution with mean  $\bar{x}_m$  and variance  $1/(m\tau)$ .
- ii. The result for  $\mu_2$  is similar to that for  $\mu_1$ .
- iii. As a function of  $(\mu_1, \mu_2)$ , the posterior p.d.f. looks like a constant times

$$\exp(-m\tau(\bar{x}_m - \mu_1)^2/2) \exp(-n\tau(\bar{y}_n - \mu_2)^2/2),$$

which is like the product of the two normal p.d.f.’s from parts (i) and (ii). Hence, the conditional posterior distribution of  $(\mu_1, \mu_2)$  given  $\tau$  is that of two independent normal random variables with the two distributions from parts (i) and (ii).

- iv. We can integrate  $\mu_1$  and  $\mu_2$  out of the joint p.d.f. Integrating  $\exp(-m\tau(\bar{x}_m - \mu_1)^2)$  yields  $(2\pi)^{1/2}\tau^{-1/2}$ . Integrating  $\exp(-n\tau(\bar{y}_n - \mu_2)^2)$  yields  $(2\pi)^{1/2}\tau^{-1/2}$  also. So, the marginal posterior p.d.f. of  $\tau$  is a constant times  $\tau^{(m+n-2)/2} \exp(-0.5\tau(s_x^2 + s_y^2))$ . This is the p.d.f. of a gamma distribution with parameters  $(m+n-2)/2$  and  $(s_x^2 + s_y^2)/2$ , except for a constant factor.
- (c) Since  $\mu_1$  and  $\mu_2$  are independent, conditional on  $\tau$ , we have that  $\mu_1 - \mu_2$  has a normal distribution conditional on  $\tau$  with mean equal to the difference of the means and variance equal to the sum of the variances. That is,  $\mu_1 - \mu_2$  has a normal distribution with mean  $\bar{x}_m - \bar{y}_n$  and variance  $\tau^{-1}(1/m + 1/n)$  given  $\tau$ . If we subtract the mean and divide by the square-root of the variance, we get a standard normal distribution for the result, which is the  $Z$  stated in this part of the problem. Since the standard normal distribution is independent of  $\tau$ , then  $Z$  is independent of  $\tau$  and has the standard normal distribution marginally.
- (d) Recall that  $\tau$  has a gamma distribution with parameters  $(m+n-2)/2$  and  $(s_x^2 + s_y^2)/2$ . If we multiply  $\tau$  by  $s_x^2 + s_y^2$ , the result  $W$  has a gamma distribution with the same first parameter but with the second parameter divided by  $s_x^2 + s_y^2$ , namely  $1/2$ .
- (e) Since  $Z$  and  $W$  are independent with  $Z$  having the standard normal distribution and  $W$  having the  $\chi^2$  distribution with  $m+n-2$  degrees of freedom, it follows from the definition of the  $t$  distribution that  $Z/(W/[m+n-2])^{1/2}$  has the  $t$  distribution with  $m+n-2$  degrees of freedom. It is easy to check that  $Z/(W/[m+n-2])^{1/2}$  is the same as (9.8.17).
9. (a) The null hypothesis can be rewritten as  $\tau_1 \geq \tau_2$ , where  $\tau_i = 1/\sigma_i^2$ . This can be further rewritten as  $\tau_1/\tau_2 \geq 1$ . Using the usual improper prior for all parameters yields the posterior distribution of  $\tau_1$  and  $\tau_2$  to be that of independent gamma random variables with  $\tau_1$  having parameters  $(m-1)/2$  and  $s_x^2/2$  while  $\tau_2$  has parameters  $(n-1)/2$  and  $s_y^2/2$ . Put another way,  $\tau_1 s_x^2$  has the  $\chi^2$  distribution with  $m-1$  degrees of freedom independent of  $\tau_2 s_y^2$  which has the  $\chi^2$  distribution with  $n-1$  degrees of freedom. This makes the distribution of

$$W = \frac{\tau_1 s_x^2 / (m-1)}{\tau_2 s_y^2 / (n-1)}$$

the  $F$  distribution with  $m-1$  and  $n-1$  degrees of freedom. The posterior probability that  $H_0$  is true is

$$\Pr(\tau_1/\tau_2 \geq 1) = \Pr\left(W \geq \frac{s_x^2 / (m-1)}{s_y^2 / (n-1)}\right) = 1 - G_{m-1, n-1}\left(\frac{s_x^2 / (m-1)}{s_y^2 / (n-1)}\right).$$

The posterior probability is at most  $\alpha_0$  if and only if

$$\frac{s_x^2 / (m-1)}{s_y^2 / (n-1)} \geq F_{m-1, n-1}^{-1}(1 - \alpha_0).$$

This is exactly the form of the rejection region for the level  $\alpha_0$   $F$  test of  $H_0$ .

- (b) This is a special case of Exercise 7.
10. (a) Using Theorem 9.8.2, the posterior distribution of

$$(26+26-2)^{1/2} \frac{\mu_1 - \mu_2 - [5.134 - 3.990]}{(1/26 + 1/26)^{1/2} (63.96 + 67.39)^{1/2}} = \frac{\mu_1 - \mu_2 - 1.144}{0.4495}$$

is the  $t$  distribution with 50 degrees of freedom.

- (b) We can compute

$$\Pr(|\mu_1 - \mu_2| \leq d) = T_{50}\left(\frac{d - 1.144}{0.4495}\right) - T_{50}\left(\frac{-d - 1.144}{0.4495}\right).$$

Figure S.9.6: Figure for Exercise 10b of Sec. 9.8.

A plot of this function is in Fig. S.9.6.

11. (a) First, let  $H_0 : \theta \in \Omega'$  and  $H_1 : \theta \in \Omega''$ . Then  $\Omega_0 = \Omega'$  and  $\Omega_1 = \Omega''$ . Since  $d_0$  is the decision that  $H_0$  is true we have  $d_0 = d'$  and  $d_1 = d''$ . Since  $w_0$  is the cost of type II error, and type I error is to choose  $\theta \in \Omega''$  when  $\theta \in \Omega'$ ,  $w_0 = w'$ , and  $w_1 = w''$ . It is straightforward to see that everything switches for the other case.
- (b) The test procedure is to

$$\text{choose } d_1 \text{ if } \Pr(\theta \in \Omega_0 | \mathbf{x}) < \frac{w_1}{w_0 + w_1}, \quad (\text{S.9.12})$$

$$\text{and choose either action if the two sides are equal.} \quad (\text{S.9.13})$$

In the first case, this translates to “choose  $d'$  if  $\Pr(\theta \in \Omega' | \mathbf{x}) < w''/(w' + w'')$ , and choose either action if the two sides are equal.” This is equivalent to “choose  $d'$  if  $\Pr(\theta \in \Omega' | \mathbf{x}) > w''/(w' + w'')$ , and choose either action if the two sides are equal.” This, in turn, is equivalent to “choose  $d'$  if  $\Pr(\theta \in \Omega'' | \mathbf{x}) < w'/(w' + w'')$ , and choose either action if the two sides are equal.” This last statement, in the second case, translates to (S.9.12). Hence, the Bayes test produces the same action ( $d'$  or  $d''$ ) regardless of which hypothesis you choose to call the null and which the alternative.

## 9.9 Foundational Issues

### Commentary

This section discusses some subtle issues that arise when the foundations of hypothesis testing are examined closely. These issues are the relationship between sample size and the level of a test and the distinction between statistical significance and practical significance. The term “statistical significance” is not introduced in the text until this section, hence instructors who do not wish to discuss this issue can avoid it altogether.

### Solutions to Exercises

1. (a) When  $\mu = 0$ ,  $X$  has the standard normal distribution. Therefore,  $c = 1.96$ . Since  $H_0$  should be rejected if  $|X| > c$ , then  $H_0$  will be rejected when  $X = 2$ .

$$(b) \frac{f(X | \mu = 0)}{f(X | \mu = 5)} = \frac{\exp\left(-\frac{1}{2}X^2\right)}{\exp\left[-\frac{1}{2}(X - 5)^2\right]} = \exp\left[\frac{1}{2}(25 - 10X)\right].$$

When  $X = 2$ , this likelihood ratio has the value  $\exp(5/2) = 12.2$ . Also,

$$\frac{f(X | \mu = 0)}{f(X | \mu = -5)} = \frac{\exp\left(-\frac{1}{2}X^2\right)}{\exp\left[-\frac{1}{2}(X + 5)^2\right]} = \exp\left[\frac{1}{2}(25 + 10X)\right].$$

When  $X = 2$ , this likelihood ratio has the value  $\exp(45/2) = 5.9 \times 10^9$ .

2. When  $\mu = 0$ ,  $100\bar{X}_n$  has the standard normal distribution. Therefore,  $\Pr(100|\bar{X}_n| > 1.96 | \mu = 0) = 0.05$ . It follows that  $c = 1.96/100 = 0.0196$ .

- (a) When  $\mu = 0.01$ , the random variable  $Z = 100(\bar{X}_n - 0.01)$  has the standard normal distribution. Therefore,

$$\begin{aligned}\Pr(|\bar{X}_n| < c | \mu = 0.01) &= \Pr(-1.96 < 100\bar{X}_n < 1.96 | \mu = 0.01) \\ &= \Pr(-2.96 < z < 0.96) \\ &= 0.8315 - 0.0015 = 0.8300.\end{aligned}$$

It follows that  $\Pr(|\bar{X}_n| \geq c | \mu = 0.01) = 1 - 0.8300 = 0.1700$ .

- (b) When  $\mu = 0.02$ , the random variable  $Z = 100(\bar{X}_n - 0.02)$  has the standard normal distribution. Therefore,

$$\begin{aligned}\Pr(|\bar{X}_n| < c | \mu = 0.02) &= \Pr(-3.96 < Z < -0.04) \\ &= \Pr(0.04 < Z < 3.96) = 1 - 0.5160.\end{aligned}$$

It follows that  $\Pr(|\bar{X}_n| < c | \mu = 0.02) = 0.5160$ .

3. When  $\mu = 0$ ,  $100\bar{X}_n$  has the standard normal distribution. The calculated value of  $100\bar{X}_n$  is  $100(0.03) = 3$ . The corresponding tail area is  $\Pr(100\bar{X}_n > 3) = 0.0013$ .

4. (a) According to Theorem 9.2.1, we reject  $H_0$  if

$$\frac{19}{(2\pi)^{n/2}} \exp\left(-\frac{1}{2} \sum_{i=1}^n x_i^2\right) < \frac{1}{(2\pi)^{n/2}} \exp\left(-\frac{1}{2} \sum_{i=1}^n (x_i - 0.5)^2\right).$$

This inequality is equivalent to

$$\frac{2 \log(19)}{n} + \frac{1}{4} < \bar{x}_n.$$

That is,  $c_n = 2 \log(19)/n + 1/4$ . For  $n = 1, 100, 100000$ , the values of  $c_n$  are 6.139, 0.3089, and 0.2506.

- (b) The size of the test is

$$\Pr(\bar{X}_n \geq c_n | \theta = 0) = 1 - \Phi(c_n \times n^{1/2}).$$

For  $n = 1, 100, 10000$ , the sizes are  $4.152 \times 10^{-10}$ , 0.001, and 0.

5. (a) We want to choose  $c_n$  so that

$$19[1 - \Phi(\sqrt{n}c_n)] = \Phi(\sqrt{n}[c_n - 0.5]).$$

Solving this equation must be done numerically. For  $n = 1$ , the equation is solved for  $c_n = 1.681$ . For  $n = 100$ , we need  $c_n = 0.3021$ . For  $n = 10000$ , we need  $c_n = 0.25$  (both sides are essentially 0).

- (b) The size of the test is  $1 - \Phi(c_n n^{1/2})$ , which is 0.0464 for  $n = 1$ , 0.00126 for  $n = 100$  and essentially 0 for  $n = 10000$ .

## 9.10 Supplementary Exercises

### Solutions to Exercises

1. According to Theorem 9.2.1, we want to reject  $H_0$  when

$$(1/2)^3 < (3/4)^x (1/4)^{3-x}.$$

We don't reject  $H_0$  when the reverse inequality holds, and we can do either if equality holds. The inequality above can be simplified to  $x > \log(8)/\log(3) = 1.892$ . That is, we reject  $H_0$  if  $X$  is 2 or 3, and we don't reject  $H_0$  if  $X$  is 0 or 1. The probability of type I error is  $3(1/2)^3 + (1/2)^3 = 1/2$  and the probability of type II error is  $(1/4)^3 + 3(1/4)^2(3/4) = 5/32$ .

2. The probability of an error of type 1 is

$$\alpha = \Pr(\text{Rej. } H_0 | H_0) = \Pr(X \leq 5 | \theta = 0.1) = 1 - (.9)^5 = .41.$$

The probability of an error of type 2 is

$$\beta = \Pr(\text{Acc. } H_0 | H_1) = \Pr(X \geq 6 | \theta = 0.2) = (.8)^5 = .33.$$

3. It follows from Sec. 9.2 that the Bayes test procedure rejects  $H_0$  when  $f_1(x)/f_0(x) > 1$ . In this problem,

$$f_1(x) = (.8)^{x-1}(.2) \quad \text{for } x = 1, 2, \dots,$$

and

$$f_0(x) = (.9)^{x-1}(.1) \quad \text{for } x = 1, 2, \dots$$

Hence,  $H_0$  should be rejected when  $2(8/9)^{x-1} \geq 1$  or  $x - 1 \leq 5.885$ . Thus,  $H_0$  should be rejected for  $X \leq 6$ .

4. It follows from Theorem 9.2.1 that the desired test will reject  $H_0$  if

$$\frac{f_1(x)}{f_0(x)} = \frac{f(x | \theta = 0)}{f(x | \theta = 2)} > \frac{1}{2}.$$

In this exercise, the ratio on the left side reduces to  $x/(1-x)$ . Hence, the test specifies rejecting  $H_0$  if  $x > 1/3$ . For this test,

$$\begin{aligned}\alpha(\delta) &= \Pr\left(X > \frac{1}{3} | \theta = 2\right) = \frac{4}{9}, \\ \beta(\delta) &= \Pr\left(X < \frac{1}{3} | \theta = 0\right) = \frac{1}{9}.\end{aligned}$$

Hence,  $\alpha(\delta) + 2\beta(\delta) = 2/3$ .

5. It follows from the previous exercise and the Neyman-Pearson lemma that the optimal procedure  $\delta$  specifies rejecting  $H_0$  when  $x/(1-x) > k'$  or, equivalently, when  $x > k$ . The constant  $k$  must be chosen so that

$$\alpha = \Pr(X > k | \theta = 2) = \int_k^1 f(x | \theta = 2) dx = (1 - k)^2.$$

Hence,  $k = 1 - \alpha^{1/2}$  and

$$\beta(\delta) = \Pr(X < k | \theta = 0) = k^2 = (1 - \alpha^{1/2})^2.$$

6. (a) The power function is given by

$$\pi(\theta | \delta) = \Pr(X > 0.9 | \theta) = \int_{0.9}^1 f(x | \theta) dx = .19 - .09\theta.$$

- (b) The size of  $\delta$  is

$$\sup_{\theta \geq 1} \pi(\theta | \delta) = .10.$$

7. A direct calculation shows that for  $\theta_1 < \theta_2$ ,

$$\frac{d}{dx} \left[ \frac{f(x | \theta_2)}{f(x | \theta_1)} \right] = \frac{2(\theta_1 - \theta_2)}{[2(1 - \theta_1)x + \theta_1]^2} < 0.$$

Hence, the ratio  $f(x | \theta_2)/f(x | \theta_1)$  is a decreasing function of  $x$  or, equivalently, an increasing function of  $r(x) = -x$ . It follows from Theorem 9.3.1 that a UMP test of the given hypotheses will reject  $H_0$  when  $r(X) \geq c$  or, equivalently, when  $X \leq k$ . Hence,  $k$  must be chosen so that

$$.05 = \Pr \left( X \leq k | \theta = \frac{1}{2} \right) = \int_0^k f \left( x | \theta = \frac{1}{2} \right) dx = \frac{1}{2}(k^2 + k), \quad \text{or} \quad k = \frac{1}{2}(\sqrt{1.4} - 1).$$

8. Suppose that the proportions of red, brown, and blue chips are  $p_1$ ,  $p_2$ , and  $p_3$ , respectively. It follows from the multinomial distribution that the probability of obtaining exactly one chip of each color is

$$\frac{3!}{1!1!1!} p_1 p_2 p_3 = 6p_1 p_2 p_3.$$

Hence,  $\Pr(\text{Rej. } H_0 | p_1, p_2, p_3) = 1 - 6p_1 p_2 p_3$ .

- (a) The size of the test is

$$\alpha = \Pr \left( \text{Rej. } H_0 \mid \frac{1}{3}, \frac{1}{3}, \frac{1}{3} \right) = \frac{7}{9}.$$

- (b) The power under the given alternative distribution is  $\Pr(\text{Rej. } H_0 | 1/7, 2/7, 4/7) = 295/343 = .860$ .

9. Let  $f_i(x)$  denote the p.d.f. of  $X$  under the hypotheses  $H_i$  ( $i = 0, 1$ ). Then

$$\frac{f_1(x)}{f_0(x)} = \begin{cases} \infty & \text{for } x \leq 0 \text{ or } x \geq 1, \\ \varphi(x) & \text{for } 0 < x < 1, \end{cases}$$

where  $\varphi(x)$  is the standard normal p.d.f. The most powerful test  $\delta$  of size 0.01 rejects  $H_0$  when  $f_1(x)/f_0(x) > k$ . Since  $\varphi(x)$  is strictly decreasing for  $0 < x < 1$ , it follows that  $\delta$  will reject  $H_0$  if

$X \leq 0$ ,  $X \geq 1$ , or  $0 < X < c$ , where  $c$  is chosen so that  $\Pr(0 < X < c | H_0) = .01$ . Since  $X$  has a uniform distribution under  $H_0$ ,  $c = .01$ . Thus,  $\delta$  specifies rejecting  $H_0$  if  $X \leq .01$  or  $X \geq 1$ . The power of  $\delta$  under  $H_1$  is

$$\Pr(X \leq .01 | H_1) + \Pr(X \geq 1 | H_1) = \Phi(.01) + [1 - \Phi(1)] = .5040 + .1587 = .6627.$$

10. The usual  $t$  statistic  $U$  is defined by Eq. (9.5.2) with  $n = 12$  and  $\mu_0 = 3$ . Because the one-sided hypotheses  $H_0$  and  $H_1$  are reversed from those in (9.5.1), we now want to reject  $H_0$  if  $U \leq c$ . If  $\mu_0 = 3$ , then  $U$  has the  $t$  distribution with 11 degrees of freedom. Under these conditions, we want  $\Pr(U \leq c) = 0.005$  or equivalently, by the symmetry of the  $t$  distribution,  $\Pr(U \leq -c) = 0.995$ . It is found from the table of the  $t$  distribution that  $-c = 3.106$ . Hence,  $H_0$  should be rejected if  $U \leq -3.106$ .
11. It is known from Example 4 that the UMP test rejects  $H_0$  if  $\bar{X}_n \geq c$ . Hence,  $c$  must be chosen so that

$$0.95 = \Pr(X_n \geq c | \theta = 1) = \Pr[Z \geq \sqrt{n}(c - 1)],$$

where  $Z$  has the standard normal distribution. Hence,  $\sqrt{n}(c - 1) = -1.645$ , and  $c = 1 - (1.645)/n^{1/2}$ . Since the power function of this test will be a strictly increasing function of  $\theta$ , the size of the test will be

$$\begin{aligned} \alpha &= \sup_{\theta \leq 0} \Pr(\text{Rej. } H_0 | \theta) = \Pr(\text{Rej. } H_0 | \theta = 0) = \Pr\left[\bar{X}_n \geq 1 - \frac{(1.645)}{n^{1/2}} \mid \theta = 0\right] \\ &= \Pr(Z \geq n^{1/2} - 1.645), \end{aligned}$$

where  $Z$  again has the standard normal distribution. When  $n = 16$ ,

$$\alpha = \Pr(Z \geq 2.355) = .0093.$$

12. For  $\theta_1 < \theta_2$ ,

$$\frac{f_n(\mathbf{x} | \theta_2)}{f_n(\mathbf{x} | \theta_1)} = \left(\frac{\theta_2}{\theta_1}\right)^8 \left(\prod_{i=1}^8 x_i\right)^{\theta_2 - \theta_1},$$

which is an increasing function of  $T = \prod_{i=1}^8 x_i$ . Hence, the UMP test specifies rejecting  $H_0$  when  $T > c$

or, equivalently, when  $-2 \sum_{i=1}^8 \log X_i < k$ . The reason for expressing the test in this final form is that when  $\theta = 1$ , the observations  $X_1, \dots, X_8$  are i.i.d. and each has a uniform distribution on the interval  $(0,1)$ . Under these conditions,  $-2 \sum_{i=1}^8 \log X_i$  has a  $\chi^2$  distribution with  $2n = 16$  degrees of freedom (see Exercise 7 of Sec. 8.2 and Exercise 5 of Sec. 8.9). Hence, in accordance with Theorem 9.3.1,  $H_0$  should be rejected if  $-2 \sum_{i=1}^8 \log X_i \leq 7.962$ , which is the 0.05 quantile of the  $\chi^2$  distribution with 16 degrees of freedom, or equivalently if  $\sum_{i=1}^8 \log x_i \geq -3.981$ .

13. The  $\chi^2$  distribution with  $\theta$  degrees of freedom is a gamma distribution with parameters  $\alpha = \theta/2$  and  $\beta = 1/2$ . Hence, it follows from Exercise 3 of Sec. 9.3 that the joint p.d.f. of  $X_1, \dots, X_n$  has a monotone likelihood ratio in the statistic  $T = \prod_{i=1}^n X_i$ . Hence, there is a UMP test of the given hypotheses, and it specifies rejecting  $H_0$  when  $T \geq c$  or, equivalently, when  $\log T = \sum_{i=1}^n \log X_i \geq k$ .
14. Let  $\bar{X}_1$  be the average of the four observations  $X_1, \dots, X_4$  and let  $\bar{X}_2$  be the average of the six observations  $X_5, \dots, X_{10}$ . Let  $S_1^2 = \sum_{i=1}^4 (X_i - \bar{X}_1)^2$  and  $S_2^2 = \sum_{i=5}^{10} (X_i - \bar{X}_2)^2$ . Then  $S_1^2/\sigma^2$  and  $S_2^2/\sigma^2$  have independent  $\chi^2$  distributions with 3 and 5 degrees of freedom, respectively. Hence,  $(5S_1^2)/(3S_2^2)$  has the desired  $F$  distribution.
15. It was shown in Sec. 9.7 that the  $F$  test rejects  $H_0$  if  $V \geq 2.20$ , where  $V$  is given by (9.7.4) and 2.20 is the 0.95 quantile of the  $F$  distribution with 15 and 20 degrees of freedom. For any values of  $\sigma_1^2$  and  $\sigma_2^2$ , the random variable  $V^*$  given by (9.7.5) has the  $F$  distribution with 15 and 20 degrees of freedom. When  $\sigma_1^2 = 2\sigma_2^2$ ,  $V^* = V/2$ . Hence, the power when  $\sigma_1^2 = 2\sigma_2^2$  is

$$P^*(\text{Rej. } H_0) = P^*(V \geq 2.20) = P^*\left(\frac{1}{2}V \geq 1.10\right) = \Pr(V^* \geq 1.1),$$

where  $P^*$  denotes a probability calculated under the assumption that  $\sigma_1^2 = 2\sigma_2^2$ .

16. The ratio  $V = S_X^2/S_Y^2$  has the  $F$  distribution with 8 and 8 degrees of freedom, and so does  $1/V = S_Y^2/S_X^2$ . Thus,

$$.05 = \Pr(T > c) = \Pr(V > c) + \Pr(1/V > c) = 2 \Pr(V > c).$$

It follows that  $c$  must be the .975 quantile of the distribution of  $V$ , which is found from the tables to be 4.43.

17. (a) Carrying out a test of size  $\alpha$  on repeated independent samples is like performing a sequence of Bernoulli trials on each of which the probability of success is  $\alpha$ . With probability 1, a success will ultimately be obtained. Thus, sooner or later,  $H_0$  will ultimately be rejected. Therefore, the overall size of the test is 1.
- (b) As we know from the geometric distribution, the expected number samples, or trials, until a success is obtained is  $1/\alpha$ .
18. If  $U$  is defined as in Eq. (8.6.9), then the prior distribution of  $U$  is the  $t$  distribution with  $2\alpha_0 = 2$  degrees of freedom. Since the  $t$  distribution is symmetric with respect to the origin, it follows that under the prior distribution,  $\Pr(H_0) = \Pr(\mu \leq 3) = \Pr(U \leq 0) = 1/2$ . It follows from (8.6.1) and (8.6.2) that under the posterior distribution,

$$\begin{aligned}\mu_1 &= \frac{3 + (17)(3.2)}{1 + 17} = 3.189, \quad \lambda_1 = 18, \\ \alpha_1 &= 1 + \frac{17}{2} = 9.5, \\ \beta_1 &= 1 + \frac{1}{2}(17) + \frac{(17)(.04)}{2(18)} = 9.519.\end{aligned}$$

If we now define  $Y$  to be the random variable in Eq. (8.6.12) then  $Y = (4.24)(\mu - 3.19)$  and  $Y$  has the  $t$  distribution with  $2\alpha_1 = 19$  degrees of freedom. Thus, under the posterior distribution,

$$\Pr(H_0) = \Pr(\mu \leq 3) = \Pr[Y \leq (4.24)(3 - 3.19)] = \Pr(Y \leq -.81) = \Pr(Y \geq .81).$$

It is found from the table of the  $t$  distribution with 19 degrees of freedom that this probability is approximately 0.21.

19. At each point  $\theta \in \Omega_1$ ,  $\pi(\theta | \delta)$  must be at least as large as it is at any point in  $\Omega_0$ , because  $\delta$  is unbiased. But  $\sup_{\theta \in \Omega_0} \pi(\theta | \delta) = \alpha$ , at every point  $\theta \in \Omega_1$ .
20. Since  $\delta$  is unbiased and has size  $\alpha$ , it follows from the previous exercise that  $\pi(\theta | \delta) \leq \alpha$  for all  $\theta$  inside the circle  $A$  and  $\pi(\theta | \delta) \geq \alpha$  for all  $\theta$  outside  $A$ . Since  $\pi(\theta | \delta)$  is continuous, it must therefore be equal to  $\alpha$  everywhere on the boundary of  $A$ . Note that this result is true regardless of whether all of any part of the boundary belongs to  $H_0$  or  $H_1$ .
21. Since  $H_0$  is simple and  $\delta$  has size  $\alpha$ , then  $\pi(\theta_0 | \delta) = \alpha$ . Since  $\delta$  is unbiased,  $\pi(\theta | \delta) \geq \alpha$  for all other values of  $\theta$ . Therefore,  $\pi(\theta | \delta)$  is a minimum at  $\theta = \theta_0$ . Since  $\pi$  is assumed to be differentiable, it follows that  $\pi'(\theta_0 | \delta) = 0$ .
22. (a) We want  $\Pr(X > c_1 | H_0) = \Pr(Y > c_2 | H_0) = .05$ . Under  $H_0$ , both  $X$  and  $Y/10$  are standard normal. Therefore,  $c_1 = 1.645$  and  $c_2 = 16.45$ .
- (b) The most powerful test of a size  $\alpha_0$ , conditional on observing  $X$  with a variance of  $\sigma^2$  is to reject  $H_0$  if  $X > \sigma\Phi^{-1}(1 - \alpha_0)$ . In this problem we are asked to find two such tests: one with  $\sigma = 1$  and  $\alpha_0 = 2.0 \times 10^{-7}$  and the other with  $\sigma = 10$  and  $\alpha_0 = 0.0999998$ . The resulting critical values are

$$\begin{aligned}\Phi^{-1}(1 - 2.0 \times 10^{-7}) &= 5.069, \\ 10\Phi^{-1}(1 - 0.0999998) &= 12.8155.\end{aligned}$$

- (c) The overall size of a test in this problem is the average of the two conditional sizes, since the two types of meteorological conditions have probability 1/2 each. In part (a), the two conditional sizes are both 0.05, so that is the average as well. In part (b), the average of the two sizes is  $(2.0 \times 10^{-7} + 0.0999998)/2 = 0.05$  also. The powers are also the averages of the two conditional powers. The power of the conditional size  $\alpha_0$  test with variance  $\sigma^2$  is

$$1 - \Phi(\sigma\Phi^{-1}(1 - \alpha_0) - 10).$$

The results are tabulated below:

Part	Good	Poor	Average
(a)	1	0	0.5
(b)	0.9999996	0.002435	0.5012

23. (a) The data consist of both  $X$  and  $Y$ , where  $X$  is defined in Exercise 22 and  $Y = 1$  if meteorological conditions are poor and  $Y = 0$  if not. The joint p.f./p.d.f. of  $(X, Y)$  given  $\Theta = \theta$  is

$$\frac{1}{2(2\pi)^{1/2}10^y} \exp\left(-\frac{1-y}{2}[x-\theta]^2 - \frac{y}{200}[x-\theta]^2\right).$$

The Bayes test will choose  $H_0$  when

$$\begin{aligned}w_0\xi_0 \frac{1}{2(2\pi)^{1/2}10^y} \exp\left(-\frac{1-y}{2}x^2 - \frac{y}{200}x^2\right) \\ > w_1\xi_1 \frac{1}{2(2\pi)^{1/2}10^y} \exp\left(-\frac{1-y}{2}[x-10]^2 - \frac{y}{200}[x-10]^2\right).\end{aligned}$$

It will choose  $H_1$  when the reverse inequality holds, and it can do either when equality holds. This inequality can be rewritten by splitting according to the value of  $y$ . That is, choose  $H_0$  if

$$\begin{cases} x < 5 + \log(w_0\xi_0/(w_1\xi_1))/10 & \text{if } y = 0, \\ x < 5 + 10\log(w_0\xi_0/(w_1\xi_1)) & \text{if } y = 1. \end{cases}$$

- (b) In order for a test to be of the form of part (a), the two critical values  $c_0$  and  $c_1$  used for  $y = 0$  and  $y = 1$  respectively must satisfy  $c_1 - 5 = 100(c_0 - 5)$ . In part (a) of Exercise 22, the two critical values are  $c_0 = 1.645$  and  $c_1 = 16.45$ . These do not even approximately satisfy  $c_1 - 5 = 100(c_0 - 5)$ .
  - (c) In part (b) of Exercise 22, the two critical values are  $c_0 = 5.069$  and  $c_1 = 12.8155$ . These approximately satisfy  $c_1 - 5 = 100(c_0 - 5)$ .
24. (a) The Poisson distribution has M.L.R. in  $Y$ , so rejection  $H_0$  when  $Y \leq c$  is a UMP test of its size. With  $c = 0$ , the size is  $\Pr(Y = 0|\theta = 1) = \exp(-n)$ .
- (b) The power function of the test is  $\Pr(Y = 0|\theta) = \exp(-n\theta)$ .
25. Let  $I$  be the random interval that corresponds to the UMP test, and let  $J$  be a random interval that corresponds to some other level  $\alpha_0$  test. Translating UMP into what it says about the random interval  $I$  compared to  $J$ , we have for all  $\theta > c$

$$\Pr(c \in I|\theta) \leq \Pr(c \in J|\theta).$$

In other words, the observed value of  $I$  is a uniformly most accurate coefficient  $1 - \alpha_0$  confidence interval if, for every random interval  $J$  such that the observed value of  $J$  is a coefficient  $1 - \alpha_0$  confidence interval and for all  $\theta_2 > \theta_1$ ,

$$\Pr(\theta_1 \in I|\theta = \theta_2) \leq \Pr(\theta_1 \in J|\theta = \theta_2).$$

# Chapter 10

## Categorical Data and Nonparametric Methods

### 10.1 Tests of Goodness-of-Fit

#### Commentary

This section ends with a discussion of some issues related to the meaning of the  $\chi^2$  goodness-of-fit test for readers who want a deeper understanding of the procedure.

#### Solutions to Exercises

1. Let  $Y = N_1$ , the number of defective items, and let  $\theta = p_1$ , the probability that each item is defective. The level  $\alpha_0$  test requires us to choose  $c_1$  and  $c_2$  such that  $\Pr(Y \leq c_1 | \theta = 0.1) + \Pr(Y \geq c_2 | \theta = 0.1)$  is close to  $\alpha_0$ . We can compute the probability that  $Y = y$  for each  $y = 0, \dots, 100$  and arrange the numbers from smallest to largest. The smallest values correspond to large values of  $y$  down to  $y = 25$ , then some values corresponding to small values of  $y$  start to appear in the list. The sum of the values reaches 0.0636 when  $c_1 = 4$  and  $c_2 = 16$ . So  $\alpha_0 = 0.0636$  is the smallest  $\alpha_0$  for which we would reject  $H_0 : \theta = 0.1$  using such a test.

2.

$$\begin{aligned} Q &= \sum_{i=1}^k \frac{(N_i - n/k)^2}{n/k} = \frac{k}{n} \sum_{i=1}^k \left( N_i^2 - 2\frac{n}{k}N_i + \frac{n^2}{k^2} \right) = \frac{k}{n} \left( \sum_{i=1}^k N_i^2 - 2\frac{n}{k} \sum_{i=1}^k N_i + \frac{n^2}{k} \right) \\ &= \frac{k}{n} \left( \sum_{i=1}^k N_i^2 - 2\frac{n^2}{k} + \frac{n^2}{k} \right) = \left( \frac{k}{n} \sum_{i=1}^k N_i^2 \right) - n. \end{aligned}$$

3. We obtain the following frequencies:

$i$	0	1	2	3	4	5	6	7	8	9
$N_i$	25	16	19	20	20	22	24	15	14	25

Since  $P_i^0 = 1/10$  for every value of  $i$ , and  $n = 200$ , we find from Eq. (10.1.2) that  $Q = 7.4$ . If  $Q$  has the  $\chi^2$  distribution with 9 degrees of freedom,  $\Pr(Q \geq 7.4) = 0.6$ .

4. We obtain the following table:

	$AA$	$Aa$	$aa$
$N_i$	10	10	4
$np_i^0$	6	12	6

It is found from Eq. (10.1.2) that  $Q = 11/3$ . If  $Q$  has a  $\chi^2$  distribution with 2 degrees of freedom, then the value of  $\Pr(Q \geq 11/3)$  is between 0.1 and 0.2.

5. (a) The number of successes is  $n\bar{X}_n$  and the number of failures is  $n(1 - \bar{X}_n)$ . Therefore,

$$\begin{aligned} Q &= \frac{(n\bar{X}_n - np_0)^2}{np_0} + \frac{[n(1 - \bar{X}_n) - n(1 - p_0)]^2}{n(1 - p_0)} \\ &= n(\bar{X}_n - p_0)^2 \left( \frac{1}{p_0} + \frac{1}{1 - p_0} \right) \\ &= \frac{n(\bar{X}_n - p_0)^2}{p_0(1 - p_0)} \end{aligned}$$

- (b) If  $p = p_0$ , then  $E(\bar{X}_n) = p_0$  and  $\text{Var}(\bar{X}_n) = p_0(1 - p_0)/n$ . Therefore, by the central limit theorem, the c.d.f. of

$$Z = \frac{\bar{X}_n - p_0}{[p_0(1 - p_0)/n]^{1/2}}$$

converges to the c.d.f. of the standard normal distribution. Since  $Q = Z^2$ , the c.d.f. of  $Q$  will converge to the c.d.f. of the  $\chi^2$  distribution with 1 degree of freedom.

6. Here,  $p_0 = 0.3$ ,  $n = 50$ , and  $\bar{X}_n = 21/50$ . By Exercise 5,  $Q = 3.44$ . If  $Q$  has a  $\chi^2$  distribution with 1 degree of freedom, then  $\Pr(Q \geq 3.4)$  is slightly greater than 0.05.

7. We obtain the following table:

	$0 < x < 0.2$	$0.2 < x < 0.5$	$0.5 < x < 0.8$	$0.8 < x < 1$
$N_i$	391	490	580	339
$np_i^0$	360	540	540	360

If  $Q$  has a  $\chi^2$  distribution with 3 degrees of freedom, then  $\Pr(Q \geq 11.34) = 0.01$ . Therefore, we should reject  $H_0$  if  $Q \geq 11.34$ . It is found from Eq. (10.1.2) that  $Q = 11.5$ .

8. If  $Z$  denotes a random variable having a standard normal distribution and  $X$  denotes the height of a man selected at random from the city, then

$$\begin{aligned} \Pr(X < 66) &= \Pr(Z < -2) = 0.0227, \\ \Pr(66 < X < 67.5) &= \Pr(-2 < Z < -0.5) = 0.2858, \\ \Pr(67.5 < X < 68.5) &= \Pr(-0.5 < Z < 0.5) = 0.3830, \\ \Pr(68.5 < X < 70) &= \Pr(0.5 < Z < 2) = 0.2858, \\ \Pr(X > 70) &= \Pr(Z > 2) = 0.0227. \end{aligned}$$

Therefore, we obtain the following table:

	$N_i$	$np_i^0$
$x < 66$	18	11.35
$66 < x < 67.5$	177	142.9
$67.5 < x < 68.5$	198	191.5
$68.5 < x < 70$	102	142.9
$x > 70$	5	11.35

It is found from Eq. (10.1.2) that  $Q = 27.5$ . If  $Q$  has a  $\chi^2$  distribution with 4 degrees of freedom, then  $\Pr(Q \geq 27.5) = 0.005$ .

9. (a) The five intervals, each of which has probability 0.2, are as follows:

$$(-\infty, -0.842), (-0.842, -0.253), (-0.253, 0.253), (0.253, 0.842), (0.842, \infty).$$

We obtain the following table:

	$N_i$	$np_i^0$
$-\infty < x < -0.842$	15	10
$-0.842 < x < -0.253$	10	10
$-0.253 < x < 0.253$	7	10
$0.253 < x < 0.842$	12	10
$0.842 < x < \infty$	6	10

The calculated value of  $Q$  is 5.4. If  $Q$  has a  $\chi^2$  distribution with 4 degrees of freedom, then  $\Pr(Q \geq 5.4) = 0.25$ .

- (b) The ten intervals, each of which has probability 0.1, are as given in the following table:

	$N_i$	$np_i^0$
$-\infty < x < -1.282$	8	5
$-1.282 < x < -0.842$	7	5
$-0.842 < x < -0.524$	3	5
$-0.524 < x < -0.253$	7	5
$-0.253 < x < 0$	5	5
$0 < x < 0.253$	2	5
$0.253 < x < 0.524$	5	5
$0.524 < x < 0.842$	7	5
$0.842 < x < 1.282$	2	5
$1.282 < x < \infty$	4	5

The calculated value of  $Q$  is 8.8. If  $Q$  has the  $\chi^2$  distribution with 9 degrees of freedom, then the value of  $\Pr(Q \geq 8.8)$  is between 0.4 and 0.5.

## 10.2 Goodness-of-Fit for Composite Hypotheses

### Commentary

The maximization of the log-likelihood in Eq. (10.2.5) could be performed numerically if one had appropriate software. The *R* functions `optim` and `nls` can be used as described in the Commentary to Sec. 7.6 in this manual.

**Solutions to Exercises.**

1. There are many ways to perform a  $\chi^2$  test. For example, we could divide the real numbers into the intervals  $(-\infty, 15]$ ,  $(15, 30]$ ,  $(30, 45]$ ,  $(45, 60]$ ,  $(60, 75]$ ,  $(75, 90]$ ,  $(90, \infty)$ . The numbers of observations in these intervals are 14, 14, 4, 4, 3, 0, 2
  - (a) The M.L.E.'s of the parameters of a normal distribution are  $\hat{\mu} = 30.05$  and  $\hat{\sigma}^2 = 537.51$ . Using the method of Chernoff and Lehmann, we compute two different  $p$ -values with 6 and 4 degrees of freedom. The probabilities for the seven intervals are 0.2581, 0.2410, 0.2413, 0.1613, 0.0719, 0.0214, 0.0049. The expected counts are 41 times each of these numbers. This makes  $Q = 24.53$ . The two  $p$ -values are both smaller than 0.0005.
  - (b) The M.L.E.'s of the parameters of a lognormal distribution are  $\hat{\mu} = 3.153$  and  $\hat{\sigma}^2 = 0.48111$ . Using the method of Chernoff and Lehmann, we compute two different  $p$ -values with 6 and 4 degrees of freedom. The probabilities for the seven intervals are 0.2606, 0.3791, 0.1872, 0.0856, 0.0407, 0.0205, 0.0261. The expected counts are 41 times each of these numbers. This makes  $Q = 5.714$ . The two  $p$ -values are both larger than 0.2.
2. First, we must find the M.L.E. of  $\Theta$ . From Eq. (10.2.5), ignoring the multinomial coefficient,

$$L(\theta) = \prod_{i=0}^4 p_i^{N_i} = C\theta^{N_1+2N_2+3N_3+4N_4}(1-\theta)^{4N_0+3N_1+2N_2+N_3}, \text{ where } C = 4^{N_1}6^{N_2}4^{N_3}.$$

Therefore,

$$\log L(\theta) = \log C + (N_1 + 2N_2 + 3N_3 + 4N_4) \log \theta + (4N_0 + 3N_1 + 2N_2 + N_3) \log(1 - \theta).$$

By solving the equation  $\partial \log L(\theta) / \partial \theta = 0$ , we obtain the result

$$\hat{\Theta} = \frac{N_1 + 2N_2 + 3N_3 + 4N_4}{4(N_0 + N_1 + N_2 + N_3 + N_4)} = \frac{N_1 + 2N_2 + 3N_3 + 4N_4}{4n}.$$

It is found that  $\hat{\Theta} = 0.4$ . Therefore, we obtain the following table:

No. of Games	$N_i$	$N\pi_i(\hat{\Theta})$
0	33	25.92
1	67	69.12
2	66	69.12
3	15	30.72
4	19	5.12

It is found from Eq. (10.2.4) that  $Q = 47.81$ . If  $Q$  has a  $\chi^2$  distribution with  $5 - 1 - 1 = 3$  degrees of freedom, then  $\Pr(Q \geq 47.81)$  is less than 0.005.

3. (a) It follows from Eqs. (10.2.2) and (10.2.6) that (aside from the multinomial coefficient)

$$\begin{aligned} \log L(\theta) &= (N_4 + N_5 + N_6) \log 2 + (2N_1 + N_4 + N_5) \log \theta_1 + (2N_2 + N_4 + N_6) \log \theta_2 \\ &\quad + (2N_3 + N_5 + N_6) \log(1 - \theta_1 - \theta_2). \end{aligned}$$

By solving the equations

$$\frac{\partial \log L(\theta)}{\partial \theta_1} = 0 \quad \text{and} \quad \frac{\partial \log L(\theta)}{\partial \theta_2} = 0,$$

we obtain the results

$$\hat{\Theta}_1 = \frac{2N_1 + N_4 + N_5}{2n} \quad \text{and} \quad \hat{\Theta}_2 = \frac{2N_2 + N_4 + N_6}{2n},$$

where  $n = \sum_{i=1}^6 N_i$ .

- (b) For the given values,  $n = 150$ ,  $\hat{\Theta}_1 = 0.2$ , and  $\hat{\Theta}_2 = 0.5$ . Therefore, we obtain the following table:

$i$	$N_i$	$n\pi_i(\hat{\Theta})$
1	2	6
2	36	37.5
3	14	13.5
4	36	30
5	20	18
6	42	45

It is found from Eq. (10.2.4) that  $Q = 4.37$ . If  $Q$  has the  $\chi^2$  distribution with  $6 - 1 - 2 = 3$  degrees of freedom, then the value of  $\Pr(Q \geq 4.37)$  is approximately 0.226.

4. Suppose that  $X$  has the normal distribution with mean 67.6 and variance 1, and that  $Z$  has the standard normal distribution. Then:

$$\begin{aligned}\pi_1(\hat{\Theta}) &= \Pr(X < 66) = \Pr(Z < -1.6) = 0.0548, \\ \pi_2(\hat{\Theta}) &= \Pr(66 < X < 67.5) = \Pr(-1.6 < Z < -0.1) = 0.4054, \\ \pi_3(\hat{\Theta}) &= \Pr(67.5 < \bar{X} < 68.5) = \Pr(-0.1 < Z < 0.9) = 0.3557, \\ \pi_4(\hat{\Theta}) &= \Pr(68.5 < X < 70) = \Pr(0.9 < Z < 2.4) = 0.1759, \\ \pi_5(\hat{\Theta}) &= \Pr(X > 70) = \Pr(Z > 2.4) = 0.0082.\end{aligned}$$

Therefore, we obtain the following table:

$i$	$N_i$	$n\pi_i(\hat{\Theta})$
1	18	27.4
2	177	202.7
3	198	177.85
4	102	87.95
5	5	4.1

The value of  $Q$  is found from Eq. (10.2.4) to be 11.2. Since  $\mu$  and  $\sigma^2$  are estimated from the original observations rather than from the grouped data, the approximate distribution of  $Q$  when  $H_0$  is true lies between the  $\chi^2$  distribution with 2 degrees of freedom and a  $\chi^2$  distribution with 4 degrees of freedom.

5. From the given observations, it is found that the M.L.E. of the mean  $\Theta$  of the Poisson distribution is  $\hat{\Theta} = \bar{X}_n = 1.5$ . From the table of the Poisson distribution with  $\Theta = 1.5$ , we can obtain the values of  $\pi_i(\hat{\Theta})$ . In turn, we can then obtain the following table:

No. of tickets	$N_i$	$n\pi_i(\hat{\Theta})$
0	52	44.62
1	60	66.94
2	55	50.20
3	18	25.10
4	8	9.42
5 or more	7	3.70

It is found from Eq. (10.2.4) that  $Q = 7.56$ . Since  $\hat{\Theta}$  is calculated from the original observations rather than from the grouped data, the approximate distribution of  $Q$  when  $H_0$  is true lies between the  $\chi^2$  distribution with 4 degrees of freedom and the  $\chi^2$  distribution with 5 degrees of freedom. The two  $p$ -values for 4 and 5 degrees of freedom are 0.1091 and 0.1822.

6. The value of  $\hat{\Theta} = \bar{X}_n$  can be found explicitly from the given data, and it equals 3.872. However, before carrying out the  $\chi^2$  test, the observations in the bottom few rows of the table should be grouped together to obtain a single cell in which the expected number of observations is not too small. Reasonable choices would be to consider a single cell for the periods in which 11 or more particles were emitted (there would be 6 observations in that cell) or to consider a single cell for the periods in which 10 or more particles were emitted (there would be 16 observations in that cell). If the total number of cells after this grouping has been made is  $k$ , then under  $H_0$  the statistic  $Q$  will have a distribution which lies between the  $\chi^2$  distribution with  $k - 2$  degrees of freedom and the  $\chi^2$  distribution with  $k - 1$  degrees of freedom. For example, with  $k = 12$ , the expected cell counts are

$$54.3, 210.3, 407.1, 525.3, 508.4, 393.7, 254.0, 140.5, 68.0, 29.2, 11.3, 5.8$$

The statistic  $Q$  is then 12.96. The two  $p$ -values for 10 and 11 degrees of freedom are 0.2258 and 0.2959.

7. There is no single correct answer to this problem. The M.L.E.'s  $\hat{\mu} = \bar{X}_n$  and  $\hat{\sigma}^2 = S_n^2/n$  should be calculated from the given observations. These observations should then be grouped into intervals and the observed number in each interval compared with the expected number in that interval if each of the 50 observations had the normal distribution with mean  $\bar{X}_n$  and variance  $S_n^2/n$ . If the number of intervals is  $k$ , then when  $H_0$  is true, the approximate distribution of the statistic  $Q$  will lie between the  $\chi^2$  distribution with  $k - 3$  degrees of freedom and the  $\chi^2$  distribution with  $k - 1$  degrees of freedom.
8. There is no single correct answer to this problem. The M.L.E.  $\hat{\beta} = 1/\bar{X}_n$  of the parameter of the exponential distribution should be calculated from the given observations. These observations should then be grouped into intervals and the observed number in each interval compared with the expected number in that interval if each of the 50 observations had an exponential distribution with parameter  $1/\bar{X}_n$ . If the number of intervals is  $k$ , then when  $H_0$  is true, the approximate distribution of the statistic  $Q$  will lie between a  $\chi^2$  distribution with  $k - 2$  degrees of freedom and the  $\chi^2$  distribution with  $k - 1$  degrees of freedom.

### 10.3 Contingency Tables

#### Solutions to Exercises.

1. Table S.10.1 contains the expected counts for this example. The value of the  $\chi^2$  statistic  $Q$  calculated

Table S.10.1: Expected cell counts for Exercise 1 of Sec. 10.3.

	Good grades	Athletic ability	Popularity
Boys	117.3	42.7	67.0
Girls	129.7	47.3	74.0

from these data is  $Q = 21.5$ . This should be compared to the  $\chi^2$  distribution with two degrees of freedom. The tail area can be calculated using statistical software as  $2.2 \times 10^{-5}$ .

$$\begin{aligned}
2. \quad Q &= \sum_{i=1}^R \sum_{j=1}^C \frac{(N_{ij} - \hat{E}_{ij})^2}{\hat{E}_{ij}} = \sum_{i=1}^R \sum_{j=1}^C \left( \frac{N_{ij}^2}{\hat{E}_{ij}} - 2N_{ij} + \hat{E}_{ij} \right) = \left( \sum_{i=1}^R \sum_{j=1}^C \frac{N_{ij}^2}{\hat{E}_{ij}} \right) - 2n + n \\
&= \left( \sum_{i=1}^R \sum_{j=1}^C \frac{N_{ij}^2}{\hat{E}_{ij}} \right) - n.
\end{aligned}$$

3. By Exercise 2,

$$Q = \sum_{i=1}^R \frac{N_{i1}^2}{\hat{E}_{i1}} + \sum_{i=1}^R \frac{N_{i2}^2}{\hat{E}_{i2}} - n.$$

But

$$\sum_{i=1}^R \frac{N_{i2}^2}{\hat{E}_{i2}} = \sum_{i=1}^R \frac{(N_{i+} - N_{i1})^2}{\hat{E}_{i2}} = \sum_{i=1}^R \frac{N_{i+}^2}{\hat{E}_{i2}} - 2 \sum_{i=1}^R \frac{N_{i+} N_{i1}}{\hat{E}_{i2}} + \sum_{i=1}^R \frac{N_{i1}^2}{\hat{E}_{i2}}.$$

In the first two sums on the right, we let  $\hat{E}_{i2} = N_{i+} N_{+2}/n$ , and in the third sum we let  $\hat{E}_{i2} = N_{+2} \hat{E}_{i1}/N_{+1}$ . We then obtain

$$\sum_{i=1}^R \frac{N_{i2}^2}{\hat{E}_{i2}} = \frac{n}{N_{+2}} \sum_{i=1}^R N_{i+} - \frac{2n}{N_{+2}} \sum_{i=1}^R N_{i1} + \frac{N_{+1}}{N_{+2}} \sum_{i=1}^R \frac{N_{i1}^2}{\hat{E}_{i1}} = \frac{n^2}{N_{+2}} - 2n \frac{N_{+1}}{N_{+2}} + \frac{N_{+1}}{N_{+2}} \sum_{i=1}^R \frac{N_{i1}^2}{\hat{E}_{i1}}.$$

It follows that

$$Q = \left( 1 + \frac{N_{+1}}{N_{+2}} \right) \sum_{i=1}^R \frac{N_{i1}^2}{\hat{E}_{i1}} + \frac{n}{N_{+2}} (n - 2N_{+1} - N_{+2}).$$

Since  $n = N_{+1} + N_{+2}$ ,

$$Q = \frac{n}{N_{+2}} \sum_{i=1}^R \frac{N_{i1}^2}{\hat{E}_{i1}} - \frac{n}{N_{+2}} N_{+1}.$$

4. The values of  $\hat{E}_{ij}$  are as given in the following table:

8	32
12	48

The value of  $Q$  is found from Eq. (10.3.4) to be 25/6. If  $Q$  has a  $\chi^2$  distribution with 1 degree of freedom, then  $\Pr(Q \geq 25/6)$  lies between 0.025 and 0.05.

5. The values of  $\hat{E}_{ij}$  are as given in the following table.

77.27	94.35	49.61	22.77
17.73	21.65	11.39	5.23

The value of  $Q$  is found from Eq. (10.3.4) to be 8.6. If  $Q$  has the  $\chi^2$  distribution with  $(2-1)(4-1) = 3$  degrees of freedom, then  $\Pr(Q \geq 8.6)$  lies between 0.025 and 0.05.

6. The values of  $\hat{E}_{ij}$  are as given in the following table:

$$\begin{array}{cc} \hline & 7.5 \quad 7.5 \\ \hline 14.5 & \quad 14.5 \\ \hline \end{array}$$

The value of  $Q$  is found from Eq. (10.3.4) to be 0.91. If  $Q$  has the  $\chi^2$  distribution with 1 degree of freedom, then  $\Pr(Q \geq 0.91)$  lies between 0.3 and 0.4.

7. (a) The values of  $p_{i+}$  and  $p_{+j}$  are the marginal totals given in the following table:

			0.3
			0.3
			0.4
0.5	0.3	0.2	1.0

It can be verified that  $p_{ij} = p_i + p_j$  for each of the 9 entries in the table. It can be seen in advance that this relation will be satisfied for every entry in the table because it can be seen that the three rows of the table are proportional to each other or, equivalently, that the three columns are proportional to each other.

- (b) Here is one example of a simulated data set

44	32	16	92
45	25	15	85
63	33	27	123
152	90	58	300

- (c) The statistic  $Q$  calculated by any student from Eq. (10.3.4) will have the  $\chi^2$  distribution with  $(3 - 1)(3 - 1) = 4$  degrees of freedom. For the data in part (b), the table of  $\hat{E}_{ij}$  values is

46.6	27.6	17.8
43.1	25.5	16.4
62.3	36.9	23.8

The value of  $Q$  is then 2.105. The  $p$ -value 0.7165.

- To test whether the values obtained by  $n$  different students form a random sample of size  $n$  from a  $\chi^2$  distribution with 4 degrees of freedom, follow these steps: (1) Partition the positive part of the real line into  $k$  intervals; (2) Determine the probabilities  $p_1^0, \dots, p_k^0$  of these intervals for the  $\chi^2$  distribution with 4 degrees of freedom; (3) Calculate the value of the statistic  $Q$  given by Eq. (10.1.2). If the hypothesis  $H_0$  is true, this statistic  $Q$  will have approximately the  $\chi^2$  distribution with  $k - 1$  degrees of freedom.
  - Let  $N_{ijk}$  denote the number of observations in the random sample that fall into the  $(i, j, k)$  cell, and let

$$\begin{aligned} N_{i++} &= \sum_{j=1}^C \sum_{k=1}^T N_{ijk}, N_{+j+} = \sum_{i=1}^R \sum_{k=1}^T N_{ijk}, \\ N_{++k} &= \sum_{i=1}^R \sum_{j=1}^C N_{ijk}. \end{aligned}$$

Then the M.L.E.'s are

$$\hat{p}_{i++} = \frac{N_{i++}}{n}, \hat{p}_{+j+} = \frac{N_{+j+}}{n}, \hat{p}_{++k} = \frac{N_{++k}}{n}.$$

Therefore, when  $H_0$  is true,

$$\hat{E}_{ijk} = n\hat{p}_{i++}\hat{p}_{+j+}\hat{p}_{++k} = \frac{N_{i++}N_{+j+}N_{++k}}{n^2}.$$

Since  $\sum_{i=1}^R \hat{p}_{i++} = \sum_{j=1}^C \hat{p}_{+j+} = \sum_{k=1}^T \hat{p}_{++k} = 1$ , the number of parameters that have been estimated is  $(R-1) + (C-1) + (T-1) = R+C+T-3$ . Therefore, when  $H_0$  is true, the approximate distribution of

$$Q = \sum_{i=1}^R \sum_{j=1}^C \sum_{k=1}^T \frac{(N_{ijk} - \hat{E}_{ijk})^2}{\hat{E}_{ijk}}$$

will be the  $\chi^2$  distribution for which the number of degrees of freedom is  $RCT - 1 - (R+C+T-3) = RCT - R - C - T + 2$ .

10. The M.L.E.'s are

$$\hat{p}_{ij+} = \frac{N_{ij+}}{n} \quad \text{and} \quad \hat{p}_{++k} = \frac{N_{++k}}{n}.$$

Therefore, when  $H_0$  is true,

$$\hat{E}_{ijk} = n\hat{p}_{ij+}\hat{p}_{++k} = \frac{N_{ij+}N_{++k}}{n}.$$

Since  $\sum_{i=1}^R \sum_{j=1}^C \hat{p}_{ij+} = \sum_{k=1}^T \hat{p}_{++k} = 1$ , the number of parameters that have been estimated is  $(RC-1) + (T-1) = RC + T - 2$ . Therefore, when  $H_0$  is true, the approximate distribution of

$$Q = \sum_{i=1}^R \sum_{j=1}^C \sum_{k=1}^T \frac{(N_{ijk} - \hat{E}_{ijk})^2}{\hat{E}_{ijk}}.$$

will be the  $\chi^2$  distribution for which the number of degrees of freedom is  $RCT - 1 - (RC + T - 2) = RCT - RC - T + 1$ .

## 10.4 Tests of Homogeneity

### Solutions to Exercises.

- Table S.10.2 contains the expected cell counts. The value of the  $\chi^2$  statistic is  $Q = 18.8$ , which should

Table S.10.2: Expected cell counts for Exercise 1 of Sec. 10.4.

	Good grades	Athletic ability	Popularity
Rural	77.0	28.0	44.0
Suburban	78.0	28.4	44.5
Urban	92.0	33.5	52.5

be compared to the  $\chi^2$  distribution with four degrees of freedom. The tail area is  $8.5 \times 10^{-4}$ .

2. The value of the statistic  $Q$  given by Eqs. (10.4.3) and (10.4.4) is 7.57. If  $Q$  has a  $\chi^2$  distribution with  $(2 - 1)(3 - 1) = 2$  degrees of freedom, then  $\Pr(Q \geq 7.57) < 0.025$ .
3. The value of the statistic  $Q$  given by Eqs. (10.4.3) and (10.4.4) is 18.9. If  $Q$  has the  $\chi^2$  distribution with  $(4 - 1)(5 - 1) = 12$  degrees of freedom, then the value of  $\Pr(Q \geq 18.9)$  lies between 0.1 and 0.05.
4. The table to be analyzed is as follows:

Person	Hits	Misses
1	8	9
2	4	12
3	7	3
4	13	11
5	10	6

The value of the statistic  $Q$  given by Eqs. (10.4.3) and (10.4.4) is 6.8. If  $Q$  has the  $\chi^2$  distribution with  $(5 - 1)(2 - 1) = 4$  degrees of freedom, then the value of  $\Pr(Q \geq 6.8)$  lies between 0.1 and 0.2.

5. The correct table to be analyzed is as follows:

Supplier	Defectives	Nondefectives
1	1	14
2	7	8
3	7	8

The value of  $Q$  found from this table is 7.2. If  $Q$  has the  $\chi^2$  distribution with  $(3 - 1)(2 - 1) = 2$  degrees of freedom, then  $\Pr(Q \geq 7.2) < 0.05$ .

6. The proper table to be analyzed is as follows:

		After demonstration	
		Hit	Miss
Before demonstration	Hit		27
	Miss		73
		35	65

Although we are given the marginal totals, we are not given the entries in the table. If we were told the value in just a single cell, such as the number of students who hit the target both before and after the demonstration, we could fill in the rest of the table.

7. The proper table to be analyzed is as follows:

		After meeting		
		Favors A	Favors B	No preference
Before meeting	Favors A			
	Favors B			
	No preference			

Each person who attended the meeting can be classified in one of the nine cells of this table. If a speech was made on behalf of  $A$  at the meeting, we could evaluate the effectiveness of the speech by comparing the numbers of persons who switched from favoring  $B$  or having no preference before the meeting to favoring  $A$  after the meeting with the number who switched from favoring  $A$  before the meeting to one of the other positions after the meeting.

## 10.5 Simpson's Paradox

### Solutions to Exercises

- If population II has a relatively high proportion of men and population I has a relatively high proportion of women, then the indicated result will occur. For example, if 90 percent of population II are men and 10 percent are women, then the proportion of population II with the characteristic will be  $(.9)(.6) + (.1)(.1) = .55$ . If 10 percent of population I are men and 90 percent are women, then the proportion of population I with the characteristic will be only  $(.1)(.8) + (.9)(.3) = .35$ .
- Each of these equalities holds if and only if  $A$  and  $B$  are independent events.
- Assume that  $\Pr(B|A) = \Pr(B|A^c)$ . This means that  $A$  and  $B$  are independent. According to the law of total probability, we can write

$$\begin{aligned}\Pr(I|B) &= \Pr(I|A \cap B)\Pr(A|B) + \Pr(I|A^c \cap B)\Pr(A^c|B) \\ &= \Pr(I|A \cap B)\Pr(A) + \Pr(I|A^c \cap B)\Pr(A^c),\end{aligned}$$

where the last equality follows from the fact that  $A$  and  $B$  are independent. Similarly,

$$\Pr(I|B^c) = \Pr(I|A \cap B^c)\Pr(A) + \Pr(I|A^c \cap B^c)\Pr(A^c).$$

If the first two inequalities in (10.5.1) hold then the weighted average of the left sides of the inequalities must be larger than the same weighted average of the right sides. In particular,

$$\Pr(I|A \cap B)\Pr(A) + \Pr(I|A^c \cap B)\Pr(A^c) > \Pr(I|A \cap B^c)\Pr(A) + \Pr(I|A^c \cap B^c)\Pr(A^c).$$

But, we have just shown that this last equality is equivalent to  $\Pr(I|B) > \Pr(I|B^c)$ , which means that the third inequality cannot hold if the first two hold.

- Define  $A$  to be the event if that a subject is a man,  $A^c$  the event that a subject is a woman,  $B$  the event that a subject receives treatment I, and  $B^c$  the event that a subject receives treatment II. Then the relation to be proved here is precisely the same as the relation that was proved in Exercise 2 in symbols.
- Suppose that the first two inequalities in (10.5.1) hold, and that  $\Pr(A|B) = \Pr(A|B^c)$ , Then

$$\begin{aligned}\Pr(I|B) &= \Pr(I|A \cap B)\Pr(A|B) + \Pr(I|A^c \cap B)\Pr(A^c|B) \\ &> \Pr(I|A \cap B^c)\Pr(A|B) + \Pr(I|A^c \cap B^c)\Pr(A^c|B) \\ &= \Pr(I|A \cap B^c)\Pr(A|B^c) + \Pr(I|A^c \cap B^c)\Pr(A^c|B^c) \\ &= \Pr(I|B^c).\end{aligned}$$

Hence, the final inequality in (10.5.1) must be reversed.

- This result can be obtained if the colleges that admit a relatively small proportion of their applicants receive a relatively large proportion of female applicants and the colleges that admit a relatively large proportion of their applicants receive a relatively small proportion of female applicants. As a specific example, suppose that the data are as given in the following table:

College	Proportion of total University applicants	Proportion male	Proportion female	Proportion of males admitted	Proportion of females admitted
1	.1	.9	.1	.32	.56
2	.1	.9	.1	.32	.56
3	.2	.8	.2	.32	.56
4	.2	.8	.2	.32	.56
5	.4	.1	.9	.05	.10

This table indicates, for example, that College 1 receives 10 percent of all the applications submitted to the university, that 90 percent of the applicants to College 1 are male and 10 percent are female, that 32 percent of the male applicants to College 1 are admitted, and that 56 percent of the female applicants are admitted. It can be seen from the last two columns of this table that in each college the proportion of females admitted is larger than the proportion of males admitted. However, in the whole university, the proportion of males admitted is

$$\frac{(.1)(.9)(.32) + (.1)(.9)(.32) + (.2)(.8)(.32) + (.2)(.8)(.32) + (.4)(.1)(.05)}{(.1)(.9) + (.1)(.9) + (.2)(.8) + (.2)(.8) + (.4)(.1)} = .3$$

and the proportion of females admitted is

$$\frac{(.1)(.1)(.56) + (.1)(.1)(.56) + (.2)(.2)(.56) + (.2)(.2)(.56) + (.4)(.9)(.10)}{(.1)(.1) + (.1)(.1) + (.2)(.2) + (.2)(.2) + (.4)(.9)} = .2.$$

7. (a) Table S.10.3 shows the proportions helped by each treatment in the four categories of subjects. The proportion helped by Treatment II is higher in each category.

Table S.10.3: Table for Exercise 7a in Sec. 10.5.

Category	Proportion helped	
	Treatment I	Treatment II
Older males	.200	.667
Younger males	.750	.800
Older females	.167	.286
Younger females	.500	.640

- (b) Table S.10.4 shows the proportions helped by each treatment in the two aggregated categories. Treatment I helps a larger proportion in each of the two categories

Table S.10.4: Table for Exercise 7b in Sec. 10.5.

Category	Proportion helped	
	Treatment I	Treatment II
Older subjects	.433	.400
Younger subjects	.700	.667

- (c) When all subjects are grouped together, the proportion helped by Treatment I is  $200/400 = 0.5$ , while the proportion helped by Treatment II is  $240/400 = 0.6$ .

## 10.6 Kolmogorov-Smirnov Tests

### Commentary

This section is optional. However, some of the topics discussed here are useful in Chapter 12. In particular, the bootstrap in Sec. 12.6 makes much use of the sample c.d.f. Some of the plots done after Markov chain Monte Carlo also make use of the sample c.d.f. The crucial material is at the start of Sec. 10.6. The Glivenko-Cantelli lemma, together with the asymptotic distribution of the Kolmogorov-Smirnov test statistic in Table 10.32 are useful if one simulates sample c.d.f.'s and wishes to compute simulation standard errors for the entire sample c.d.f.

Empirical c.d.f.'s can be computed by the *R* function `ecdf`. The argument is a vector of data values. The result is an *R* function that computes the empirical c.d.f. at its argument. For example, if `x` has a sample of observations, then `empd.x=ecdf(x)` will create a function `empd.x` which can be used to compute values of the empirical c.d.f. For example, `empd.x(3)` will be the proportion of the sample with values at most 3. Kolmogorov-Smirnov tests can be performed using the *R* function `ks.test`. The first argument is a vector of data values. The second argument depends on whether one is doing a one-sample or two-sample test. In the two-sample case, the second argument is the second sample. In the one-sample case, the second argument is the name of a function that will compute the hypothesized c.d.f. If that function has any additional arguments, they can be provided next or named explicitly later in the argument list.

### Solutions to Exercises.

1.  $F_n(x) = 0$  for  $x < y_1$ , and  $F_n(y_1) = 0.2$ . Suppose first that  $F(y_1) \geq 0.1$ . Since  $F$  is continuous, the values of  $F(x)$  will be arbitrarily close to  $F(y_1)$  for  $x$  arbitrarily close to  $y_1$ . Therefore,  $\sup_{x < y_1} |F_n(x) - F(x)| = F(y_1) - 0.1 \geq 0.1$ , and it follows that  $D_n \geq 0.1$ . Suppose next that  $F(y_1) \leq 0.1$ . Since  $F_n(y_1) = 0.2$ , it follows that  $|F_n(y_1) - F(y_1)| \geq 0.1$ . Therefore, it is again true that  $D_n \geq 0.1$ . We can now conclude that it must always be true that  $D_n \geq 0.1$ . If the values of  $F(y_i)$  are as specified in the second part of the exercise, for  $i = 1, \dots, 5$ , then:

$$|F_n(x) - F(x)| = \begin{cases} F(x) \leq 0.1 & \text{for } x < y_1, \\ 0.2 - 0.1 = 0.1 & \text{for } x = y_1, \\ |F(x) - 0.2| \leq 0.1 & \text{for } y_1 < x < y_2, \\ 0.4 - 0.3 = 0.1 & \text{for } x = y_2, \\ |F(x) - 0.4| \leq 0.1 & \text{for } y_2 < x < y_3, \\ \text{etc.} & \end{cases}$$

Hence,  $D_n = \sup_{-\infty < x < \infty} |F_n(x) - F(x)| = 0.1$ .

2.  $F_n(x) = \begin{cases} 0 & \text{for } x < y_1, \\ 0.2 & \text{for } y_1 \leq x < y_2, \\ 0.4 & \text{for } y_2 \leq x < y_3, \\ 0.6 & \text{for } y_3 \leq x < y_4, \\ 0.8 & \text{for } y_4 \leq x < y_5, \\ 1 & \text{for } x \geq y_5. \end{cases}$

If  $F$  satisfies the inequalities given in the exercise, then  $|F_n(x) - F(x)| \leq 0.2$  for every value of  $x$ . Hence,  $D_n \leq 0.2$ . Conversely, if  $F(y_i) > 0.2i$  for some value of  $i$ , then  $F(x) - F_n(x) > 0.2$  for values of  $x$  approaching  $y_i$  from below. Hence,  $D_n > 0.2$ . Also, if  $F(y_i) < 0.2(i-1)$  for some value of  $i$ , then  $F_n(y_i) - F(y_i) > 0.2$ . Hence, again  $D_n > 0.2$ .

3. The largest value of the difference between the sample c.d.f. and the c.d.f. of the normal distribution with mean 3.912 and variance 0.25 occurs right before  $x = 4.22$ , the 12th observation. For  $x$  just below 4.22, the sample c.d.f. is  $F_n(x) = 0.48$ , while the normal c.d.f. is  $\Phi([4.22 - 3.912]/0.5) = 0.73$ . The difference is  $D_n^* = 0.25$ . The Kolmogorov-Smirnov test statistic is  $23^{1/2} \times 0.25 = 1.2$ . The tail area can be found from Table 10.32 as 0.11.
4. When the observations are ordered, we obtain Table S.10.5. The maximum value of  $|F_n(x) - F(x)|$

Table S.10.5: Table for Exercise 4 in Sec. 10.6.

$i$	$y_i = F(y_i)$	$F_n(y_i)$	$i$	$y_i = F(y_i)$	$F_n(y_i)$
1	.01	.04	14	.41	.56
2	.06	.08	15	.42	.60
3	.08	.12	16	.48	.64
4	.09	.16	17	.57	.68
5	.11	.20	18	.66	.72
6	.16	.24	19	.71	.76
7	.22	.28	20	.75	.80
8	.23	.32	21	.78	.84
9	.29	.36	22	.79	.88
10	.30	.40	23	.82	.92
11	.35	.44	24	.88	.96
12	.38	.48	25	.90	1.00
13	.40	.52			

occurs at  $x = y_{15}$  where its value is  $0.60 - 0.42 = 0.18$ . Since  $n = 25$ ,  $n^{1/2}D_n^* = 0.90$ . From Table 10.32,  $H(0.90) = 0.6073$ . Therefore, the tail area corresponding to the observed value of  $D_n^*$  is  $1 - 0.6073 = 0.3927$ .

5. Here,

$$F(x) = \begin{cases} \frac{3}{2}x & \text{for } 0 < x \leq 1/2, \\ \frac{1}{2}(1+x) & \text{for } \frac{1}{2} < x < 1. \end{cases}$$

Therefore, we obtain Table S.10.6. The supremum of  $|F_n(x) - F(x)|$  occurs as  $x \rightarrow y_{18}$  from below.

Table S.10.6: Table for Exercise 5 in Sec. 10.6.

$i$	$y_i$	$F(y_i)$	$F_n(y_i)$	$i$	$y_i$	$F(y_i)$	$F_n(y_i)$
1	.01	.015	.04	14	.41	.615	.56
2	.06	.09	.08	15	.42	.63	.60
3	.08	.12	.12	16	.48	.72	.64
4	.09	.135	.16	17	.57	.785	.68
5	.11	.165	.20	18	.66	.83	.72
6	.16	.24	.24	19	.71	.855	.76
7	.22	.33	.28	20	.75	.875	.80
8	.23	.345	.32	21	.78	.89	.84
9	.29	.435	.36	22	.79	.895	.88
10	.30	.45	.40	23	.82	.91	.92
11	.35	.525	.44	24	.88	.94	.96
12	.38	.57	.48	25	.90	.95	1.00
13	.40	.60	.52				

Here,  $F(x) \rightarrow 0.83$  while  $F_n(x)$  remains at 0.68. Therefore,  $D_n^* = 0.83 - 0.68 = 0.15$ . It follows that

$n^{1/2}D_n^* = 0.75$  and, from Table 10.32,  $H(0.75) = 0.3728$ . Therefore, the tail area corresponding to the observed value of  $D_n^*$  is  $1 - 0.3728 = 0.6272$ .

6. Since the p.d.f. of the uniform distribution is identically equal to 1, the value of the joint p.d.f. of the 25 observations under the uniform distribution has the value  $L_1 = 1$ . Also, sixteen of the observations are less than  $1/2$  and nine are greater than  $1/2$ . Therefore, the value of the joint p.d.f. of the observations under the other distribution is  $L_2 = (3/2)^{16}(1/2)^9 = 1.2829$ . The posterior probability that the observations came from a uniform distribution is

$$\frac{\frac{1}{2}L_1}{\frac{1}{2}L_1 + \frac{1}{2}L_2} = 0.438$$

7. We first replace each observed value  $x_i$  by the value  $(x_i - 26)/2$ . Then, under the null hypothesis, the transformed values will form a random sample from a standard normal distribution. When these transformed values are ordered, we obtain Table S.10.7. The maximum value of  $|F_n(x) - \Phi(x)|$

Table S.10.7: Table for Exercise 7 in Sec. 10.6.

$i$	$y_i$	$\Phi(y_i)$	$F_n(y_i)$	$i$	$y_i$	$\Phi(y_i)$	$F_n(y_i)$

21	-0.3245	.3728	.42	46	$1/4$ 1.4615	.9281	.92
22	-0.309	.3787	.44	47	$1/4$ 1.6315	.9487	.94
23	-0.266	.3951	.46	48	$1/4$ 1.7925	.9635	.96
24	-0.078	.4689	.48	49	$1/4$ 1.889	.9705	.98
25	-0.0535	.4787	.50	50	$1/4$ 2.216	.9866	1.00

is attained at  $x = y_{23}$  and its value is 0.0649. Since  $n = 50$ ,  $n^{1/2}D_n^* = 0.453$ . It follows from Table 10.32 that  $H(0.453) = 0.02$ . Therefore, the tail area corresponding to the observed value of  $D_n^*$  is  $1 - 0.02 = 0.98$ .

8. We first replace each observed value  $x_i$  by the value  $(x_i - 24)/2$ . Then, under the null hypothesis, the transformed values will form a random sample from a standard normal distribution. Each of the transformed values will be one unit larger than the corresponding transformed value in Exercise 7. The ordered values are therefore omitted from the tabulation in Table S.10.8. The supremum of  $|F_n(x) - \Phi(x)|$  occurs as  $x \rightarrow y_{18}$  from below. Here,  $\Phi(x) \rightarrow 0.7068$  while  $F_n(x)$  remains at 0.34.

Table S.10.8: Table for Exercise 8 in Sec. 10.6.

$i$	$\Phi(y_i)$	$F_n(y_i)$	$i$	$\Phi(y_i)$	$F_n(y_i)$
1	.1130	.02	26	.8389	.52
2	.1779	.04	27	.8408	.54
3	.3114	.06	28	.8437	.56
4	.3710	.08	29	.8752	.58

6	.4174	.12	31	.8997	.62
7	.4209	.14	32	.9045	.64
8	.4502	.16	33	.9189	.66
9	.4691	.18	34	.9193	.68
10	.4793	.20	35	.9229	.70
11	.5136	.22	36	.9309	.72
12	.5630	.24	37	.9467	.74
13	.5856	.26	38	.9544	.76
14	.5921	.28	39	.9570	.78
15	.6263	.30	40	.9579	.80
16	.6449	.32	41	.9751	.82
17	.6743	.34	42	.9805	.84
18	.7068	.36	43	.9830	.86
19	.7178	.38	44	.9852	.88
20	.7454	.40	45	.9875	.90
21	.7503	.42	46	.9931	.92
22	.7552	.44	47	.9958	.94
23	.7685	.46	48	.9974	.96
24	.8217	.48	49	.9980	.98
25	.8280	.50	50	.9993	1.00

Therefore,  $D_n^* = 0.7068 - 0.34 = 0.3668$ . It follows that  $n^{1/2}D_n^* = 2.593$  and, from Table 10.32,  $H(2.593) = 1.0000$ . Therefore, the tail area corresponding to the observed value of  $D_n^*$  is 0.0000.

9. We shall denote the 25 ordered observations in the first sample by  $x_1 < \dots < x_{25}$  and shall denote the 20 ordered observations in the second sample by  $y_1 < \dots < y_{20}$ . We obtain Table S.10.9. The maximum value of  $|F_m(x) - G_n(x)|$  is attained at  $x = -0.39$ , where its value is  $0.32 - 0.05 = 0.27$ . Therefore,  $D_{mn} = 0.27$  and, since  $m = 25$  and  $n = 20$ ,  $(mn/[m+n])^{1/2} D_{mn} = 0.9$ . From Table 10.32,  $H(0.9) = 0.6073$ . Hence, the tail area corresponding to the observed value of  $D_{mn}$  is  $1 - 0.6073 = 0.3927$ .
10. We shall add 2 units to each of the values in the first sample and then carry out the same procedure as in Exercise 9. We now obtain Table S.10.10. The maximum value of  $|F_m(x) - G_n(x)|$  is attained at  $x = 1.56$ , where its value is  $0.80 - 0.24 = 0.56$ . Therefore,  $D_{mn} = 0.56$  and  $(mn/[m+n])^{1/2} D_{mn} = 1.8667$ . From Table 10.32,  $H(1.8667) = 0.998$ . Therefore, the tail area corresponding to the observed value of  $D_{mn}$  is  $1 - 0.998 = 0.002$ .
11. We shall multiply each of the observations in the second sample by 3 and then carry out the same procedure as in Exercise 9. We now obtain Table S.10.11. The maximum value of  $|F_m(x) - G_n(x)|$  is attained at  $x = 1.06$ , where its value is  $0.80 - 0.30 = 0.50$ . Therefore,  $D_{mn} = 0.50$  and  $(mn/[m+n])^{1/2} D_{mn} = 1.667$ . From Table 10.32,  $H(1.667) = 0.992$ . Therefore, the tail area corresponding to the observed value of  $D_{mn}$  is  $1 - 0.992 = 0.008$ .
12. The maximum difference between the c.d.f. of the normal distribution with mean 3.912 and variance 0.25 and the empirical c.d.f. of the observed data is  $D_n^* = 0.2528$  which occurs at the observation 4.22 where the empirical c.d.f. jumps from  $11/23 = 0.4783$  to  $12/23 = 0.5217$  and the normal c.d.f. equals  $\Phi([4.22 - 3.912]/0.5) = 0.7311$ . We now compare  $(23)^{1/2} D_n^* = 1.2123$  to Table 10.32, where we find that  $H(1.2123) \approx 0.89$ . The tail area ( $p$ -value) is then about 0.11.

## 10.7 Robust Estimation

### Commentary

In recent years, interest has grown in the use of robust statistical methods. Although many robust methods are more suitable for advanced courses, this section introduces some robust methods that can be understood at the level of the rest of this text. This includes  $M$ -estimators of a location parameter.

The software  $R$  contains some functions that can be used for robust estimation. The function `quantile` computes sample quantiles. The first argument is a vector of observed values. The second argument is a vector of probabilities for the desired quantiles. For example `quantile(x, c(0.25, 0.75))` computes the sample quartiles of the data  $x$ . The function `median` computes the sample median. The function `mad` computes the median absolute deviation of a sample. If you issue the command `library(MASS)`, some additional functions become available. One such function is `huber`, which computes  $M$ -estimators as on page 673 with  $\hat{\sigma}$  equal to the median absolute deviation. The first argument is the vector of data values, and the second argument is  $k$ , in the notation of the text. To find the  $M$ -estimator with a general  $\hat{\sigma}$ , replace the second argument by  $k\hat{\sigma}$  divided by the mean absolute deviation of the data.

### Solutions to Exercises.

1. The observed values ordered from smallest to largest are 2.1, 2.2, 21.3, 21.5, 21.7, 21.7, 21.8, 22.1, 22.1, 22.2, 22.4, 22.5, 22.9, 23.0, 63.0.

- (a) The sample mean is the average of the numbers, 22.17.
- (b) The trimmed mean for a given value of  $k$  is found by dropping  $k$  values from each end of this ordered sequence and averaging the remaining values. In this problem we get

$k$	1	2	3	4
kth level trimmed mean	20.57	22.02	22	22

- (c) The sample median is the middle observation, 22.1.
  - (d) The median absolute deviation is 0.4. Suppose that we start iterating with the sample average 22.17. The 7th and 8th iterations are both 22.
2. The observed values ordered from smallest to largest are  $-2.40, -2.00, -0.11, 0.00, 0.03, 0.10, 0.12, 0.23, 0.24, 0.24, 0.36, 0.69, 1.24, 1.78$ .

- (a) The sample mean is the average of these values, 0.0371.
- (b) The trimmed mean for a given value of  $k$  is found by dropping  $k$  values from each end of this ordered sequence and averaging the remaining values. In this problem we get

$k$	1	2	3	4
kth level trimmed mean	0.095	0.19	0.165	0.16

- (c) Since the number of observed values is even, the sample median is the average of the two middle values 0.12 and 0.23, which equals 0.175.
  - (d) The median absolute deviation is 0.18. Suppose that we start iterating with the sample average 0.0371. The 9th and 10th iterations are both 0.165.
3. The distribution of  $\tilde{\theta}_{.5,n}$  will be approximately normal with mean  $\theta$  and standard deviation  $1/[2n^{1/2}f(\theta)]$ . In this exercise,

$$f(x) = \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{1}{2}(x-\theta)^2\right].$$

Hence,  $f(\theta) = 1/\sqrt{2\pi}$ . Since  $n = 100$ , the standard deviation of the approximate distribution of  $\tilde{\theta}_{.5,n}$  is  $\sqrt{2\pi}/20 = 0.1253$ . It follows that the distribution of  $Z = (\tilde{\theta}_{.5,n} - \theta)/0.1253$  will be approximately standard normal. Thus,

$$\Pr(|\tilde{\theta}_{.5,n} - \theta| \leq 0.1) = \Pr\left(|Z| \leq \frac{0.1}{0.1253}\right) = \Pr(|Z| \leq 0.798) = 2\Phi(0.798) - 1 = 0.575.$$

4. Here,

$$f(x) = \frac{1}{\pi[1 + (x - \theta)^2]}$$

Therefore,  $f(\theta) = 1/\pi$  and, since  $n = 100$ , it follows that the distribution of  $\tilde{\theta}_{.5,n}$  will be approximately normal with mean  $\theta$  and standard deviation  $\pi/20 = 0.1571$ . Thus, the distribution of  $Z = (\tilde{\theta}_{.5,n} - \theta)/0.1571$  will be approximately standard normal. Hence,

$$\Pr(|\tilde{\theta}_{.5,n} - \theta| \leq 0.1) = \Pr\left(|Z| \leq \frac{0.1}{0.1571}\right) = \Pr(|Z| \leq 0.637) = 2\Phi(0.637) - 1 = 0.476.$$

5. Let the first density on the right side of Eq. (10.7.1) be called  $h$ . Since both  $h$  and  $g$  are symmetric with respect to  $\mu$ , so also is  $f(x)$ . Therefore, both the sample mean  $\bar{X}_n$  and the sample median  $\tilde{X}_n$  are unbiased estimators of  $\mu$ . It follows that the M.S.E. of  $\bar{X}_n$  is equal to  $\text{Var}(\bar{X}_n)$  and that the M.S.E. of  $\tilde{X}_n$  is equal to  $\text{Var}(\tilde{X}_n)$ . The variance of a single observation  $X$  is

$$\begin{aligned}\text{Var}(X) &= \int_{-\infty}^{\infty} (x - \mu)^2 f(x) dx \\ &= \frac{1}{2} \int_{-\infty}^{\infty} (x - \mu)^2 h(x) dx + \frac{1}{2} \int_{-\infty}^{\infty} (x - \mu)^2 g(x) dx \\ &= \frac{1}{2} (1) + \frac{1}{2} (4) = \frac{5}{2}.\end{aligned}$$

Since  $n = 100$ ,  $\text{Var}(\bar{X}_n) = (1/100)(5/2) = 0.025$ .

The variance of  $\tilde{X}_n$  will be approximately  $1/[4nh^2(\mu)]$ . Since

$$h(x) = \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{1}{2}(x - \mu)^2\right] \quad \text{and } g(x) = \frac{1}{2\sqrt{2\pi}} \exp\left[-\frac{1}{2(4)}(x - \mu)^2\right],$$

it follows that

$$f(\mu) = \frac{1}{2}h(\mu) + \frac{1}{2}g(\mu) = \frac{1}{2} \cdot \frac{1}{\sqrt{2\pi}} + \frac{1}{2} \cdot \frac{1}{2\sqrt{2\pi}} = \frac{3}{4\sqrt{2\pi}}.$$

Therefore,  $\text{Var}(\tilde{X}_n)$  is approximately  $2\pi/225 = 0.028$ .

6. Let  $g_n(\mathbf{x})$  be the joint p.d.f. of the data given that they came from the uniform distribution, and let  $f_n(\mathbf{x})$  be the joint p.d.f. given that they come from the p.d.f. in Exercise 5. According to Bayes' theorem, the posterior probability that they came from the uniform distribution is

$$\frac{\frac{1}{2}g_n(\mathbf{x})}{\frac{1}{2}g_n(\mathbf{x}) + \frac{1}{2}f_n(\mathbf{x})}.$$

It is easy to see that  $g_n(\mathbf{x}) = 1$  for these data, while  $f_n(\mathbf{x}) = (3/2)^{16}(1/2)^9 = 1.283$ . This makes the posterior probability of the uniform distribution  $1/2.283 = 0.4380$ .

7. (a) The mean  $\bar{X}_n$  is the mean of each  $X_i$ . Since  $f(x)$  is a weighted average of two other p.d.f.'s, the  $\int xf(x)dx$  is the same mixture of the means of the other two distributions. Since each of the distributions in the mixture has mean  $\mu$ , so does the distribution with p.d.f.  $f$ .
- (b) The variance  $\bar{X}_n$  is  $1/n$  times the variance of  $X_i$ . The variance of  $X_i$  is  $E(X_i^2) - \mu^2$ . Since the p.d.f. of  $X_i$  is a weighted average of two other p.d.f.'s, the mean of  $X_i^2$  is the same weighted average of the two means of  $X_i^2$  from the two p.d.f.'s. The mean of  $X_i^2$  from the first p.d.f. (the normal distribution with mean  $\mu$  and variance  $\sigma^2$ ) is  $\mu^2 + \sigma^2$ . The mean of  $X_i^2$  from the second p.d.f. (the normal distribution with mean  $\mu$  and variance  $100\sigma^2$ ) is  $\mu^2 + 100\sigma^2$ . The weighted average is

$$(1 - \epsilon)(\mu^2 + \sigma^2) + \epsilon(\mu^2 + 100\sigma^2) = \mu^2 + \sigma^2(1 + 99\epsilon).$$

The variance of  $X_i$  is then  $(1 + 99\epsilon)\sigma^2$ , and the variance  $\bar{X}_n$  is  $(1 + 99\epsilon)\sigma^2/n$ .

8. When  $\epsilon = 1$ , the distribution whose p.d.f. is in Eq. (10.7.2) is the normal distribution with mean  $\mu$  and variance  $100\sigma^2$ . When  $\epsilon = 0$ , the distribution is the normal distribution with mean  $\mu$  and variance  $\sigma^2$ . The ratio of the variances of the sample mean and sample median from a normal distribution does not depend on the variance of the normal distribution, hence the ratio will be the same whether the variance is  $\sigma^2$  or  $100\sigma^2$ . The reason that the ratio doesn't depend on the variance of the specific normal distribution is that both the sample mean and the sample median have variances that equal the variance of the original distribution times constants that depend only on the sample size.

9. The likelihood function is

$$\frac{1}{2^n \sigma^n} \exp\left(-\frac{1}{\sigma} \sum_{i=1}^n |x_i - \theta|\right).$$

It is easy to see that, no matter what  $\sigma$  equals, the M.L.E. of  $\theta$  is the number that minimizes  $\sum_{i=1}^n |x_i - \theta|$ .

This is the same as the number that minimizes  $\sum_{i=1}^n |x_i - \theta|/n$ . The value  $\sum_{i=1}^n |x_i - \theta|/n$  is the mean of  $|X - \theta|$  when the c.d.f. of  $X$  is the sample c.d.f. of  $X_1, \dots, X_n$ . The mean of  $|X - \theta|$  is minimized by  $\theta$  equal to a median of the distribution of  $X$  according to Theorem 4.5.3. The median of the sample distribution is the sample median.

10. The likelihood was given in Exercise 9. The logarithm of the likelihood equals

$$-n \log(2\sigma) - \frac{1}{\sigma} \sum_{i=1}^n |x_i - \theta|.$$

For convenience, assume that  $x_1 < x_2 < \dots < x_n$ . Let  $\theta$  be a given number between two consecutive  $x_i$  values. In particular, let  $x_k < \theta < x_{k+1}$ . For known  $\sigma$ , the likelihood can be written as a constant plus a constant times

$$\sum_{i=k+1}^n x_i - (n - k)\theta - \sum_{i=1}^k x_i + k\theta.$$

For  $\theta$  between  $x_k$  and  $x_{k+1}$ , the derivative of this is  $k - (n - k)$ , the difference between the number of observations below  $\theta$  and the number above  $\theta$ .

11. Let  $x_q$  be the  $q$  quantile of  $X$ . The result will follow if we can prove that the  $q$  quantile of  $aX + b$  is  $ax_q + b$ . Since

$$\Pr(aX + b \leq ax_q + b) = \Pr(X \leq x_q),$$

for all  $a > 0$  and  $b$  and  $q$ , it follows that  $ax_q + b$  is the  $q$  quantile of  $aX + b$ .

12. According to the solution to Exercise 11, the median of  $aX + b$  is  $am + b$ , where  $m$  is the median of  $X$ . The median absolute deviation of  $X$  is the median of  $|X - m|$ , which equals  $\sigma$ . The median absolute deviation of  $aX + b$  is the median of  $|aX + b - (am + b)| = a|X - m|$ . According to the solution to Exercise 11, the median of  $a|X - m|$  is  $a$  times the median of  $|X - m|$ , that is,  $a\sigma$ .
13. The Cauchy distribution is symmetric around 0, so the median is 0, and the median absolute deviation is the median of  $Y = |X|$ . If  $F$  is the c.d.f. of  $X$ , then the c.d.f. of  $Y$  is

$$G(y) = \Pr(Y \leq y) = \Pr(|X| \leq y) = \Pr(-y \leq X \leq y) = F(y) - F(-y),$$

because  $X$  has a continuous distribution. Because  $X$  has a symmetric distribution around 0,  $F(-y) = 1 - F(y)$ , and  $G(y) = 2F(y) - 1$ . The median of  $Y$  is where  $G(y) = 0.5$ , that is  $2F(y) - 1 = 0.5$  or  $F(y) = 0.75$ . So, the median of  $Y$  is the 0.75 quantile of  $X$ , namely  $y = 1$ .

14. (a) The c.d.f. of  $X$  is  $F(x) = 1 - \exp(-x\lambda)$ , so the quantile function is  $F^{-1}(p) = -\log(1-p)/\lambda$ . The IQR is

$$F^{-1}(0.75) - F^{-1}(0.25) = -\frac{\log(0.25)}{\lambda} + \frac{\log(0.75)}{\lambda} = \frac{\log(3)}{\lambda}.$$

- (b) The median of  $X$  is  $\log(2)/\lambda$ , and the median absolute deviation is the median of  $|X - \log(2)/\lambda|$ . It is the value  $x$  such that  $\Pr(\log(2)/\lambda - x \leq X \leq \log(2)/\lambda + x) = 0.5$ . If we try letting  $x = \log(3)/[2\lambda]$  (half of the IQR), then

$$\begin{aligned} \Pr(\log(2)/\lambda - x \leq X \leq \log(2)/\lambda + x) &= [1 - \exp(-\log(2\sqrt{3}))] - [1 - \exp(-\log(2/\sqrt{3}))] \\ &= \frac{1}{2}[\sqrt{3} - 1/\sqrt{3}] = 0.5773. \end{aligned}$$

This is greater than 0.5, so the median absolute deviation is smaller than 1/2 of the IQR.

15. (a) The quantile function of the normal distribution with mean  $\mu$  and variance  $\sigma^2$  is the inverse of the c.d.f.,  $F(x) = \Phi([x - \mu]/\sigma)$ . So,

$$F^{-1}(p) = \mu + \sigma\Phi^{-1}(p). \tag{S.10.1}$$

The IQR is

$$F^{-1}(0.75) - F^{-1}(0.25) = \sigma[\Phi^{-1}(0.75) - \Phi^{-1}(0.25)].$$

Since the standard normal distribution is symmetric around 0,  $\Phi^{-1}(0.25) = -\Phi^{-1}(0.75)$ , so the IQR is  $2\sigma\Phi^{-1}(0.75)$ .

- (b) Let  $F$  be the c.d.f. of a distribution that is symmetric around its median  $\mu$ . The median absolute deviation is then the value  $x$  such that  $F(\mu + x) - F(\mu - x) = 0.5$ . By symmetry around the median, we know that  $F(\mu - x) = 1 - F(\mu + x)$ , so  $x$  solves  $2F(\mu + x) - 1 = 0.5$  or  $F(\mu + x) = 0.75$ . That is,  $x = F^{-1}(0.75) - \mu$ . For the case of normal random variables, use Eq. (S.10.1) to conclude that  $x = \sigma\Phi^{-1}(0.75)$ .

16. Here are the sorted values from smallest to largest:

$$-67, -48, 6, 8, 14, 16, 23, 24, 28, 29, 41, 49, 56, 60, 75.$$

- (a) The average is 20.93.
- (b) The trimmed means are

$k$	1	2	3	4
Trimmed mean	25.54	26.73	25.78	25

- (c) The sample median is 24.
- (d) The median absolute deviation divided by 0.6745 is 25.20385. Starting at  $\theta = 0$  and iterating the procedure described on page 673 of the text, we get the following sequence of values for  $\theta$ :

$$20.805, 24.017, 26.278, 24.342, 24.373, 24.376, 24.377, 24.377, \dots$$

After 9 iterations, the value stays the same to 7 significant digits.

17. Let  $\mu$  stand for the median of the distribution, and let  $\mu + c$  be the 0.75 quantile. By symmetry, the 0.25 quantile is  $\mu - c$ . Also,  $f(\mu + c) = f(\mu - c)$ . The large sample joint distribution of the 0.25 and 0.75 sample quantiles is a bivariate normal distribution with means  $\mu - c$  and  $\mu + c$ , variances both equal to  $3/[16nf(\mu + c)^2]$ , and covariance  $1/[16nf(\mu + c)^2]$ . The IQR is the difference between these two sample quantiles, so its large sample distribution is normal with mean  $2c$  and variance

$$\frac{3}{16nf(\mu + c)^2} + \frac{3}{16nf(\mu + c)^2} - 2\frac{1}{16nf(\mu + c)^2} = \frac{1}{4nf(\mu + c)^2}.$$

## 10.8 Sign and Rank Tests

### Commentary

This section ends with a derivation of the power function of the Wilcoxon-Mann-Whitney ranks test. This derivation is a bit more technical than the rest of the section and is perhaps suitable only for the more mathematically inclined reader.

If one is using the software *R*, the function `wilcox.test` performs the Wilcoxon-Mann-Whitney ranks test. The two arguments are the two samples whose distributions are being compared.

### Solutions to Exercises.

1. Let  $W$  be the number of  $(X_i, Y_i)$  pairs with  $X_i \leq Y_i$ . Then  $W$  has a binomial distribution with parameters  $n$  and  $p$ . To test  $H_0$ , we reject  $H_0$  if  $W$  is too large. In particular, if  $c$  is chosen so that

$$\sum_{w=c+1}^n \binom{n}{w} \left(\frac{1}{2}\right)^n < \alpha_0 \leq \sum_{w=c}^n \binom{n}{w} \left(\frac{1}{2}\right)^n,$$

then we can reject  $H_0$  if  $W \geq c$  for a level  $\alpha_0$  test.

2. The largest difference between the two sample c.d.f.'s occurs between 2.336 and 2.431 and equals  $|0.8 - 0.125| = 0.675$ . The test statistic is then

$$\left(\frac{8 \times 10}{8 + 10}\right)^{1/2} 0.675 = 1.423.$$

The tail area is between 0.0397 and 0.0298.

3. This test was performed in Example 9.6.5, and the tail area is 0.003.
4. By ordering all the observations, we obtain Table S.10.12. The sum of the ranks of  $x_1, \dots, x_{25}$  is

Table S.10.12: Table for Exercise 4 of Sec. 10.8.

Rank	Observed value	Sample	Rank	Observed value	Sample
1	0.04	$x$	21	1.01	$y$
2	0.13	$x$	22	1.07	$y$
3	0.16	$x$	23	1.12	$x$
4	0.28	$x$	24	1.15	$x$
5	0.35	$x$	25	1.20	$x$
6	0.39	$x$	26	1.25	$y$
7	0.40	$x$	27	1.26	$y$
8	0.44	$x$	28	1.31	$y$
9	0.49	$x$	29	1.38	$x$
10	0.58	$x$	30	1.48	$y$
11	0.68	$y$	31	1.50	$x$
12	0.71	$x$	32	1.54	$x$
13	0.72	$x$	33	1.59	$y$
14	0.75	$x$	34	1.63	$y$
15	0.77	$x$	35	1.64	$x$
16	0.83	$x$	36	1.73	$x$
17	0.86	$y$	37	1.78	$y$
18	0.89	$y$	38	1.81	$y$
19	0.90	$x$	39	1.82	$y$
20	0.91	$x$	40	1.95	$y$

$S = 399$ . Since  $m = 25$  and  $n = 15$ , it follows from Eqs. (10.8.3) and (10.8.4) that  $E(S) = 512.5$ ,  $\text{Var}(S) = 1281.25$ , and  $\sigma = (1281.25)^{1/2} = 35.7946$ . Hence,  $Z = (399 - 512.5)/35.7946 = -3.17$ . It can be found from a table of the standard normal distribution that the corresponding two-sided tail area is 0.0015.

5. Since there are 25 observations in the first sample,  $F_m(x)$  will jump by the amount 0.04 at each observed value. Since there are 15 observations in the second sample,  $G_n(x)$  will jump by the amount 0.0667 at each observed value. From the table given in the solution to Exercise 4, we obtain Table S.10.13. It can be seen from this table that the maximum value of  $|F_m(x) - G_n(x)|$  occurs when  $x$  is equal to the observed value of rank 16, and its value at this point is  $.60 - .0667 = .5333$ . Hence,  $D_{mn} = 0.5333$  and  $\left(\frac{mn}{m+n}\right)^{1/2} D_{mn} = \left(\frac{375}{40}\right)^{1/2} (0.5333) = 1.633$ . It is found from Table 10.32 that the corresponding tail area is almost exactly 0.01.
6. It is found from the values given in Tables 10.44 and 10.45 that  $\bar{x} = \sum_{i=1}^{25} x_i/25 = 0.8044$ ,  $\bar{y} = \sum_{i=1}^{15} y_i/15 = 1.3593$ ,  $S_x^2 = \sum_{i=1}^{25} (x_i - \bar{x})^2 = 5.8810$ , and  $S_y^2 = \sum_{i=1}^{15} (y_i - \bar{y})^2 = 2.2447$ . Since  $m = 25$  and  $n = 15$ , it follows from Eq. (9.6.3) that  $U = -3.674$ . It can be found from a table of the  $t$  distribution with  $m + n - 2 = 38$  degrees of freedom that the corresponding two-sided tail area is less than 0.01.
7. We need to show that  $F(\theta + G^{-1}(p)) = p$ . Compute

$$F(\theta + G^{-1}(p)) = \int_{-\infty}^{\theta+G^{-1}(p)} f(x)dx = \int_{-\infty}^{\theta+G^{-1}(p)} g(x - \theta)dx = \int_{-\infty}^{G^{-1}(p)} g(y)dy = G(G^{-1}(p)) = p,$$

where the third equality follows by making the change of variables  $y = x - \theta$ .

Table S.10.13: Table for Exercise 5 of Sec. 10.8.

Rank of observations	$F_m(x)$	$G_n(x)$	Rank of observations	$F_m(x)$	$G_n(x)$
1	.04	0	21	.68	.2667

8. Since  $Y + \theta$  and  $X$  have the same distribution, it follows that if  $\theta > 0$  then the values in the first sample will tend to be larger than the values in the second sample. In other words, when  $\theta > 0$ , the sum  $S$  of the ranks in the first sample will tend to be larger than it would be if  $\theta = 0$  or  $\theta < 0$ . Therefore, we will reject  $H_0$  if  $Z > c$ , where  $Z$  is as defined in this section and  $c$  is an appropriate constant. If we want the test to have a specified level of significance  $\alpha_0$  ( $0 < \alpha_0 < 1$ ), then  $c$  should be chosen so that when  $Z$  has a standard normal distribution,  $\Pr(Z > c) = \alpha_0$ . It should be kept in mind that the level of significance of this test will only be approximately  $\alpha_0$  because for finite sample sizes, the distribution of  $Z$  will only be approximately a standard normal distribution when  $\theta = 0$ .
9. To test these hypotheses, add  $\theta_0$  to each observed value  $y_i$  in the second sample and then carry out the Wilcoxon-Mann-Whitney procedure on the original values in the first sample and the new values in the second sample.
10. For each value of  $\theta_0$ , carry out a test of the hypotheses given in Exercise 7 at the level of significance  $1 - \alpha$ . The confidence interval for  $\theta$  will contain all values of  $\theta_0$  for which the null hypothesis  $H_0$  would be accepted.
11. Let  $r_1 < r_2 < \dots < r_m$  denote the ranks of the observed values in the first sample, and let  $X_{i_1} < X_{i_2} < \dots < X_{i_m}$  denote the corresponding observed values. Then there are  $r_1 - 1$  values of  $Y$  in the second sample that are smaller than  $X_{i_1}$ . Hence, there are  $r_1 - 1$  pairs  $(X_{i_1}, Y_j)$  with  $X_{i_1} > Y_j$ . Similarly, there are  $r_2 - 2$  values of  $Y$  in the second sample that are smaller than  $X_{i_2}$ . Hence, there are  $r_2 - 2$  pairs  $(X_{i_2}, Y_j)$  with  $X_{i_2} > Y_j$ . By continuing in this way, we see that the number  $U$  is equal to
- $$(r_1 - 1) + (r_2 - 2) + \dots + (r_m - m) = \sum_{i=1}^m r_i - \sum_{i=1}^m i = S - \frac{1}{2}m(m+1).$$
12. Using the result in Exercise 11, we find that  $E(S) = E(U) + m(m+1)/2$ , where  $U$  is defined in Exercise 11 to be the number of  $(X_i, Y_j)$  pairs for which  $X_i \geq Y_j$ . So, we need to show that  $E(U) = nm \Pr(X_1 \geq Y_1)$ .

We can let  $Z_{i,j} = 1$  if  $X_i \geq Y_j$  and  $Z_{i,j} = 0$  otherwise. Then

$$U = \sum_i \sum_j Z_{i,j}, \quad (\text{S.10.2})$$

and

$$E(U) = \sum_{i=1}^m \sum_{j=1}^n E(Z_{i,j}).$$

Since all of the  $X_i$  are i.i.d. and all of the  $Y_j$  are i.i.d., it follows that  $E(Z_{i,j}) = E(Z_{1,1})$  for all  $i$  and  $j$ . Of course  $E(Z_{1,1}) = \Pr(X_1 \geq Y_1)$ , so  $E(U) = mn \Pr(X_1 \geq Y_1)$ .

13. Since  $S$  and  $U$  differ by a constant, we need to show that  $\text{Var}(U)$  is given by Eq. (10.8.6). Once again, write

$$U = \sum_i \sum_j Z_{i,j},$$

where  $Z_{i,j} = 1$  if  $X_i \geq Y_j$  and  $Z_{i,j} = 0$  otherwise. Hence,

$$\text{Var}(U) = \sum_i \sum_j \text{Var}(Z_{i,j}) + \sum_{(i',j') \neq (i,j)} \text{Cov}(Z_{i,j}, Z_{i',j'}).$$

The first sum is  $mn[\Pr(X_1 \geq Y_1) - \Pr(X_1 \geq Y_1)^2]$ . The second sum can be broken into three parts:

- The terms with  $i' = i$  but  $j' \neq j$ .
- The terms with  $j' = j$  but  $i' \neq i$ .
- The terms with both  $i' \neq i$  and  $j' \neq j$ .

For the last set of terms  $\text{Cov}(Z_{i,j}, Z_{i',j'}) = 0$  since  $(X_i, Y_j)$  is independent of  $(X_{i'}, Y_{j'})$ . For each term in the first set

$$E(Z_{i,j} Z_{i,j'}) = \Pr(X_1 \geq Y_1, X_1 \geq Y_2),$$

so the covariances are

$$\text{Cov}(Z_{i,j}, Z_{i,j'}) = \Pr(X_1 \geq Y_1, X_1 \geq Y_2) - \Pr(X_1 \geq Y_1)^2.$$

There are  $mn(n-1)$  terms of this sort. Similarly, for the second set of terms

$$\text{Cov}(Z_{i',j}, Z_{i,j}) = \Pr(X_1 \geq Y_1, X_2 \geq Y_1) - \Pr(X_1 \geq Y_1)^2.$$

There are  $nm(m-1)$  of these terms. The variance is then

$$nm [\Pr(X_1 \geq Y_1) + (n-1) \Pr(X_1 \geq Y_1, X_1 \geq Y_2) + (m-1) \Pr(X_1 \geq Y_1, X_2 \geq Y_1) - (m+n-1) \Pr(X_1 \geq Y_1)^2].$$

14. When  $F = G$ ,  $\Pr(X_1 \geq Y_1) = 1/2$ , so Eq. (10.8.5) yields

$$E(S) = \frac{mn}{2} + \frac{m(m+1)}{2} = \frac{m(m+n+1)}{2},$$

which is the same as (10.8.3). When  $F = G$ ,

$$\Pr(X_1 \geq Y_1, X_1 \geq Y_2) = 1/3 = \Pr(X_1 \geq Y_1, X_2 \geq Y_1),$$

so the corrected version of (10.8.6) yields

$$\begin{aligned} nm \left[ \frac{1}{2} - (m+n-1) \frac{1}{4} + (m+n-2) \frac{1}{3} \right] &= \frac{mn}{12} [6 - 3m - 3n + 3 + 4m + 4n - 8] \\ &= \frac{mn(m+n+1)}{12}, \end{aligned}$$

which is the same as (10.8.4).

15. (a) Arrange the observations so that  $|D_1| \leq \dots \leq |D_n|$ . Then  $D_i > 0$  if and only if  $X_i > Y_i$  if and only if  $W_i = 1$ . Since rank  $i$  gets added into  $S_W$  if and only if  $D_i > 0$ , we see that  $\sum_{i=1}^n iW_i$  adds just those ranks that correspond to positive  $D_i$ .
- (b) Since the distribution of each  $D_i$  is symmetric around 0, the magnitude  $|D_1|, \dots, |D_n|$  are independent of the sign indicators  $W_1, \dots, W_n$ . Using the result of part (a), if we assume that the  $|D_i|$  are ordered from smallest to largest,  $E(S_W) = \sum_{i=1}^n iE(W_i)$ . Since the  $|D_i|$  are independent of the  $W_i$ , we have  $E(W_i) = 1/2$  even after we condition on the  $|D_i|$  being arranged from smallest to largest. Since  $\sum_{i=1}^n i = n(n+1)/2$ , we have  $E(S_W) = n(n+1)/4$ .
- (c) Since the  $W_i$  are independent before we condition on the  $|D_i|$  and they are independent of the  $|D_i|$ , then the  $W_i$  are independent conditional on the  $|D_i|$ . Hence,  $\text{Var}(S_W) = \sum_{i=1}^n i^2 \text{Var}(W_i)$ . Since  $\text{Var}(W_i) = 1/4$  for all  $i$  and  $\sum_{i=1}^n i^2 = n(n+1)(2n+1)/6$ , we have  $\text{Var}(S_W) = n(n+1)(2n+1)/24$ .
16. For  $i = 1, \dots, 15$ , let

$$D_i = (\text{thickness for material A in pair } i) - (\text{thickness for material B in pair } i).$$

- (a) Of the 15 values of  $D_i$ , 10 are positive, 3 are negative, and 2 are zero. If we first regard the zeroes as positive, then there are 12 positive differences with  $n = 15$ , and it is found from the binomial tables that the corresponding tail area is 0.0176. If we next regard the zeroes as negative, then there are only 10 positive differences with  $n = 15$ , and it is found from the tables that the corresponding tail area is 0.1509. The results are not conclusive because of the zeroes present in the sample.
- (b) For the Wilcoxon signed-ranks test, use Table S.10.14. Two different methods have been used. In Method (I), the differences that are equal to 0 are regarded as positive, and whenever two or more values of  $|D_i|$  are tied, the positive differences  $D_i$  are assigned the largest possible ranks and the negative differences  $D_i$  are assigned the smallest ranks. In Method (II), the differences that are 0

Table S.10.14: Computation of Wilcoxon signed-ranks test statistic for Exercise 16b in Sec. 10.8.

Pair	$D_i$	Method (I) Rank of $ D_i $	Method (I) Signed rank	Method (II) Rank of $ D_i $	Method (II) Signed rank
1	-0.8	6	-6	7	-7
2	1.6	12	12	11	11
3	-0.5	5	-5	5	-5
4	0.2	3	3	3	3
5	-1.6	11	-11	13	-13
6	0.2	4	4	4	4
7	1.6	13	13	12	12
8	1.0	9	9	9	9
9	0.8	7	7	6	6
10	0.9	8	8	8	8
11	1.7	14	14	14	14
12	1.2	10	10	10	10
13	1.9	15	15	15	15
14	0	2	2	2	-2
15	0	1	1	1	-1

are regarded as negative, and among tied values of  $|D_i|$ , the negative differences are assigned the largest ranks and the positive differences are assigned the smallest ranks. Let  $S_n$  denote the sum of the positive ranks. Since  $n = 15$ ,  $E(S_n) = 60$  and  $\text{Var}(S_n) = 310$ . Hence,  $\sigma_n = \sqrt{310} = 17.607$ . For Method (I),  $S_n = 98$ . Therefore,  $Z_n = (98 - 60)/17.607 = 2.158$  and it is found from a table of the standard normal distribution that the corresponding tail area is 0.0155. For Method (II),  $S_n = 92$ . Therefore,  $Z_n = 1.817$  and it is found that the corresponding tail area is 0.0346. By either method of analysis, the null hypothesis would be rejected at the 0.05 level of significance, but not at the 0.01 level.

- (c) The average of the pairwise differences (material A minus material B) is 0.5467. The value of  $\sigma'$  computed from the differences is 1.0197, so the  $t$  statistic is 2.076, and the  $p$ -value is 0.0284.

## 10.9 Supplementary Exercises

### Solutions to Exercises

1. Here,  $\alpha_0/2 = 0.025$ . From a table of binomial probabilities we find that

$$\sum_{x=0}^5 \binom{20}{x} 0.5^{20} = 0.021 \leq 0.025 \leq \sum_{x=0}^6 \binom{20}{x} 0.5^{20} = 0.058.$$

So, the sign test would reject the null hypothesis that  $\theta = \theta_0$  if the number  $W$  of observations with values at most  $\theta_0$  satisfies either  $W \leq 5$  or  $W \geq 20 - 5$ . Equivalently, we would accept the null hypothesis if  $6 \leq W \leq 14$ . This, in turn, is true if and only if  $\theta_0$  is strictly between the sixth and fourteenth ordered values of the original data. These values are 141 and 175, so our 95 percent confidence interval is (141, 175).

2. It follows from Eq. (10.1.2) that

$$Q = \sum_{i=1}^5 \frac{(N_i - 80)^2}{80} = \frac{1}{80} \left[ \sum_{i=1}^5 N_i^2 - 2(80)(400) + 5(80)^2 \right] = \frac{1}{80} \sum_{i=1}^5 N_i^2 - 400.$$

It is found from the  $\chi^2$  distribution with 4 degrees of freedom that  $H_0$  should be rejected for  $Q > 13.28$  or, equivalently, for  $\sum_{i=1}^5 N_i^2 > 80(413.28) = 33,062.4$ .

3. Under  $H_0$ , the proportion  $p_i^0$  of families with  $i$  boys is as follows:

$i$	$p_i^0$	$np_i^0$
0	1/8	16
1	3/8	48
2	3/8	48
3	1/8	16

Hence, it follows from Eq. (10.1.2) that

$$Q = \frac{(26 - 16)^2}{16} + \frac{(32 - 48)^2}{48} + \frac{(40 - 48)^2}{48} + \frac{(30 - 16)^2}{16} = 25.1667.$$

Under  $H_0$ ,  $Q$  has the  $\chi^2$  distribution with 3 degrees of freedom. Hence, the tail area corresponding to  $Q = 25.1667$  is less than 0.005, the smallest probability in the table in the back of the book. It follows that  $H_0$  should be rejected for any level of significance greater than this tail area.

4. The likelihood function of  $p$  based on the observed data is

$$(q^3)^{26}(3pq^2)^{32}(3p^2q)^{40}(p^3)^{30} = (\text{const.}) p^{202}q^{182},$$

where  $q = 1 - p$ . Hence, the M.L.E. of  $\hat{p}$  based on these data is  $\hat{p} = 202/384 = .526$ . Under  $H_0$ , the estimated expected proportion  $\hat{p}_i^0$  of families with  $i$  boys is as follows:

$i$	$\hat{p}_i^0$	$n\hat{p}_i^0$
0	$\hat{q}^3 = .1065$	13.632
1	$3\hat{p}\hat{q}^2 = .3545$	45.376
2	$3\hat{p}^2\hat{q} = .3935$	50.368
3	$\hat{p}^3 = .1455$	18.624

It follows from Eq. (10.2.4) that

$$Q = \frac{(26 - 13.632)^2}{13.632} + \frac{(32 - 45.376)^2}{45.376} + \frac{(40 - 50.368)^2}{50.368} + \frac{(30 - 18.624)^2}{18.624} = 24.247.$$

Under  $H_0$ ,  $Q$  has the  $\chi^2$  distribution with 2 degrees of freedom. The tail area corresponding to  $Q = 24.247$  is again less than 0.005.  $H_0$  should be rejected for any level of significance greater than this tail area.

5. The expected numbers of observations in each cell, as specified by Eq. (10.4.4), are presented in the following table:

	A	B	AB	O
Group 1	19.4286	11	4.8571	14.7143
Group 2	38.8571	22	9.7143	29.4286
Group 3	77.7143	44	19.4286	58.8571

It is now found from Eq. (10.4.3) that  $Q = 6.9526$ . Under the hypothesis  $H_0$  that the distribution is the same in all three groups,  $Q$  will have approximately the  $\chi^2$  distribution with  $3 \times 2 = 6$  degrees of freedom. It is found from the tables that the 0.9 quantile of that distribution is 10.64, so  $H_0$  should not be rejected.

6. If Table 10.47 is changed in such a way that the row and column totals remain unchanged, then the expected numbers given in the solution of Exercise 5 will remain unchanged. If we switch one person in group 1 from  $B$  to  $AB$  and one person in group 2 from  $AB$  to  $B$ , then all row and column totals will be unchanged and the new observed numbers in each of the four affected cells will be further from their expected values than before. Hence, the value of the  $\chi^2$  statistic  $Q$  as given by Eq. (10.4.3) is increased. Continuing to switch persons in this way will continue to increase  $Q$ . There are other similar switches that will also increase  $Q$ , such as switching one person in group 2 from  $O$  to  $A$  and one person in group 3 from  $A$  to  $O$ .

7.

$$\begin{aligned}
 (N_{11} - \hat{E}_{11})^2 &= \left( N_{11} - \frac{N_{1+}N_{+1}}{n} \right)^2 \\
 &= \left[ N_{11} - \frac{(N_{11} + N_{12})(N_{11} + N_{21})}{n} \right]^2 \\
 &= \frac{1}{n^2} [nN_{11} - (N_{11} + N_{12})(N_{11} + N_{21})]^2 \\
 &= \frac{1}{n^2} (N_{11}N_{22} - N_{12}N_{21})^2,
 \end{aligned}$$

since  $n = N_{11} + N_{21} + N_{12} + N_{22}$ . Exactly the same value is obtained for  $(N_{12} - \hat{E}_{12})^2$ ,  $(N_{21} - \hat{E}_{21})^2$ , and  $(N_{22} - \hat{E}_{22})^2$ .

8. It follows from Eq. (10.3.4) and Exercise 7 that

$$Q = \frac{1}{n^2} (N_{11}N_{22} - N_{12}N_{21})^2 \sum_{i=1}^2 \sum_{j=1}^2 \frac{1}{\hat{E}_{ij}}.$$

But

$$\begin{aligned}
 \sum_{i=1}^2 \sum_{j=1}^2 \frac{1}{\hat{E}_{ij}} &= \frac{n}{N_{1+}N_{+1}} + \frac{n}{N_{1+}N_{+2}} + \frac{n}{N_{2+}N_{+1}} + \frac{n}{N_{2+}N_{+2}} \\
 &= \frac{n(N_{2+}N_{+2} + N_{2+}N_{+1} + N_{1+}N_{+2} + N_{1+}N_{+1})}{N_{1+}N_{2+}N_{+1}N_{+2}} \\
 &= \frac{n^3}{N_{1+}N_{2+}N_{+1}N_{+2}},
 \end{aligned}$$

since  $N_{1+} + N_{2+} = N_{+1} + N_{+2} = n$ . Hence,  $Q$  has the specified form.

9. In this exercise,  $N_{1+} = N_{2+} = N_{+1} = N_{+2} = 2n$  and  $N_{11}N_{22} - N_{12}N_{21} = (n+a)^2 - (n-a)^2 = 4na$ . It now follows from Exercise 8 (after we replace  $n$  by  $4n$  in the expression for  $Q$ ) that  $Q = 4a^2/n$ . Since  $H_0$  should be rejected if  $Q > 6.635$ , it follows that  $H_0$  should be rejected if  $a > (6.635n)^{1/2}/2$  or  $a < -(6.635n)^{1/2}/2$ .
10. In this exercise  $N_{1+} = N_{2+} = N_{+1} = N_{+2} = n$  and  $N_{11}N_{22} - N_{12}N_{21} = (2\alpha-1)n^2$ . It now follows from Exercise 8 (after we replace  $n$  by  $2n$  in the expression for  $Q$ ) that  $Q = 2n(2\alpha-1)^2$ . Since  $H_0$  should be rejected if  $Q > 3.841$ , it follows that  $H_0$  should be rejected if either

$$\alpha > \frac{1}{2} \left[ 1 + \left( \frac{3.841}{2n} \right)^{1/2} \right]$$

or

$$\alpha < \frac{1}{2} \left[ 1 - \left( \frac{3.841}{2n} \right)^{1/2} \right].$$

11. Results of this type are an example of Simpson's paradox. If there is a higher rate of respiratory diseases among older people than among younger people, and if city A has a higher proportion of older people than city B, then results of this type can very well occur.
12. Results of this type are another example of Simpson's paradox. If scores on the test tend to be higher for certain classes, such as seniors and juniors, and lower for the other classes, such as freshmen and sophomores, and if school B has a higher proportion of seniors and juniors than school A, then results of this type can very well occur.
13. The fundamental aspect of this exercise is that it is not possible to assess the effectiveness of the treatment without having any information about how the levels of depression of the patients would have changed over the three-month period if they had not received the treatment. In other words, without the presence of a control group of similar patients who received some other standard treatment or no treatment at all, there is little meaningful statistical analysis that can be carried out. We can compare the proportion of patients at various levels who showed improvement after the treatment with the proportion who remained the same or worsened, but without a control group we have no way of deciding whether these proportions are unusually large or small.
14. If  $Y_1 < Y_2 < Y_3$  are the order statistics of the sample, then  $Y_2$  is the sample median. For  $0 < y < 1$ ,

$$\begin{aligned} G(y) &= \Pr(Y_2 < y) \\ &= \Pr(\text{At least two obs.} < y) \\ &= \Pr(\text{Exactly two obs.} < y) + \Pr(\text{All three obs.} < y) \\ &= 3(y^\theta)^2(1-y^\theta) + (y^\theta)^3 \\ &= 3y^{2\theta} - 2y^{3\theta}. \end{aligned}$$

Hence, for  $0 < y < 1$ , the p.d.f. of  $Y_2$  is  $g(y) = G'(y) = 6\theta(y^{2\theta-1} - y^{3\theta-1})$ .

15. The c.d.f. of this distribution is  $F(x) = x^\theta$ , so the median of the distribution is the point  $m$  such that  $m^\theta = 1/2$ . Thus,  $m = (1/2)^{1/\theta}$  and  $f(m) = \theta 2^{1/\theta}/2$ . It follows from Theorem 10.7.1 that the asymptotic distribution of the sample median will be normal with mean  $m$  and variance

$$\frac{1}{4nf^2(m)} = \frac{1}{n\theta^2 2^{2/\theta}}.$$

16. We know from Exercise 1 of Sec. 8.4 that the variance of the  $t$  distribution is finite only for  $\alpha > 2$  and its value is  $\alpha/(\alpha - 2)$ . Hence, it follows from the central limit theorem that for  $\alpha > 2$ , the asymptotic distribution of  $\bar{X}_n$  will be normal with mean 0 and variance

$$\sigma_1^2 = \frac{\alpha}{n(\alpha - 2)}.$$

Since the median of the  $t$  distribution is 0, it follows from Theorem 10.7.1 (with  $n$  replaced by  $\alpha$ ) that the asymptotic distribution of  $\tilde{X}_n$  will be normal with mean 0 and variance

$$\sigma_2^2 = \frac{\alpha\pi\Gamma^2\left(\frac{\alpha}{2}\right)}{4n\Gamma^2\left(\frac{\alpha+1}{2}\right)}.$$

Thus,  $\sigma_1^2 < \sigma_2^2$  if and only if

$$\frac{\pi(\alpha - 2)\Gamma^2\left(\frac{\alpha}{2}\right)}{4\Gamma^2\left(\frac{\alpha+1}{2}\right)} > 1.$$

If we denote the left side of this inequality by  $L$ , then we obtain the following values:

$\alpha$	$\Gamma\left(\frac{\alpha}{2}\right)$	$\Gamma\left(\frac{\alpha+1}{2}\right)$	$L$
3	$\frac{1}{2}\sqrt{\pi}$	1	$\pi^2/16$
4	1	$\frac{3}{2} \cdot \frac{1}{2} \cdot \sqrt{\pi}$	$8/9$
5	$\frac{3}{2} \cdot \frac{1}{2} \cdot \sqrt{\pi}$	2	$27\pi^2/(16)^2 = 1.04$ .

Thus,  $\sigma_1^2 < \sigma_2^2$  for  $\alpha = 5, 6, 7, \dots$ .

17. As shown in Exercise 5 of Sec. 10.7,  $E(\bar{X}_n) = E(\tilde{X}_n) = \theta$ , so the M.S.E. of each of these estimators is equal to its variance. Furthermore,  $\text{Var}(\bar{X}_n) = \frac{1}{n}[\alpha \cdot 1 + (1 - \alpha)\sigma^2]$  and

$$\text{Var}(\tilde{X}_n) = \frac{1}{4n[h(\theta|\theta)]^2},$$

where

$$[h(\theta|\theta)]^2 = \frac{1}{2\pi} \left( \alpha + \frac{1-\alpha}{\sigma} \right)^2.$$

- (a) For  $\sigma^2 = 100$ ,  $\text{Var}(\tilde{X}_n) < \text{Var}(\bar{X}_n)$  if and only if

$$\frac{50\pi}{[10\alpha + (1 - \alpha)]^2} < \alpha + 100(1 - \alpha).$$

Some numerical calculations show that this inequality is satisfied for  $.031 < \alpha < .994$ .

- (b) For  $\alpha = \frac{1}{2}$ ,  $\text{Var}(\tilde{X}_n) < \text{Var}(\bar{X}_n)$  if and only if  $\sigma < .447$  or  $\sigma > 1/.447 = 2.237$ .

18. The simplest and most intuitive way to establish this result is to note that for any fixed values  $y_1 < y_2 < \dots < y_n$ ,

$$\begin{aligned} g(y_1, \dots, y_n) \Delta y_1 \cdots \Delta y_n &\approx \\ \Pr(y_1 < Y_1 < y_1 + \Delta y_1, \dots, y_n < Y_n < y_n + \Delta y_n) &= \\ \Pr(\text{Exactly one observation in the interval } (y_j, y_j + \Delta y_j) \text{ for } j = 1, \dots, n) &= \\ n! \prod_{j=1}^n [F(y_j + \Delta y_j) - F(y_j)] &\approx \\ n! \prod_{j=1}^n [f(y_j) \Delta y_j] &= n! f(y_1) \cdots f(y_n) \Delta y_1 \cdots \Delta y_n, \end{aligned}$$

where the factor  $n!$  appears because there are  $n!$  different arrangements of  $X_1, \dots, X_n$  such that exactly one of them is in each of the intervals  $(y_j, y_j + \Delta y_j)$ ,  $j = 1, \dots, n$ . Another, and somewhat more complicated, way to establish this result is to determine the general form of the joint c.d.f.  $G(y_1, \dots, y_n)$  of  $Y_1, \dots, Y_n$  for  $y_1 < y_2 < \dots < y_n$ , and then to note that

$$g(y_1, \dots, y_n) = \frac{\partial^n G(y_1, \dots, y_n)}{\partial y_1 \cdots \partial y_n} = n! f(y_1) \cdots f(y_n).$$

19. It follows from Exercise 18 that the joint p.d.f.  $g(y_1, y_2, y_3) = 3!$ , a constant, for  $0 < y_1 < y_2 < y_3 < 1$ . Since the required conditional p.d.f. of  $Y_2$  is proportional to  $g(y_1, y_2, y_3)$ , as a function of  $y_2$  for fixed  $y_1$  and  $y_3$ , it follows that this conditional p.d.f. is also constant. In other words, the required conditional distribution is uniform on the interval  $(y_1, y_3)$ .
20. We have  $Y_r < \theta < Y_{r+3}$  if and only if at least  $r$  observations and at most  $r+2$  observations are below  $\theta$ . Let  $X$  stand for the number of observations out of the sample of size 20 that are below  $\theta$ . Then  $X$  has a binomial distribution with parameters 20 and 0.3. It follows that

$$\Pr(Y_r < \theta < Y_{r+3}) = \Pr(r \leq X \leq r+2).$$

For each value of  $r$ , we can find this probability using a binomial distribution table or a computer. By searching through all values of  $r$ , we find that  $r = 5$  yields a probability of 0.5348, which is the highest.

21. As shown in Exercise 10 of Sec. 10.8, we add  $\theta_0$  to each observation  $Y_j$  and then carry out the Wilcoxon-Mann-Whitney test on the sum  $S_{\theta_0}$  of the ranks of the  $X_i$ 's among these new values  $Y_1 + \theta_0, \dots, Y_n + \theta_0$ . We accept  $H_0$  if and only if

$$\frac{|S_{\theta_0} - E(S)|}{[\text{Var}(S)]^{1/2}} < c \left(1 - \frac{\alpha}{2}\right),$$

where  $E(S)$  and  $\text{Var}(S)$  are given by (10.8.3) and (10.8.4). However, by Exercise 11 of Sec. 10.8,

$$S_{\theta_0} = U_{\theta_0} + \frac{1}{2}m(m+1).$$

When we make this substitution for  $S_{\theta_0}$  in the above inequality, we obtain the desired result.

22. We know from general principles that the set of all values  $\theta_0$  for which  $H_0$  would be accepted in Exercise 21 will form a confidence interval with the required confidence coefficient  $1 - \alpha$ . But if  $U_{\theta_0}$ , the number of differences  $X_i - Y_j$  that are greater than  $\theta_0$ , is greater than the lower limit given in Exercise 21 then  $\theta_0$  must be less than  $B$ . Similarly, if  $U_{\theta_0}$  is less than the upper limit given in Exercise 22, then  $\theta_0$  must be greater than  $A$ . Hence,  $A < \theta < B$  is a confidence interval.

23. (a) We know that  $\theta_p = b$  if and only if  $\Pr(X \leq b) = p$ . So, let  $Y_i = 1$  if  $X_i \leq b$  and  $Y_i = 0$  if not. Then  $Y_1, \dots, Y_n$  are i.i.d. with a Bernoulli distribution with parameter  $p$  if and only if  $H_0$  is true. Define  $W = \sum_{i=1}^n Y_i$ . To test  $H_0$ , reject  $H_0$  if  $W$  is too big or too small. For an equal tailed level  $\alpha_0$  test, choose two numbers  $c_1 < c_2$  such that

$$\begin{aligned}\sum_{w=0}^{c_1} \binom{n}{w} p^w (1-p)^{n-w} &\leq \frac{\alpha_0}{2} < \sum_{w=0}^{c_1+1} \binom{n}{w} p^w (1-p)^{n-w}, \\ \sum_{w=c_2}^n \binom{n}{w} p^w (1-p)^{n-w} &\leq \frac{\alpha_0}{2} < \sum_{w=c_2-1}^n \binom{n}{w} p^w (1-p)^{n-w}.\end{aligned}$$

Then a level  $\alpha_0$  test rejects  $H_0$  if  $W \leq c_1$  or  $W \geq c_2$ .

- (b) For each  $b$ , we have shown how to construct a test of  $H_{0,b} : \theta_p = b$ . For given observed data  $X_1, \dots, X_n$  find all values of  $b$  such that the test constructed in part (a) accepts  $H_{0,b}$ . The set of all such  $b$  forms our coefficient  $1 - \alpha_0$  confidence interval. It is clear from the form of the test that, once we find three values  $b_1 < b_2 < b_3$  such that  $H_{0,b_2}$  is accepted and  $H_{0,b_1}$  and  $H_{0,b_3}$  are rejected, we don't have to check any more values of  $b < b_1$  or  $b > b_3$  since all of those would be rejected also. Similarly, if we find  $b_4 < b_5$  such that both  $H_{0,b_4}$  and  $H_{0,b_5}$  are accepted, the so are  $H_{0,b}$  for all  $b_4 < b < b_5$ . This will save some time locating all of the necessary  $b$  values.

# Chapter 11

## Linear Statistical Models

### 11.1 The Method of Least Squares

#### Commentary

If one is using the software *R*, the functions `lsfit` and `lm` will perform least squares. While `lsfit` has simpler syntax, `lm` is more powerful. The first argument to `lsfit` is a matrix or vector with one row for each observation and one column for each *x* variable in the notation of the text (call this *x*). The second argument is a vector of the response values, one for each observation (call this *y*). By default, an intercept is fit. To prevent an intercept from being fit, use the optional argument `intercept=FALSE`. To perform the fit and store the result in `regfit`, use `regfit=lsfit(x,y)`. The result `regfit` is a “list” which contains (among other things) `coef`, the vector of coefficients  $\beta_0, \dots, \beta_k$  in the notation of the text, and `residuals` which are defined later in the text. To access the parts of `regfit`, use `regfit$coef`, etc. To use `lm`, `regfit=lm(y~x)` will perform least squares with an intercept and store the result in `regfit`. To prevent an intercept from being fit, use `regfit=lm(y~x-1)`. The result of `lm` also contains `coefficients` and `residuals` plus `fitted.values` which equals the original *y* minus `residuals`. The components of the output are accessed as above.

The `plot` function in *R* is useful for visualizing data in linear models. In the notation above, suppose that *x* has only one column. Then `plot(x,y)` will produce a scatterplot of *y* versus *x*. The least-squares line can be added to the plot by `lines(x,regfit$fitted.values)`. (If one used `lsfit`, one can create the fitted values by `regfit$fitted.values=y-regfit$residuals`.)

#### Solutions to Exercises

1. First write  $c_1x_i + c_2 = c_1(x_i - \bar{x}_n) + (c_1\bar{x}_n + c_2)$  for every *i*. Then

$$(c_1x_i + c_2)^2 = c_1^2(x_i - \bar{x}_n)^2 + (c_1\bar{x}_n + c_2)^2 + 2c_1(x_i - \bar{x}_n)(c_1\bar{x}_n + c_2).$$

The sum over all *i* from 1 to *n* of the first two terms on the right produce the formula we desire. The sum of the last term over all *i* is 0 because  $c_1(c_1\bar{x}_n + c_2)$  is the same for all *i* and  $\sum_{i=1}^n (x_i - \bar{x}_n) = 0$ .

2. (a) The result can be obtained from Eq. (11.1.1) and the following relations:

$$\begin{aligned}\sum_{i=1}^n (x_i - \bar{x}_n)(y_i - \bar{y}_n) &= \sum_{i=1}^n (x_i y_i - \bar{x}_n y_i - \bar{y}_n x_i + \bar{x}_n \bar{y}_n) \\ &= \sum_{i=1}^n x_i y_i - \bar{x}_n \sum_{i=1}^n y_i - \bar{y}_n \sum_{i=1}^n x_i + n \bar{x}_n \bar{y}_n \\ &= \sum_{i=1}^n x_i y_i - n \bar{x}_n \bar{y}_n - n \bar{x}_n \bar{y}_n + n \bar{x}_n \bar{y}_n\end{aligned}$$

$$\begin{aligned}
&= \sum_{i=1}^n x_i y_i - n \bar{x}_n \bar{y}_n, \text{ and} \\
\sum_{i=1}^n (x_i - \bar{x}_n)^2 &= \sum_{i=1}^n (x_i^2 - 2\bar{x}_n x_i + \bar{x}_n^2) \\
&= \sum_{i=1}^n x_i^2 - 2\bar{x}_n \sum_{i=1}^n x_i + n\bar{x}_n^2 \\
&= \sum_{i=1}^n x_i^2 - 2n\bar{x}_n^2 + n\bar{x}_n^2 \\
&= \sum_{i=1}^n x_i^2 - n\bar{x}_n^2.
\end{aligned}$$

(b) The result can be obtained from part (a) and the following relation:

$$\begin{aligned}
\sum_{i=1}^n (x_i - \bar{x}_n)(y_i - \bar{y}_n) &= \sum_{i=1}^n (x_i - \bar{x}_n)y_i - \sum_{i=1}^n (\bar{x}_i - \bar{x}_n)\bar{y}_n \\
&= \sum_{i=1}^n (x_i - \bar{x}_n)y_i - \bar{y}_n \sum_{i=1}^n (x_i - \bar{x}_n) \\
&= \sum_{i=1}^n (x_i - \bar{x}_n)y_i, \quad \text{since } \sum_{i=1}^n (x_i - \bar{x}_n) = 0.
\end{aligned}$$

(c) This result can be obtained from part (a) and the following relation:

$$\begin{aligned}
\sum_{i=1}^n (x_i - \bar{x}_n)(y_i - \bar{y}_n) &= \sum_{i=1}^n x_i(y_i - \bar{y}_n) - \bar{x}_n \sum_{i=1}^n (y_i - \bar{y}_n) \\
&= \sum_{i=1}^n x_i(y_i - \bar{y}_n), \quad \text{since } \sum_{i=1}^n (y_i - \bar{y}_n) = 0.
\end{aligned}$$

3. It must be shown that  $\bar{y}_n = \hat{\beta}_0 + \hat{\beta}_1 \bar{x}_n$ . But this result follows immediately from the expression for  $\hat{\beta}_0$  given in Eq. (11.1.1).
4. Since the values of  $\beta_0$  and  $\beta_1$  to be chosen must satisfy the relation  $\partial Q / \partial \beta_0 = 0$ , it follows from Eq. (11.1.3) that they must satisfy the relation  $\sum_{i=1}^n (y_i - \hat{y}_i) = 0$ . Similarly, since they must also satisfy relation  $\partial Q / \partial \beta_1 = 0$ , it follows from Eq. (11.1.4) that  $\sum_{i=1}^n (y_i - \hat{y}_i)x_i = 0$ . These two relations are equivalent to the normal equations (11.1.5), for which  $\hat{\beta}_0$  and  $\hat{\beta}_1$  are the unique solution.
5. The least squares line will have the form  $x = \gamma_0 + \gamma_1 y$ , where  $\gamma_0$  and  $\gamma_1$  are defined similarly to  $\hat{\beta}_0$  and  $\hat{\beta}_1$  in Eq. (11.1.1) with the roles of  $x$  and  $y$  interchanged. Thus,

$$\gamma_1 = \frac{\sum_{i=1}^n x_i y_i - n \bar{x}_n \bar{y}_n}{\sum_{i=1}^n y_i^2 - n \bar{y}_n^2}$$

and  $\hat{\gamma}_0 = \bar{x}_n - \hat{\gamma}_1 \bar{y}_n$ . It is found that  $\hat{\gamma}_1 = 0.9394$  and  $\hat{\gamma}_0 = 1.5691$ . Hence, the least squares line is  $x = 1.5691 + 0.9394 y$  or, equivalently,  $y = -1.6703 + 1.0645x$ . This line and the line  $y = -0.786 + 0.685x$  given in Fig. 11.4 can now be sketched on the same graph.

6. The sum of the squares of the deviations from the least squares parabola is the minimum possible value of  $\sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_i - \beta_2 x_i^2)^2$  as  $\beta_0, \beta_1$ , and  $\beta_2$  vary over all possible real numbers. The sum of the squares of the deviations from the least squares line is the minimum possible value of this same sum when  $\beta_2$  is restricted to have the value 0. This minimum cannot therefore be smaller than the first minimum.

7. (a) Here,  $n = 8$ ,  $\bar{x}_n = 2.25$ ,  $\bar{y}_n = 42.125$ ,  $\sum_{i=1}^n x_i y_i = 764$ , and  $\sum_{i=1}^n x_i^2 = 51$ . Therefore, by Eq. (11.1.1),  $\hat{\beta}_1 = 0.548$  and  $\hat{\beta}_0 = 40.893$ . Hence, the least squares line is  $y = 40.893 + 0.548x$ .

- (b) The normal equations (11.1.8) are found to be:

$$\begin{aligned} 8\beta_0 + 18\beta_1 + 51\beta_2 &= 337, \\ 18\beta_0 + 51\beta_1 + 162\beta_2 &= 764, \\ 51\beta_0 + 162\beta_1 + 548.25\beta_2 &= 2167.5. \end{aligned}$$

Solving these three simultaneous linear equations, we obtain the solution:

$$\hat{\beta}_0 = 38.483, \quad \hat{\beta}_1 = 3.440, \quad \text{and} \quad \hat{\beta}_2 = -0.643.$$

8. If the polynomial is to pass through the  $k+1$  given points, then the following  $k+1$  equations must be satisfied:

$$\begin{aligned} \beta_0 + \beta_1 x_1 + \cdots + \beta_k x_1^k &= y_1, \\ \beta_0 + \beta_1 x_2 + \cdots + \beta_k x_2^k &= y_2, \\ \dots &\dots \\ \beta_0 + \beta_1 x_{k+1} + \cdots + \beta_k x_{k+1}^k &= y_{k+1}. \end{aligned}$$

These equations form a set of  $k+1$  simultaneous linear equations in  $\beta_0, \dots, \beta_k$ . There will be a unique polynomial having the required properties if and only if these equations have a unique solution. These equations will have a unique solution if and only if the  $(k+1) \times (k+1)$  matrix of coefficients of  $\beta_0, \dots, \beta_k$  is nonsingular (i.e., has a nonzero determinant). Thus, it must be shown that

$$\det \begin{bmatrix} 1 & x_1 & x_1^2 & \cdots & x_1^k \\ 1 & x_2 & x_2^2 & \cdots & x_2^k \\ \dots & \dots & \dots & \dots & \dots \\ 1 & x_{k+1} & x_{k+1}^2 & \cdots & x_{k+1}^k \end{bmatrix} \neq 0.$$

This determinant will be 0 if and only if the  $k+1$  columns of the matrix are linearly dependent; i.e., if and only if there exist constants  $a_1, \dots, a_{k+1}$ , not all of which are 0, such that

$$a_1 \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix} + a_2 \begin{bmatrix} x_1 \\ \vdots \\ x_{k+1} \end{bmatrix} + a_3 \begin{bmatrix} x_1^2 \\ \vdots \\ x_{k+1}^2 \end{bmatrix} + \cdots + a_{k+1} \begin{bmatrix} x_1^k \\ \vdots \\ x_{k+1}^k \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \end{bmatrix}.$$

But if such constants exist, then the  $k+1$  distinct values  $x_1, \dots, x_{k+1}$  will all be roots of the equation

$$a_1 + a_2 x + a_3 x^2 + \cdots + a_{k+1} x^k.$$

It is impossible, however, for a polynomial of degree  $k$  or less to have  $k+1$  distinct roots unless all the coefficients  $a_1, \dots, a_{k+1}$  are 0. It now follows that the determinant cannot be 0.

9. The normal equations (11.1.13) are found to be

$$\begin{aligned} 10\beta_0 + 1170\beta_1 + 18\beta_2 &= 1359, \\ 1170\beta_0 + 138,100\beta_1 + 2130\beta_2 &= 160,380, \\ 18\beta_0 + 2130\beta_1 + 38\beta_2 &= 2483. \end{aligned}$$

Solving these three simultaneous linear equations, we obtain the solution  $\hat{\beta}_0 = 3.7148$ ,  $\hat{\beta}_1 = 1.1013$ , and  $\hat{\beta}_2 = 1.8517$ .

10. We begin by taking the partial derivative of the following sum with respect to  $\beta_0$ ,  $\beta_1$ , and  $\beta_2$ , respectively:

$$\sum_{i=1}^n (y_i - \beta_0 x_{i1} - \beta_1 x_{i2} - \beta_2 x_{i2}^2)^2.$$

By setting each of these derivatives equal to 0, we obtain the following normal equations:

$$\begin{aligned} \beta_0 \sum_{i=1}^n x_{i1}^2 + \beta_1 \sum_{i=1}^n x_{i1} x_{i2} + \beta_2 \sum_{i=1}^n x_{i1} x_{i2}^2 &= \sum_{i=1}^n x_{i1} y_i, \\ \beta_0 \sum_{i=1}^n x_{i1} x_{i2} + \beta_1 \sum_{i=1}^n x_{i2}^2 + \beta_2 \sum_{i=1}^n x_{i2}^3 &= \sum_{i=1}^n x_{i2} y_i, \\ \beta_0 \sum_{i=1}^n x_{i1} x_{i2}^2 + \beta_1 \sum_{i=1}^n x_{i2}^3 + \beta_2 \sum_{i=1}^n x_{i2}^4 &= \sum_{i=1}^n x_{i2}^2 y_i. \end{aligned}$$

When the given numerical data are used, these equations are found to be:

$$\begin{aligned} 138,100\beta_0 + 2130\beta_1 + 4550\beta_2 &= 160,380, \\ 2130\beta_0 + 38\beta_1 + 90\beta_2 &= 2483, \\ 4550\beta_0 + 90\beta_1 + 230\beta_2 &= 5305. \end{aligned}$$

Solving these three simultaneous linear equations, we obtain the solution  $\hat{\beta}_0 = 1.0270$ ,  $\hat{\beta}_1 = 17.2934$ , and  $\hat{\beta}_2 = -4.0186$ .

11. In Exercise 9, it is found that

$$\sum_{i=1}^{10} (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_{i1} - \hat{\beta}_2 x_{i2})^2 = 102.28.$$

In Exercise 10, it is found that

$$\sum_{i=1}^{10} (y_i - \hat{\beta}_0 x_{i1} - \hat{\beta}_1 x_{i2} - \hat{\beta}_2 x_{i2}^2)^2 = 42.72.$$

Therefore, a better fit is obtained in Exercise 10.

## 11.2 Regression

### Commentary

The regression fallacy is an interesting issue that students ought to see. The description of the regression fallacy appears in Exercise 19 of this section. The discussion at the end of the section on “Design of the Experiment” is mostly of mathematical interest and could be skipped without disrupting the flow of material.

If one is using the software *R*, the variances and covariance of the least-squares estimators can be computed using the function `ls.diag` or the function `summary.lm`. The first takes as argument the result of `lsfit`, and the second takes as argument the result of `lm`. Both functions return a list containing a matrix that can be extracted via `$cov.unscaled`. For example, using the notation in the Commentary to Sec. 11.1 above, if we had used `lsfit`, then `morefit=ls.diag(regfit)` would contain the matrix `morefit$cov.unscaled`. This matrix, multiplied by the unknown parameter  $\sigma^2$ , would contain the variances of the least-squares estimators on its diagonal and the covariances between them in the off-diagonal locations. (If we had used `lm`, then `morefit=summary.lm(regfit)` would be used.)

### Solutions to Exercises

1. After we have replaced  $\beta_0$  and  $\beta_1$  in (11.2.2) with  $\hat{\beta}_0$  and  $\hat{\beta}_1$ , the maximization with respect to  $\sigma^2$  is exactly the same as the maximization carried out in Example 7.5.6 in the text for finding the M.L.E. of  $\sigma^2$ .
2. Since  $E(Y_i) = \beta_0 + \beta_1 x_i$ , it follows from Eq. (11.2.7) that

$$E(\hat{\beta}_1) = \frac{\sum_{i=1}^n (x_i - \bar{x}_n)(\beta_0 + \beta_1 x_i)}{\sum_{i=1}^n (x_i - \bar{x}_n)^2} = \frac{\beta_0 \sum_{i=1}^n (x_i - \bar{x}_n) + \beta_1 \sum_{i=1}^n x_i(x_i - \bar{x}_n)}{\sum_{i=1}^n (x_i - \bar{x}_n)^2}.$$

But  $\sum_{i=1}^n (x_i - \bar{x}_n) = 0$  and

$$\sum_{i=1}^n x_i(x_i - \bar{x}_n) = \sum_{i=1}^n x_i(x_i - \bar{x}_n) - \bar{x}_n \sum_{i=1}^n (x_i - \bar{x}_n) = \sum_{i=1}^n (x_i - \bar{x}_n)^2.$$

It follows that  $E(\hat{\beta}_1) = \beta_1$ .

3.  $E(\bar{Y}_n) = \frac{1}{n} \sum_{i=1}^n E(Y_i) = \frac{1}{n} \sum_{i=1}^n (\beta_0 + \beta_1 x_i) = \beta_0 + \beta_1 \bar{x}_n$ .

Hence, as shown near the end of the proof of Theorem 11.2.2,

$$E(\hat{\beta}_0) = E(\bar{Y}_n) - \bar{x}_n E(\hat{\beta}_1) = (\beta_0 + \beta_1 \bar{x}_n) - \bar{x}_n \beta_1 = \beta_0.$$

4. Let  $s_x^2 = \sum_{i=1}^n (x_i - \bar{x}_n)^2$ . Then

$$\hat{\beta}_0 = \bar{Y}_n - \hat{\beta}_1 \bar{x}_n = \frac{1}{n} \sum_{i=1}^n Y_i - \bar{x}_n \frac{\sum_{i=1}^n (x_i - \bar{x}_n) Y_i}{s_x^2} = \sum_{i=1}^n \left[ \frac{1}{n} - \frac{\bar{x}_n (x_i - \bar{x}_n)}{s_x^2} \right] Y_i.$$

Since  $Y_1, \dots, Y_n$  are independent and each has variance  $\sigma^2$ ,

$$\begin{aligned}\text{Var}(\hat{\beta}_0) &= \sum_{i=1}^n \left[ \frac{1}{n} - \frac{\bar{x}_n}{s_x^2} (x_i - \bar{x}_n) \right]^2 \text{Var}(Y_i) \\ &= \sigma^2 \sum_{i=1}^n \left[ \frac{1}{n^2} + \frac{\bar{x}_n^2}{s_x^4} (x_i - \bar{x}_n)^2 - \frac{2\bar{x}_n}{ns_x^2} (x_i - \bar{x}_n) \right] \\ &= \sigma^2 \left( \frac{1}{n} + \frac{\bar{x}_n^2}{s_x^2} - 0 \right) = \frac{s_x^2 + n\bar{x}_n^2}{ns_x^2} \sigma^2 = \frac{\sum_{i=1}^n x_i^2}{ns_x^2} \sigma^2,\end{aligned}$$

as shown in part (a) of Exercise 2 of Sec. 11.1.

5. Since  $\bar{Y}_n = \hat{\beta}_0 + \hat{\beta}_1 \bar{x}_n$ , then

$$\text{Var}(\bar{Y}_n) = \text{Var}(\hat{\beta}_0) + \bar{x}_n^2 \text{Var}(\hat{\beta}_1) + 2\bar{x}_n \text{Cov}(\hat{\beta}_0, \hat{\beta}_1).$$

Therefore, if  $\bar{x}_n \neq 0$ ,

$$\begin{aligned}\text{Cov}(\hat{\beta}_0, \hat{\beta}_1) &= \frac{1}{2\bar{x}_n} \left[ \text{Var}(\bar{Y}_n) - \text{Var}(\hat{\beta}_0) - \bar{x}_n^2 \text{Var}(\hat{\beta}_1) \right] \\ &= \frac{1}{2\bar{x}_n} \left( \frac{\sigma^2}{n} - \frac{\sum_{i=1}^n x_i^2}{ns_x^2} \sigma^2 - \frac{\bar{x}_n^2}{s_x^2} \sigma^2 \right) \\ &= \frac{\sigma^2}{2\bar{x}_n} \left( \frac{s_x^2 - \sum_{i=1}^n x_i^2 - n\bar{x}_n^2}{ns_x^2} \right) \\ &= \frac{\sigma^2}{2\bar{x}_n} \left( \frac{-2n\bar{x}_n^2}{ns_x^2} \right) = \frac{-\bar{x}_n \sigma^2}{s_x^2}.\end{aligned}$$

If  $\bar{x}_n = 0$ , then  $\hat{\beta}_0 = \bar{Y}_n = \frac{1}{n} \sum_{i=1}^n Y_i$ , and

$$\text{Cov}(\hat{\beta}_0, \hat{\beta}_1) = \text{Cov} \left( \frac{1}{n} \sum_{i=1}^n Y_i, \frac{1}{s_x^2} \sum_{j=1}^n x_j Y_j \right) = \frac{1}{ns_x^2} \sum_{i=1}^n \sum_{j=1}^n x_j \text{Cov}(Y_i, Y_j),$$

by Exercise 8 of Sec. 4.6. Since  $Y_1, \dots, Y_n$  are independent and each has variance  $\sigma^2$ , then  $\text{Cov}(Y_i, Y_j) = 0$  for  $i \neq j$  and  $\text{Cov}(Y_i, Y_j) = \sigma^2$  for  $i = j$ .

Hence,

$$\text{Cov}(\hat{\beta}_0, \hat{\beta}_1) = \frac{\sigma^2}{ns_x^2} \sum_{i=1}^n x_i = 0.$$

6. Both  $\hat{\beta}_0$  and  $\hat{\beta}_1$  are linear functions of the random variables  $Y_1, \dots, Y_n$  which are independent and have identical normal distributions. As stated in the text, it can therefore be shown that the joint distribution of  $\hat{\beta}_0$  and  $\hat{\beta}_1$  is a bivariate normal distribution. It follows from Eq. (11.2.6) that  $\hat{\beta}_0$  and  $\hat{\beta}_1$  are uncorrelated when  $\bar{x}_n = 0$ . Therefore, by the property of the bivariate normal distribution discussed in Sec. 5.10,  $\hat{\beta}_0$  and  $\hat{\beta}_1$  are independent when  $\bar{x}_n = 0$ .
7. (a) The M.L.E.'s  $\hat{\beta}_0$  and  $\hat{\beta}_1$  are the same as the least squares estimates found in Sec. 11.1 for Table 11.1. The value of  $\hat{\sigma}^2$  can then be found from Eq. (11.2.3).  
(b) Also,  $\text{Var}(\hat{\beta}_0) = 0.2505\sigma^2$  can be determined from Eq. (11.2.5) and  $\text{Var}(\hat{\beta}_1) = 0.0277\sigma^2$  from Eq. (11.2.9).  
(c) It can be found from Eq. (11.2.6) that  $\text{Cov}(\hat{\beta}_0, \hat{\beta}_1) = -0.0646\sigma^2$ . By using the values of  $\text{Var}(\hat{\beta}_0)$  and  $\text{Var}(\hat{\beta}_1)$  found in part (b), we obtain

$$\rho(\hat{\beta}_0, \hat{\beta}_1) = \frac{\text{Cov}(\hat{\beta}_0, \hat{\beta}_1)}{[\text{Var}(\hat{\beta}_0) \text{Var}(\hat{\beta}_1)]^{1/2}} = -0.775.$$

8.  $\hat{\theta} = 3\hat{\beta}_0 - 2\hat{\beta}_1 + 5 = 1.272$ . Since  $\hat{\theta}$  is an unbiased estimator of  $\theta$ , the M.S.E. of  $\hat{\theta}$  is the same as  $\text{Var}(\hat{\theta})$  and

$$\text{Var}(\hat{\theta}) = 9\text{Var}(\hat{\beta}_0) + 4\text{Var}(\hat{\beta}_1) - 12\text{Cov}(\hat{\beta}_0, \hat{\beta}_1) = 3.140\sigma^2.$$

9. The unbiased estimator is  $3\hat{\beta}_0 + c_1\hat{\beta}_1$ . The M.S.E. of an unbiased estimator is its variance, and

$$\text{Var}(\hat{\theta}) = 9\text{Var}(\hat{\beta}_0) + 6c_1\text{Cov}(\hat{\beta}_0, \hat{\beta}_1) + c_1^2\text{Var}(\hat{\beta}_1).$$

Using the values in Exercise 7, we get

$$\text{Var}(\hat{\theta}) = \sigma^2[9 \times 0.2505 - 6c_1(0.0646) + c_1^20.0277].$$

We can minimize this by taking the derivative with respect to  $c_1$  and setting the derivative equal to 0. We get  $c_1 = 6.996$ .

10. The prediction is  $\hat{Y} = \hat{\beta}_0 + 2\hat{\beta}_1 = 0.584$ . The M.S.E. of this prediction is

$$\text{Var}(\hat{Y}) + \text{Var}(Y) = \text{Var}(\hat{\beta}_0) + 4\text{Var}(\hat{\beta}_1) + 4\text{Cov}(\hat{\beta}_0, \hat{\beta}_1) + \sigma^2 = 1.103\sigma^2.$$

Alternatively, the M.S.E. of  $\hat{Y}$  could be calculated from Eq. (11.2.11) with  $x = 2$ .

11. By Eq. (11.2.11), the M.S.E. is

$$\left[ \frac{1}{ns_x^2} \sum_{i=1}^n (x_i - x)^2 + 1 \right] \sigma^2.$$

We know that  $\sum_{i=1}^n (x_i - x)^2$  will be a minimum (and, hence, the M.S.E. will be a minimum) when  $x = \bar{x}_n$ .

12. The M.L.E.'s  $\hat{\beta}_0$  and  $\hat{\beta}_1$  have the same values as this least squares estimates found in part (a) of Exercise 7 of Sec. 11.1. The value of  $\hat{\sigma}^2$  can then be found from Eq. (11.2.3). Also,  $\text{Var}(\hat{\beta}_0)$  can be determined from Eq. (11.2.5) and  $\text{Var}(\hat{\beta}_1)$  from Eq. (11.2.9).

13. It can be found from Eq. (11.2.6) that  $\text{Cov}(\hat{\beta}_0, \hat{\beta}_1) = -0.214\sigma^2$ . By using the values of  $\text{Var}(\hat{\beta}_0)$  and  $\text{Var}(\hat{\beta}_1)$  found in Exercise 12, we obtain

$$\rho(\hat{\beta}_0, \hat{\beta}_1) = \frac{\text{Cov}(\hat{\beta}_0, \hat{\beta}_1)}{[\text{Var}(\hat{\beta}_0) \text{Var}(\hat{\beta}_1)]^{1/2}} = -0.891.$$

14.  $\hat{\theta} = 5 - 4\hat{\beta}_0 + \hat{\beta}_1 = -158.024$ . Since  $\hat{\theta}$  is an unbiased estimator of  $\theta$ , the M.S.E. is the same as  $\text{Var}(\hat{\theta})$  and

$$\text{Var}(\hat{\theta}) = 16 \text{Var}(\hat{\beta}_0) + \text{Var}(\hat{\beta}_1) - 8 \text{Cov}(\hat{\beta}_0, \hat{\beta}_1) = 11.524\sigma^2.$$

15. This exercise, is similar to Exercise 9.  $\text{Var}(\hat{\theta})$  attains its minimum value when  $c_1 = -\bar{x}_n$ .

16. The prediction is  $\hat{Y} = \hat{\beta}_0 + 3.25\hat{\beta}_1 = 42.673$ . The M.S.E. of this prediction is

$$\text{Var}(\hat{Y}) + \text{Var}(Y) = \text{Var}(\hat{\beta}_0) + (3.25)^2 \text{Var}(\hat{\beta}_1) + 6.50 \text{Cov}(\hat{\beta}_0, \hat{\beta}_1) + \sigma^2 = 1.220\sigma^2.$$

Alternatively, the M.S.E. of  $\hat{Y}$  could be calculated from Eq. (11.2.11) with  $x = 3.25$ .

17. It was shown in Exercise 11, that the M.S.E. of  $\hat{Y}$  will be a minimum when  $x = \bar{x}_n = 2.25$ .

18. (a) It is easiest to use a computer to find the least-squares coefficients. These are  $\hat{\beta}_0 = -1.234$  and  $\hat{\beta}_1 = 2.702$ .

- (b) The predicted 1980 selling price for a species that sold for  $x = 21.4$  in 1970 is

$$\hat{\beta}_0 + \hat{\beta}_1 x = -1.234 + 2.702 \times 21.4 = 56.59.$$

- (c) The average of the  $x_i$  values is 41.1, and  $s_x^2 = 18430$ . Use Eq. (11.2.11) to compute the M.S.E. as

$$\sigma^2 \left[ 1 + \frac{1}{14} + \frac{(21.4 - 41.1)^2}{18430} \right] = 1.093\sigma^2.$$

19. The formula for  $E(X_2|x_1)$  is Eq. (5.10.6), which we repeat here for the case in which  $\mu_1 = \mu_2 = \mu$  and  $\sigma_1 = \sigma_2 = \sigma$ :

$$E(X_2|x_1) = \mu + \rho\sigma \left( \frac{x_1 - \mu}{\sigma} \right) = \mu + \rho(x_1 - \mu).$$

We are asked to show that  $|E(X_2|x_1) - \mu| < |x_1 - \mu|$  for all  $x_1$ . Since  $0 < \rho < 1$ ,

$$|E(X_2|x_1) - \mu| = |\mu + \rho(x_1 - \mu) - \mu| = \rho|x_1 - \mu| < |x_1 - \mu|.$$

## 11.3 Statistical Inference in Simple Linear Regression

### Commentary

Computation and plotting of residuals is really only feasible with the help of a computer, except in problems that are so small that you can't learn much from residuals anyway. There is a subsection at the end of this section on joint inference about  $\beta_0$  and  $\beta_1$ . This material is mathematically more challenging than the rest of the section and might be suitable only for special sets of students.

If one is using the software *R*, both `lm` and `lsfit` provide the residuals. These can then be plotted against any other available variables using `plot`. Normal quantile plots are done easily using `qqnorm` with one argument being the residuals. The function `qqline` (with the same argument) will add a straight line to the plot to help identify curvature and outliers.

## Solutions to Exercises

1. It is found from Table 11.9 that  $\bar{x}_n = 0.42$ ,  $\bar{y}_n = 0.33$ ,  $\sum_{i=1}^n x_i^2 = 10.16$ ,  $\sum_{i=1}^n x_i y_i = 5.04$ ,  $\hat{\beta}_1 = 0.435$  and  $\hat{\beta}_0 = 0.147$  by Eq. (11.1.1), and  $S^2 = 0.451$  by Eq. (11.3.9). Therefore, from Eq. (11.3.19) with  $n = 10$  and  $\beta_0^* = 0.7$ , it is found that  $U_0 = -6.695$ . It is found from a table of the  $t$  distribution with  $n - 2 = 8$  degrees of freedom that to carry out a test at the 0.05 level of significance,  $H_0$  should be rejected if  $|U_0| > 2.306$ . Therefore  $H_0$  is rejected.

2. In this exercise, we must test the following hypotheses:

$$\begin{aligned} H_0 : \beta_0 &= 0, \\ H_1 : \beta_0 &\neq 0. \end{aligned}$$

Hence,  $\beta_0^* = 0$  and it is found from Eq. (11.3.19) that  $U_0 = 1.783$ . Since  $|U_0| < 2.306$ , the critical value found in Exercise 1, we should not reject  $H_0$ .

3. It follows from Eq. (11.3.22), with  $\beta_1^* = 1$ , that  $U_1 = -6.894$ . Since  $|U_1| > 2.306$ , the critical value found in Exercise 1, we should reject  $H_0$ .

4. In this exercise, we want to test the following hypotheses:

$$\begin{aligned} H_0 : \beta_1 &= 0, \\ H_1 : \beta_1 &\neq 0. \end{aligned}$$

Hence,  $\beta_1^* = 0$  and it is found from Eq. (11.3.22) that  $U_1 = 5.313$ . Since  $|U_1| > 2.306$ , we should reject  $H_0$ .

5. The hypotheses to be tested are:

$$\begin{aligned} H_0 : 5\beta_0 - \beta_1 &= 0, \\ H_1 : 5\beta_0 - \beta_1 &\neq 0. \end{aligned}$$

Hence, in the notation of (11.3.13),  $c_0 = 5$ ,  $c_1 = -1$ , and  $c_* = 0$ . It is found that  $\sum_{i=1}^n (c_0 x_i - c_1)^2 = 306$  and, from Eq. (11.3.14), that  $U_{01} = 0.664$ . It is found from a table of the  $t$  distribution with  $n - 2 = 8$  degrees of freedom that to carry out a test at the 0.10 level of significance,  $H_0$  should be rejected if  $|U_{01}| > 1.860$ . Therefore,  $H_0$  is not rejected.

6. The hypotheses to be tested are:

$$\begin{aligned} H_0 : \beta_0 + \beta_1 &= 1, \\ H_1 : \beta_0 + \beta_1 &\neq 1. \end{aligned}$$

Therefore,  $c_0 = c_1 = c_* = 1$ . It is found that  $\sum_{i=1}^n (c_0 x_i - c_1)^2 = 11.76$  and, from Eq. (11.3.14), that  $U_{01} = -4.701$ . It is found from a table of the  $t$  distribution with  $n - 2 = 8$  degrees of freedom that to carry out a test at the 0.10 level of significance,  $H_0$  should be rejected if  $|U_{01}| > 3.355$ . Therefore,  $H_0$  is rejected.

7.

$$\begin{aligned}
 \text{Cov}(\hat{\beta}_1, D) &= \text{Cov}(\hat{\beta}_1, \hat{\beta}_0 + \hat{\beta}_1 \bar{x}_n) \\
 &= \text{Cov}(\hat{\beta}_1, \hat{\beta}_0) + \bar{x}_n \text{Cov}(\hat{\beta}_1, \hat{\beta}_1) \\
 &= \text{Cov}(\hat{\beta}_0, \hat{\beta}_1) + \bar{x}_n \text{Var}(\hat{\beta}_1) \\
 &= 0, \text{ by Eqs. (11.2.9) and (11.2.6).}
 \end{aligned}$$

Since  $\hat{\beta}_0$  and  $\hat{\beta}_1$  have a bivariate normal distribution, it follows from Exercise 10 of Sec. 5.10 that  $D$  and  $\hat{\beta}_1$  will also have a bivariate normal distribution. Therefore, as discussed in Sec. 5.10, since  $D$  and  $\hat{\beta}_1$  are uncorrelated they are also independent.

8. (a) We shall add  $n\bar{x}_n^2(\hat{\beta}_1 - \hat{\beta}_1^*)^2$  and subtract the same amount to the right side of  $Q^2$ , as given by Eq. (11.3.30). The  $Q^2$  can be rewritten as follows:

$$\begin{aligned}
 Q^2 &= \left( \sum_{i=1}^n x_i^2 - n\bar{x}_n^2 \right) (\hat{\beta}_1 - \beta_1^*)^2 + n[(\hat{\beta}_0 - \beta_0^*)^2 + 2\bar{x}_n(\hat{\beta}_0 - \beta_0^*)(\hat{\beta}_1 - \beta_1^*) + \bar{x}_n^2(\hat{\beta}_1 - \beta_1^*)^2] \\
 &= \sigma^2 \frac{(\hat{\beta}_1 - \beta_1^*)^2}{\text{Var}(\hat{\beta}_1)} + n[(\hat{\beta}_0 - \beta_0^*) + \bar{x}_n(\hat{\beta}_1 - \beta_1^*)]^2.
 \end{aligned}$$

Hence,

$$\frac{Q^2}{\sigma^2} = \frac{(\hat{\beta}_1 - \beta_1^*)^2}{\text{Var}(\hat{\beta}_1)} + \frac{n}{\sigma^2}(D - \beta_0^* - \beta_1^*\bar{x}_n)^2.$$

It remains to show that  $\text{Var}(D) = \frac{\sigma^2}{n}$ . But

$$\text{Var}(D) = \text{Var}(\hat{\beta}_0) + \bar{x}_n^2 \text{Var}(\hat{\beta}_1) + 2\bar{x}_n \text{Cov}(\hat{\beta}_0, \hat{\beta}_1).$$

The desired result can now be obtained from Eqs. (11.2.9), (11.2.5), and (11.2.6).

- (b) It follows from Exercise 7 that the random variables  $\hat{\beta}_1$  and  $D$  are independent and each has a normal distribution. When  $H_0$  is true,  $E(\hat{\beta}_1) = \beta_1^*$  and  $E(D) = \beta_0^* + \beta_1^*\bar{x}_n$ . Hence,  $H_0$  is true, each of the two summands on the right side of the equation given in part (a) is the square of a random variable having a standard normal distribution.
9. Here,  $\beta_0^* = 0$  and  $\beta_1^* = 1$ . It is found that  $Q^2 = 2.759$ ,  $S^2 = 0.451$ , and  $U^2 = 24.48$ . It is found from a table of the  $F$  distribution with 2 and 8 degrees of freedom that to carry out a test at the 0.05 level of significance,  $H_0$  should be rejected if  $U^2 > 4.46$ . Therefore,  $H_0$  is rejected.
10. To attain a confidence coefficient of 0.95, it is found from a table of the  $t$  distribution with 8 degrees of freedom that the confidence interval will contain all values of  $\beta_0^*$  for which  $|U_0| < 2.306$ . When we use the numerical values found in Exercise 1, we find that this is the interval of all values of  $\beta_0^*$  such that  $-2.306 < 12.111(0.147 - \beta_0^*) < 2.306$  or, equivalently,  $-0.043 < \beta_0^* < 0.338$ . This interval is, therefore, the confidence interval for  $\beta_0$ .
11. The solution here is analogous to the solution of Exercise 9. Since the confidence coefficient is again 0.95, the confidence interval will contain all values of  $\beta_1^*$  for which  $|U_1| < 2.306$  or, equivalently, for which  $-2.306 < 12.207(0.435 - \beta_1^*) < 2.306$ . The interval is, therefore, found to be  $0.246 < \beta_1 < 0.624$ .
12. We shall first determine a confidence interval for  $5\beta_0 - \beta_1$  with confidence coefficient 0.90. It is found from a table of the  $t$  distribution with 8 degrees of freedom (as in Exercise 5) that this confidence interval will contain all values of  $c_*$  for which  $|U_{01}| < 1.860$  or, equivalently, for which  $-1.860 <$

$2.207(0.301 - c_*) < 1.860$ . This interval reduces to  $-0.542 < c_* < 1.144$ . Since this is a confidence interval for  $5\beta_0 - \beta_1$ , the corresponding confidence interval for  $5\beta_0 - \beta_1 + 4$  is the interval with end points  $(-0.542) + 4 = 3.458$  and  $(1.144) + 4 = 5.144$ .

13. We must determine a confidence interval for  $y = \beta_0 + \beta_1$  with confidence coefficient 0.99. It is found from a table of the  $t$  distribution with 8 degrees of freedom (as in Exercise 6) that this confidence interval will contain all values of  $c_*$  for which  $|U_{01}| < 3.355$  or, equivalently, for which  $-3.355 < 11.257(0.582 - b) < 3.355$ . This interval reduces to  $0.284 < c_* < 0.880$ . This interval is, therefore, the confidence interval for  $y$ .
14. We must determine a confidence interval for  $y = \beta_0 + 0.42\beta_1$ . Since the confidence coefficient is again 0.99, as in Exercise 13, this interval will again contain all values of  $c_*$  for which  $|U_{01}| < 3.355$ . Since  $c_0 = 1$  and  $c_1 = 0.42 = \bar{x}_n$  in this exercise, the value of  $\sum_{i=1}^n (c_0 x_i - c_1)^2$ , which is needed in determining  $U_{01}$ , is equal to  $\sum_{i=1}^n (x_i - \bar{x}_n)^2 = 8.396$ . Also,  $c_0 \hat{\beta}_0 + c_1 \hat{\beta}_1 = \hat{\beta}_0 + \hat{\beta}_1$ ,  $\bar{x}_n = \bar{y}_n = 0.33$ . Hence it is found that the confidence interval for  $y$  contains all values of  $c_*$  for which  $-3.355 < 13.322(0.33 - c_*) < 3.355$  or, equivalently, for which  $0.078 < c_* < 0.582$ .
15. Let  $q$  be the  $1 - \alpha_0/2$  quantile of the  $t$  distribution  $n - 2$  degrees of freedom. A confidence interval for  $\beta_0 + \beta_1 x$  contains all values of  $c_*$  for which  $|U_{01}| < c$ , where  $c_0 = 1$  and  $c_1 = x$  in Eq. (11.3.14). The inequality  $|U_{01}| < q$  can be reduced to the following form

$$\hat{\beta}_0 + x \hat{\beta}_1 - q \left[ \frac{S^2 \sum_{i=1}^n (x_i - x)^2}{n(n-2)s_x^2} \right]^{1/2} < b < \hat{\beta}_0 + x \hat{\beta}_1 + q \left[ \frac{S^2 \sum_{i=1}^n (x_i - x)^2}{n(n-2)s_x^2} \right]^{1/2}$$

The length of this interval is

$$2q \left[ \frac{S^2}{n(n-2)s_x^2} \sum_{i=1}^n (x_i - x)^2 \right]^{1/2}$$

The length will, therefore, be a minimum for the value of  $x$  which minimizes  $\sum_{i=1}^n (x_i - x)^2$ . We know that this quantity is a minimum when  $x = \bar{x}_n$ .

16. It is known from elementary calculus that the set of points  $(x, y)$  which satisfy an inequality of the form  $Ax^2 + Bxy + Cy^2 < c^2$  will be an ellipse (with center at the origin) if and only if  $B^2 - 4AC < 0$ . It follows from Eqs. (11.3.30) and (11.3.32) that  $U^2 < \gamma$  if and only if

$$n(\beta_0^* - \hat{\beta}_0)^2 + 2n\bar{x}_n(\beta_0^* - \hat{\beta}_0)(\beta_1^* - \hat{\beta}_1) + \left( \sum_{i=1}^n x_i^2 \right) (\beta_1^* - \hat{\beta}_1)^2 < \gamma \frac{2}{n-2} S^2.$$

Hence, the set of points  $(\beta_0^*, \beta_1^*)$  which satisfy this inequality will be an ellipse [with center at  $(\hat{\beta}_0, \hat{\beta}_1)$ ] if and only if

$$(2n\bar{x}_n)^2 - 4n \sum_{i=1}^n x_i^2 < 0$$

or, equivalently, if and only if

$$\sum_{i=1}^n x_i^2 - n\bar{x}_n^2 > 0.$$

Since the left side of this relation is equal to  $\sum_{i=1}^n (x_i - \bar{x}_n)^2$ , it must be positive, assuming that the numbers  $x_1, \dots, x_n$  are not all the same.

17. To attain a confidence coefficient of 0.95, it is found from a table of the  $F$  distribution with 2 and 8 degrees of freedom (as in Exercise 9) that the confidence ellipse for  $(\beta_0, \beta_1)$  will contain all points  $(\beta_0^*, \beta_1^*)$  for which  $U^2 < 4.46$ . Hence, it will contain all points for which

$$10(\beta_0^* - 0.147)^2 + 8.4(\beta_0^* - 0.147)(\beta_1^* - 0.435) + 10.16(\beta_1^* - 0.435)^2 < 0.503.$$

18. (a) The upper and lower limits of the confidence band are defined by (11.3.33). In this exercise,  $n = 10$  and  $(2\gamma)^{1/2} = 2.987$ . The values of  $\hat{\beta}_0$ ,  $\hat{\beta}_1$ , and  $S^2$  have been found in Exercise 1.

Numerical computation yields the following points on the upper and lower limits of the confidence band:

$x$	Upper limit	Lower limit
-2	-0.090	-1.356
-1	.124	-.700
0	.395	-.101
$\bar{x}_n = 0.42$	.554	.106
1	.848	.316
2	1.465	.569

The upper and lower limits containing these points are shown as the solid curves in Fig. S.11.1.

- (b) The upper and lower limits are now given by (11.3.25), where  $T_{n-2}(1 - \alpha_0/2) = 2.306$ . The corresponding values of these upper and lower limits are as follows:

$x$	Upper limit	Lower limit
-2	-.234	-1.212
-1	.030	-.606
0	.338	-.044
$\bar{x}_n = 0.42$	.503	.157
1	.787	.377
2	1.363	.671

These upper and lower limits are shown as the dashed curves in Fig. S.11.1.

19. If  $S^2$  is defined by Eq. (11.3.9), then  $S^2/\sigma^2$  has a  $\chi^2$  distribution with  $n - 2$  degrees of freedom. Therefore,  $E(S^2/\sigma^2) = n - 2$ ,  $E(S^2) = (n - 2)\sigma^2$ , and  $E(S^2/[n - 2]) = \sigma^2$ .
20. (a) The prediction is  $\hat{\beta}_0 + \hat{\beta}_1 X = 68.17 - 1.112 \times 24 = 41.482$ .
- (b) The 95% prediction interval is centered at the prediction from part (a) and has half-width equal to

$$T_{30}^{-1}(0.975)4.281 \left[ 1 + \frac{1}{32} + \frac{(24 - 30.91)^2}{2054.8} \right]^{1/2} = 8.978.$$

So, the interval is  $41.482 \pm 8.978 = [32.50, 50.46]$ .

Figure S.11.1: Confidence bands and intervals for Exercise 18a in Sec. 11.3.

21. (a) A computer is useful to perform the regressions and plots for this exercise. The two plots for parts (a) and (b) are side-by-side in Fig. S.11.2. The plot for part (a) shows residuals that are more spread out for larger values of 1970 price than they are for smaller values. This suggests that the variance of  $Y$  is not constant as  $X$  changes.
- (b) The plot for part (b) in Fig. S.11.2 has more uniform spread in the residuals as 1970 price varies. However, there appear to be two points that are not fit very well.

22. In this problem we are asked to regress logarithm of 1980 fish price on the 1970 fish price. (It would have made more sense to regress on the logarithm of 1970 fish price, but the problem didn't ask for that.) The summary of the regression fit is  $\hat{\beta}_0 = 3.099$ ,  $\hat{\beta}_1 = 0.0266$ ,  $\sigma' = 0.6641$ ,  $\bar{x}_n = 41.1$ , and  $s_x^2 = 18430$ .

- (a) The test statistic is given in Eq. (11.3.22),

$$U = s_x \frac{\hat{\beta}_1 - 2}{\sigma'} = 135.8 \frac{0.0266 - 2}{0.6641} = -403.5.$$

We would reject  $H_0$  at level 0.01 if  $U$  is greater than the 0.99 quantile of the  $t$  distribution with 12 degrees of freedom. We do not reject the null hypothesis at level 0.01.

- (b) A 90% confidence interval is centered at 0.0266 and has half-width equal to

$$T_{12}^{-1}(0.95) \frac{\sigma'}{s_x} = 1.782 \frac{0.6641}{135.8} = 0.00872.$$

So, the interval is  $0.0266 \pm 0.00872 = [0.0179, 0.0353]$ .

Figure S.11.2: Residual plots for Exercise 21a of Sec. 11.3. The plot on the left is for part (a) and the plot on the right is for part (b).

- (c) A 90% prediction interval for the logarithm of 1980 price is centered at  $3.099 + 0.0266 \times 21.4 = 3.668$  and has half-width equal to

$$\begin{aligned} T_{12}^{-1}(0.95)\sigma' \left[ 1 + \frac{1}{n} + \frac{(x - \bar{x}_n)^2}{s_x^2} \right]^{1/2} &= 1.782 \times 0.6641 \left[ 1 + \frac{1}{14} + \frac{(21.4 - 41.1)^2}{18430} \right]^{1/2} \\ &= 1.237. \end{aligned}$$

So, the interval for the logarithm of 1980 price is  $3.668 \pm 1.237 = [2.431, 4.905]$ . To convert this to 1980 price take  $e$  to the power of both endpoints to get  $[11.37, 134.96]$ .

If we had been asked to regress on the logarithm of 1970 fish price, the summary results would have been  $\hat{\beta}_0 = 1.132$ ,  $\hat{\beta}_1 = 0.9547$ ,  $\sigma' = 0.2776$ ,  $\bar{x}_n = 3.206$ , and  $s_x^2 = 19.11$ . The test statistic for part (a) would have been  $4.371(0.9547 - 2)/0.2776 = -16.46$ . Still, we would not reject the null hypothesis at level 0.01. The confidence interval for  $\beta_1$  would have been  $0.9547 \pm 1.782(0.2776/4.371) = [0.8415, 1.067]$ . The prediction interval for the logarithm of price would have been

$$1.132 + 0.9547 \log(21.4) \pm 0.2776 \left( 1 + \frac{1}{14} + \frac{(\log(21.4) - 3.206)^2}{19.11} \right)^{1/2} = [3.769, 4.344].$$

The interval for 1980 price would then be  $[43.34, 77.02]$ .

23. Define

$$W_{01} = \left[ \frac{c_0^2}{n} + \frac{(c_0 \bar{x}_n - c_1)^2}{s_x^2} \right]^{-1/2} \frac{c_0(\hat{\beta}_0 - \beta_0) + c_2(\hat{\beta}_1 - \beta_1)}{\sigma'},$$

which has the  $t$  distribution with  $n - 2$  degrees of freedom. Hence

$$\Pr(W_{01} \geq T_{n-2}^{-1}(1 - \alpha_0)) = \alpha_0.$$

Suppose that  $c_0\beta_0 + c_1\beta_1 < c_*$ . Because  $[(c_0^2/n) + (c_0 \bar{x}_n - c_1)^2/s_x^2]/\sigma' > 0$ , it follows that  $W_{01} > U_{01}$ . Finally, the probability of type I error is

$$\Pr(U_{01} \geq T_{n-2}^{-1}(1 - \alpha_0)) \leq \Pr(W_{01} \geq T_{n-2}^{-1}(1 - \alpha_0)) = \alpha_0,$$

where the first inequality follows from  $W_{01} > U_{01}$ .

24. (a) When  $c_0 = 1$  and  $c_1 = x > 0$ , the smallest possible value of  $\beta_0^* + x\beta_1^*$  occurs at the smallest values of  $\beta_0^*$  and  $\beta_1^*$  simultaneously. These values are

$$\begin{aligned}\hat{\beta}_0 - \sigma' \left[ \frac{1}{n} + \frac{\bar{x}_n^2}{s_x^2} \right]^{1/2} T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{4} \right), \\ \hat{\beta}_1 - \frac{\sigma'}{s_x} T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{4} \right).\end{aligned}$$

Similarly, the largest values occur when  $\beta_0^*$  and  $\beta_1^*$  both take their largest possible values, namely

$$\begin{aligned}\hat{\beta}_0 + \sigma' \left[ \frac{1}{n} + \frac{\bar{x}_n^2}{s_x^2} \right]^{1/2} T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{4} \right), \\ \hat{\beta}_1 + \frac{\sigma'}{s_x} T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{4} \right).\end{aligned}$$

The confidence interval is then

$$\begin{aligned}\left( \hat{\beta}_0 + \hat{\beta}_1 x - \sigma' \left\{ \left[ \frac{1}{n} + \frac{\bar{x}_n^2}{s_x^2} \right]^{1/2} + \frac{x}{s_x} \right\} T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{4} \right), \right. \\ \left. \hat{\beta}_0 + \hat{\beta}_1 x + \sigma' \left\{ \left[ \frac{1}{n} + \frac{\bar{x}_n^2}{s_x^2} \right]^{1/2} + \frac{x}{s_x} \right\} T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{4} \right) \right).$$

- (b) When  $c_0 = 1$  and  $c_1 = x < 0$ , the smallest possible value of  $\beta_0^* + x\beta_1^*$  occurs when  $\beta_0^*$  takes its smallest possible value and  $\beta_1^*$  takes its largest possible value. Similarly, the largest possible value of  $\beta_0^* + x\beta_1^*$  occurs when  $\beta_0^*$  takes its largest possible value and  $\beta_1^*$  takes its smallest possible value. All of these extreme values are given in part (a). The resulting interval is then

$$\begin{aligned}\left( \hat{\beta}_0 + \hat{\beta}_1 x - \sigma' \left\{ \left[ \frac{1}{n} + \frac{\bar{x}_n^2}{s_x^2} \right]^{1/2} - \frac{x}{s_x} \right\} T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{4} \right), \right. \\ \left. \hat{\beta}_0 + \hat{\beta}_1 x + \sigma' \left\{ \left[ \frac{1}{n} + \frac{\bar{x}_n^2}{s_x^2} \right]^{1/2} - \frac{x}{s_x} \right\} T_{n-2}^{-1} \left( 1 - \frac{\alpha_0}{4} \right) \right).$$

25. (a) The simultaneous intervals are the same as (11.3.33) with  $[2F_{2,n-2}^{-1}(1-\alpha_0)]^{1/2}$  replaced by  $T_{n-2}^{-1}(1-\alpha_0/4)$ , namely for  $i = 0, 1$ ,

$$\beta_0 + \beta_1 x_i \pm T_{n-2}^{-1}(1 - \alpha_0/4) \sigma' \left[ \frac{1}{n} + \frac{(x_i - \bar{x}_n)^2}{s_x^2} \right]^{1/2}.$$

- (b) Set  $x = \alpha x_0 + (1 - \alpha)x_1$  and solve for  $\alpha$ . The result is, by straightforward algebra,

$$\alpha(x) = \frac{x - x_1}{x_0 - x_1}.$$

- (c) First, notice that for all  $x$ ,

$$\beta_0 + \beta_1 x = \alpha(x)[\beta_0 + \beta_1 x_0] + [1 - \alpha(x)][\beta_0 + \beta_1 x_1]. \quad (\text{S.11.1})$$

That is, each parameter for which we want a confidence interval is a convex combination of the parameters for which we already have confidence intervals.

Suppose that  $C$  occurs. There are three cases that depend on where  $\alpha(x)$  lies relative to the interval  $[0, 1]$ . The first case is when  $0 \leq \alpha(x) \leq 1$ . In this case, the smallest of the four numbers defining  $L(x)$  and  $U(x)$  is  $L(x) = \alpha(x)A_0 + [1 - \alpha(x)]A_1$  and the largest is  $U(x) = \alpha(x)B_0 + [1 - \alpha(x)]B_1$ ,

because both  $\alpha(x)$  and  $1 - \alpha(x)$  are nonnegative. For all such  $x$ ,  $A_0 < \beta_0 + \beta_1 x_0 < B_0$  and  $A_1 < \beta_0 + \beta_1 x_1 < B_1$  together imply that

$$\alpha(x)A_0 + [1 - \alpha(x)]A_1 < \alpha(x)[\beta_0 + \beta_1 x_0] + [1 - \alpha(x)][\beta_0 + \beta_1 x_1] < \alpha(x)B_0 + [1 - \alpha(x)]B_1.$$

Combining this with (S.11.1) and the formulas for  $L(x)$  and  $U(x)$  yields  $L(x) < \beta_0 + \beta_1 x < U(x)$  as desired. The other two cases are similar, so we shall do one only of them. If  $\alpha(x) < 0$ , then  $1 - \alpha(x) > 0$ . In this case, the smallest of the four numbers defining  $L(x)$  and  $U(x)$  is  $L(x) = \alpha(x)B_0 + [1 - \alpha(x)]A_1$ , and the largest is  $U(x) = \alpha(x)A_0 + [1 - \alpha(x)]B_1$ . For all such  $x$ ,  $A_0 < \beta_0 + \beta_1 x_0 < B_0$  and  $A_1 < \beta_0 + \beta_1 x_1 < B_1$  together imply that

$$\alpha(x)B_0 + [1 - \alpha(x)]A_1 < \alpha(x)[\beta_0 + \beta_1 x_0] + [1 - \alpha(x)][\beta_0 + \beta_1 x_1] < \alpha(x)A_0 + [1 - \alpha(x)]B_1.$$

Combining this with (S.11.1) and the formulas for  $L(x)$  and  $U(x)$  yields  $L(x) < \beta_0 + \beta_1 x < U(x)$  as desired.

## 11.4 Bayesian Inference in Simple Linear Regression

### Commentary

This section only discusses Bayesian analysis with improper priors. There are a couple of reasons for this. First, the posterior distribution that results from the improper prior makes many of the Bayesian inferences strikingly similar to their non-Bayesian counterparts. Second, the derivation of the posterior distribution from a proper prior is mathematically much more difficult than the derivation given here, and I felt that this would distract the reader from the real purpose of this section, namely to illustrate Bayesian posterior inference. This section describes some inferences that are similar to non-Bayesian inferences as well as some that are uniquely Bayesian.

### Solutions to Exercises

- The posterior distribution of  $\beta_1$  is given as a special case of (11.4.1), namely that  $U = s_x(\beta_1 - \hat{\beta}_1)/\sigma'$  has the  $t$  distribution with  $n - 2$  degrees of freedom. The coefficient  $1 - \alpha_0$  confidence interval from Sec. 11.3 has endpoints  $\hat{\beta}_1 \pm T_{n-2}^{-1}(1 - \alpha_0/2)\sigma'/s_x$ . So, we can compute the posterior probability that  $\beta_1$  is in the interval as follows:

$$\begin{aligned} & \Pr\left(\hat{\beta}_1 - T_{n-2}^{-1}(1 - \alpha_0/2)\frac{\sigma'}{s_x} < \beta_1 < \hat{\beta}_1 + T_{n-2}^{-1}(1 - \alpha_0/2)\frac{\sigma'}{s_x}\right) \\ &= \Pr\left(-T_{n-2}^{-1}(1 - \alpha_0/2) < s_x \frac{\beta_1 - \hat{\beta}_1}{\sigma'} < T_{n-2}^{-1}(1 - \alpha_0/2)\right). \end{aligned} \quad (\text{S.11.2})$$

Since the  $t$  distributions are symmetric around 0,  $-T_{n-2}^{-1}(1 - \alpha_0/2) = T_{n-2}^{-1}(\alpha_0/2)$ . Also, the random variable between the inequalities on the right side of (S.11.2) is  $U$ , which has the  $t$  distribution with  $n - 2$  degrees of freedom. Hence the right side of (S.11.2) equals

$$\Pr(U < T^{-1}(1 - \alpha_0/2)) - \Pr(U \leq T^{-1}(\alpha_0/2)) = 1 - \alpha_0/2 - \alpha_0/2 = 1 - \alpha_0.$$

- The posterior distribution of  $\beta_1$  is given in (11.4.1), namely that

$$U = \left[ \frac{c_0^2}{n} + \frac{(c_0 \bar{x}_n - c_1)^2}{s_x^2} \right]^{-1/2} \frac{c_0 \beta_0 + c_1 \beta_1 - [c_0 \hat{\beta}_0 + c_1 \hat{\beta}_1]}{\sigma'}$$

has the  $t$  distribution with  $n - 2$  degrees of freedom. The coefficient  $1 - \alpha_0$  confidence interval from Sec. 11.3 has endpoints

$$c_0\hat{\beta}_0 + c_1\hat{\beta}_1 \pm T_{n-2}^{-1}(1 - \alpha_0/2)\sigma' \left[ \frac{c_0^2}{n} + \frac{(c_0\bar{x}_n - c_1)^2}{s_x^2} \right]^{1/2}.$$

So, we can compute the posterior probability that  $\beta_1$  is in the interval as follows:

$$\begin{aligned} & \Pr \left( c_0\hat{\beta}_0 + c_1\hat{\beta}_1 - T_{n-2}^{-1}(1 - \alpha_0/2)\sigma' \left[ \frac{c_0^2}{n} + \frac{(c_0\bar{x}_n - c_1)^2}{s_x^2} \right]^{1/2} < c_0\beta_0 + c_1\beta_1 \right. \\ & \quad \left. < c_0\hat{\beta}_0 + c_1\hat{\beta}_1 - T_{n-2}^{-1}(1 - \alpha_0/2)\sigma' \left[ \frac{c_0^2}{n} + \frac{(c_0\bar{x}_n - c_1)^2}{s_x^2} \right]^{1/2} \right) \\ &= \Pr \left( -T_{n-2}^{-1}(1 - \alpha_0/2) < U < T_{n-2}^{-1}(1 - \alpha_0/2) \right). \end{aligned}$$

As in the proof of Exercise 1, this equals  $1 - \alpha_0$ .

3. The joint distribution of  $(\beta_0, \beta_1)$  given  $\tau$  is a bivariate normal distribution as specified in Theorem 11.4.1. Using the means, variances, and correlation given in that theorem, we compute the mean of  $\beta_0 + \beta_1 x$  as  $\hat{\beta}_0 + \hat{\beta}_1 x = \hat{Y}$ . The variance of  $\beta_0 + \beta_1 x$  given  $\tau$  is

$$\frac{1}{\tau} \left[ \frac{1}{n} + \frac{\bar{x}_n^2}{s_x^2} + \frac{x^2}{s_x^2} - 2xn \frac{\bar{x}_n}{\left( n \sum_{i=1}^n x_i^2 \right)^{1/2}} \right] \left( \frac{1}{n} + \frac{\bar{x}_n^2}{s_x^2} \right)^{1/2} \frac{1}{s_x}.$$

Use the fact that  $1/n + \bar{x}_n^2/s_x^2 = \sum_{i=1}^n x_i^2/[ns_x^2]$  to simplify the above variance to the expression

$$\frac{1}{\tau} \left[ \frac{1}{n} + \frac{(x - \bar{x}_n)^2}{s_x^2} \right]^{1/2}.$$

It follows that the conditional distribution of  $\tau^{1/2}(\beta_0 - \beta_1 x - \hat{Y})$  is the normal distribution with mean 0 and variance as stated in the exercise.

4. The summaries from a simple linear regression are  $\hat{\beta}_0 = 0.1472$ ,  $\hat{\beta}_1 = 0.4352$ ,  $\sigma' = 0.2374$ ,  $\bar{x}_n = 0.42$ ,  $n = 10$  and  $s_x^2 = 8.396$ .
- The posterior distribution of the parameters is given in Theorem 11.4.1. With the numerical summaries above (recall that  $\sum_{i=1}^n x_i^2 = s_x^2 + n\bar{x}_n^2 = 10.16$ ), we get the following posterior. Conditional on  $\tau$ ,  $(\beta_0, \beta_1)$  has a bivariate normal distribution with mean vector  $(0.1472, 0.4352)$ , correlation  $-0.4167$ , and variances  $0.1210/\tau$  and  $0.1191/\tau$ . The distribution of  $\tau$  is a gamma distribution with parameters 4 and 0.2254.
  - The interval is centered at 0.4352 with half-width equal to  $T_8^{-1}(0.95)$  times  $0.2374/8.396^{1/2} = 0.0819$ . So, the interval is  $[0.2828, 0.5876]$ .

- (c) The posterior distribution of  $\beta_0$  is that  $U = (\beta_0 - 0.1472)/0.1210^{1/2}$  has the  $t$  distribution with 8 degrees of freedom. So the probability that  $\beta_0$  is between 0 and 2 is the probability that  $U$  is between  $(0 - 0.1472)/0.3479 = -0.4232$  and  $(2 - 0.1472)/0.3479 = 5.326$ . The probability that a  $t$  random variable with 8 degrees of freedom is between these two numbers can be found using a computer program, and it equals 0.6580.
5. The summary data are in the solution to Exercise 4.
- According to Theorem 11.4.1, the posterior distribution of  $\beta_1$  is that  $2.898(\beta_1 - 0.4352)/0.2374$  has the  $t$  distribution with eight degrees of freedom.
  - According to Theorem 11.4.1, the posterior distribution of  $\beta_0 + \beta_1$  is that
- $$\left(0.1 + \frac{(0.42 - 1)^2}{2.898^2}\right)^{-1/2} \frac{\beta_0 + \beta_1 - 0.5824}{0.2374}$$
- has the  $t$  distribution with eight degrees of freedom.
6. The summary information from the regression is  $\hat{\beta}_0 = 1.132$ ,  $\hat{\beta}_1 = 0.9547$ ,  $\sigma' = 0.2776$ ,  $\bar{x}_n = 3.206$ ,  $n = 14$ , and  $s_x^2 = 19.11$ .
- The posterior distribution of  $\beta_1$  is that  $U = 19.11^{1/2}(\beta_1 - 0.9547)/0.2776$  has the  $t$  distribution with 12 degrees of freedom.
  - The probability that  $\beta_1 \leq 2$  is the same as the probability that  $U \leq 19.11^{1/2}(2 - 0.9547)/0.2776 = 16.46$ , which is essentially 1.
  - The interval for log-price will be centered at  $1.132 + 0.9547 \times \log(21.4) = 4.057$  and have half-width  $T_{12}^{-1}(0.975)$  times  $0.2776[1 + 1/14 + (3.206 - \log(21.4))^2/19.11]^{1/2} = 0.2875$ . So, the interval for log-price is  $[3.431, 4.683]$ . The interval for 1980 price is  $e$  to the power of the endpoints,  $[30.90, 108.1]$ .
7. The conditional mean of  $\beta_0$  given  $\beta_1$  can be computed using results from Sec. 5.10. In particular,

$$E(\beta_0|\beta_1) = \hat{\beta}_0 - \frac{n\bar{x}_n s_x \left( \frac{1}{n} + \bar{x}_n^2/s_x^2 \right)^{1/2}}{\left( n \sum_{i=1}^n x_i^2 \right)^{1/2}} (\beta_1 - \hat{\beta}_1).$$

Now, use the fact that  $\sum_{i=1}^n x_i^2 = s_x^2 + n\bar{x}_n^2$ . The result is

$$E(\beta_0|\beta_1) = \hat{\beta}_0 + \bar{x}_n(\beta_1 - \hat{\beta}_1).$$

## 11.5 The General Linear Model and Multiple Regression

### Commentary

If one is using the software  $R$ , the commands to fit multiple linear regression models are the same as those that fit simple linear regression as described in the Commentaries to Secs. 11.1–11.3. One need only put the additional predictor variables into additional columns of the  $\mathbf{x}$  matrix.

## Solutions to Exercises

- After we have replaced  $\beta_0, \dots, \beta_p$  in (11.5.4) by their M.L.E.'s  $\hat{\beta}_0, \dots, \hat{\beta}_p$ , the maximization with respect to  $\sigma^2$  is exactly the same as the maximization carried out in Example 7.5.6 in the text for finding the M.L.E. of  $\sigma^2$  or the maximization carried out in Exercise 1 of Sec. 11.2.
- (The statement of the exercise should say that  $S^2/\sigma^2$  has a  $\chi^2$  distribution.) According to Eq. (11.5.8),

$$\sigma'^2 = \frac{S^2}{n-p}.$$

Since we assume that  $S^2/\sigma^2$  has a  $\chi^2$  distribution with  $n - p$  degrees of freedom, the mean of  $S^2$  is  $\sigma^2(n - p)$ , hence the mean of  $\sigma'^2$  is  $\sigma^2$ , and  $\sigma'^2$  is unbiased.

- This problem is a special case of the general linear model with  $p = 1$ . The design matrix  $\mathbf{Z}$  defined by Eq. (11.5.9) has dimension  $n \times 1$  and is specified as follows:

$$\mathbf{Z} = \begin{bmatrix} x_1 \\ \vdots \\ x_n \end{bmatrix}.$$

Therefore,  $\mathbf{Z}'\mathbf{Z} = \sum_{i=1}^n x_i^2$  and  $(\mathbf{Z}'\mathbf{Z})^{-1} = \frac{1}{\sum_{i=1}^n x_i^2}$ .

It follows from Eq. (11.5.10) that

$$\hat{\beta} = \frac{\sum_{i=1}^n x_i Y_i}{\sum_{i=1}^n x_i^2}.$$

- From Theorem 11.5.3,  $E(\hat{\beta}) = \beta$  and  $\text{Var}(\hat{\beta}) = \sigma^2 / \sum_{i=1}^n x_i^2$ .
- It is found that  $\sum_{i=1}^n x_i y_i = 342.4$  and  $\sum_{i=1}^n x_i^2 = 66.8$ . Therefore, from Exercises 3 and 4,  $\hat{\beta} = 5.126$  and  $\text{Var}(\hat{\beta}) = 0.0150\sigma^2$ . Also,  $S^2 = \sum_{i=1}^n (y_i - \hat{\beta}x_i)^2 = 169.94$ . Therefore, by Eq. (11.5.7),  $\hat{\sigma}^2 = (169.94)/10 = 16.994$ .
- By Eq. (11.5.21), the following statistic will have the  $t$  distribution with 9 degrees of freedom when  $H_0$  is true:

$$U = \left[ \frac{9}{(0.0150)(169.94)} \right]^{1/2} (\hat{\beta} - 10) = -9.158.$$

The corresponding two-sided tail area is smaller than 0.01, the smallest two-sided tail area available from the table in the back of the book.

7. The values  $\hat{\beta}_0$ ,  $\hat{\beta}_1$ , and  $\hat{\beta}_2$  were determined in Example 11.1.3.

By Eq. (11.5.7),

$$\hat{\sigma}^2 = \frac{1}{10} S^2 = \frac{1}{10} \sum_{i=1}^{10} (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i - \hat{\beta}_2 x_i^2)^2 = \frac{1}{10} (9.37) = 0.937.$$

8. The design matrix  $\mathbf{Z}$  has the following form:

$$\mathbf{Z} = \begin{bmatrix} 1 & x_1 & x_1^2 \\ 1 & x_2 & x_2^2 \\ \dots & \dots & \dots \\ 1 & x_n & x_n^2 \end{bmatrix}$$

Therefore,  $\mathbf{Z}'\mathbf{Z}$  is the  $3 \times 3$  matrix of coefficients on the left side of the three equations in (11.1.14):

$$\mathbf{Z}'\mathbf{Z} = \begin{bmatrix} 10 & 23.3 & 90.37 \\ 23.3 & 90.37 & 401 \\ 90.37 & 401 & 1892.7 \end{bmatrix}.$$

It will now be found that

$$(\mathbf{Z}'\mathbf{Z})^{-1} = \begin{bmatrix} 0.400 & -0.307 & 0.046 \\ -0.307 & 0.421 & -0.074 \\ 0.046 & -0.074 & 0.014 \end{bmatrix}.$$

The elements of  $(\mathbf{Z}'\mathbf{Z})^{-1}$ , multiplied by  $\sigma^2$ , are the variances and covariances of  $\hat{\beta}_0$ ,  $\hat{\beta}_1$ , and  $\hat{\beta}_2$ .

9. By Eq. (11.5.21), the following statistic will have the  $t$  distribution with 7 degrees of freedom when  $H_0$  is true:

$$U_2 = \left[ \frac{7}{(0.014)(9.37)} \right]^{1/2} \hat{\beta}_2 = 0.095.$$

The corresponding two-sided tail area is greater than 0.90. The null hypothesis would not be rejected at any reasonable level of significance.

10. By Eq. (11.5.21), the following statistic will have the  $t$  distribution with 7 degrees of freedom when  $H_0$  is true:

$$U_1 = \left[ \frac{7}{(0.421)(9.37)} \right]^{1/2} (\hat{\beta}_1 - 4) = -4.51.$$

The corresponding two-sided tail area is less than 0.01.

11. It is found that  $\sum_{i=1}^n (y_i - \bar{y}_n)^2 = 26.309$ . Therefore,

$$R^2 = 1 - \frac{S^2}{26.309} = 0.644.$$

12. The values of  $\hat{\beta}_0, \hat{\beta}_1$  and  $\hat{\beta}_2$  were determined in Example 11.1.5.

By Eq. (11.5.7),

$$\hat{\sigma}^2 = \frac{1}{10} S^2 = \frac{1}{10} \sum_{i=1}^n (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_{i1} - \hat{\beta}_2 x_{i2})^2 = \frac{1}{10} (8.865) = 0.8865.$$

13. The design matrix  $\mathbf{Z}$  has the following form:

$$\mathbf{Z} = \begin{bmatrix} 1 & x_{11} & x_{12} \\ 1 & x_{21} & x_{22} \\ \dots & \dots & \dots \\ 1 & x_{n1} & x_{n2} \end{bmatrix}.$$

Therefore,  $\mathbf{Z}'\mathbf{Z}$  is the  $3 \times 3$  matrix of coefficients on the left side of the three equations in (11.1.14):

$$\mathbf{Z}'\mathbf{Z} = \begin{bmatrix} 10 & 23.3 & 650 \\ 23.3 & 90.37 & 1563.6 \\ 650 & 1563.6 & 42,334 \end{bmatrix}.$$

It will now be found that

$$(\mathbf{Z}'\mathbf{Z})^{-1} = \begin{bmatrix} 222.7 & 4.832 & -3.598 \\ 4.832 & 0.1355 & -0.0792 \\ -3.598 & -0.0792 & 0.0582 \end{bmatrix}.$$

The elements of  $(\mathbf{Z}'\mathbf{Z})^{-1}$ , multiplied by  $\sigma^2$ , are the variances and covariances of  $\hat{\beta}_0, \hat{\beta}_1$ , and  $\hat{\beta}_2$ .

14. By Eq. (11.5.21), the following statistics will have the  $t$  distribution with 7 degrees of freedom when  $H_0$  is true:

$$U_1 = \left[ \frac{7}{(0.1355)(8.865)} \right]^{1/2} \hat{\beta}_1 = 1.087.$$

The corresponding two-sided tail area is between 0.30 and 0.40.

15. By Eq. (11.5.21), the following statistic will have the  $t$  distribution with 7 degrees of freedom when  $H_0$  is true:

$$U_2 = \left[ \frac{7}{(0.0582)(8.865)} \right]^{1/2} (\hat{\beta}_2 + 1) = 4.319.$$

The corresponding two-sided tail area is less than 0.01.

16. Just as in Exercise 11,  $\sum_{i=1}^n (y_i - \bar{y}_n)^2 = 26.309$ . Therefore,

$$R^2 = 1 - \frac{S^2}{26.309} = 0.663.$$

17.

$$\begin{aligned}
\text{Cov}(\hat{\beta}_j, A_{ij}) &= \text{Cov}\left(\hat{\beta}_j, \hat{\beta}_i - \frac{\zeta_{ij}}{\zeta_{jj}}\hat{\beta}_j\right) \\
&= \text{Cov}(\hat{\beta}_j, \hat{\beta}_i) - \frac{\zeta_{ij}}{\zeta_{jj}} \text{Cov}(\hat{\beta}_j, \hat{\beta}_j) \\
&= \text{Cov}(\hat{\beta}_i, \hat{\beta}_j) - \frac{\zeta_{ij}}{\zeta_{jj}} \text{Var}(\hat{\beta}_j) \\
&= \zeta_{ij}\sigma^2 - \frac{\zeta_{ij}}{\zeta_{jj}}\zeta_{jj}\sigma^2 = 0.
\end{aligned}$$

Just as in simple linear regression, it can be shown that the joint distribution of two estimators  $\hat{\beta}_i$  and  $\hat{\beta}_j$  will be a bivariate normal distribution. Since  $A_{ij}$  is a linear function of  $\hat{\beta}_i$  and  $\hat{\beta}_j$ , the joint distribution of  $A_{ij}$  and  $\hat{\beta}_j$  will also be a bivariate normal distribution. Therefore, since  $A_{ij}$  and  $\hat{\beta}_j$  are uncorrelated, they are also independent.

18.

$$\begin{aligned}
\text{Var}(A_{ij}) &= \text{Var}\left(\hat{\beta}_i - \frac{\zeta_{ij}}{\zeta_{jj}}\hat{\beta}_j\right) \\
&= \text{Var}(\hat{\beta}_i) + \left(\frac{\zeta_{ij}}{\zeta_{jj}}\right)^2 \text{Var}(\hat{\beta}_j) - 2\frac{\zeta_{ij}}{\zeta_{jj}} \text{Cov}(\hat{\beta}_i, \hat{\beta}_j) \\
&= \zeta_{ii}\sigma^2 + \frac{\zeta_{ij}^2}{\zeta_{jj}}\sigma^2 - 2\frac{\zeta_{ij}^2}{\zeta_{jj}}\sigma^2 = \left(\zeta_{ii} - \frac{\zeta_{ij}^2}{\zeta_{jj}}\right)\sigma^2.
\end{aligned}$$

Now consider the right side of the equation given in the hint for this exercise.

$$\begin{aligned}
[A_{ij} - E(A_{ij})]^2 &= [\hat{\beta}_i - \beta_i - \frac{\zeta_{ij}}{\zeta_{jj}}(\hat{\beta}_j - \beta_j)]^2 \\
&= (\hat{\beta}_i - \beta_i)^2 - \frac{2\zeta_{ij}}{\zeta_{jj}}(\hat{\beta}_i - \beta_i)(\hat{\beta}_j - \beta_j) + \frac{\zeta_{ij}^2}{\zeta_{jj}^2}(\hat{\beta}_j - \beta_j)^2.
\end{aligned}$$

If each of the two terms on the right side of the equation given in the hint is put over the least common denominator  $(\zeta_{ii}\zeta_{jj} - \zeta_{ij}^2)\sigma^2$ , the right side can be reduced to the form given for  $W^2$  in the text of the exercise. In the equation for  $W^2$  given in the hint,  $W^2$  has been represented as the sum of two independent random variables, each of which is the square of a variable having a standard normal distribution. Therefore,  $W^2$  has a  $\chi^2$  distribution with 2 degrees of freedom.

19. (a) Since  $W^2$  is a function only of  $\hat{\beta}_i$  and  $\hat{\beta}_j$ , it follows that  $W^2$  and  $S^2$  are independent. Also,  $W^2$  has a  $\chi^2$  distribution with 2 degrees of freedom and  $S^2/\sigma^2$  has a  $\chi^2$  distribution with  $n-p$  degrees of freedom. Therefore,  $\frac{W^2/2}{S^2/[\sigma^2(n-p)]}$  has the  $F$  distribution with 2 and  $n-p$  degrees of freedom.
- (b) If we replace  $\beta_i$  and  $\beta_j$  in  $W^2$  by their hypothesized values  $\beta_i^*$  and  $\beta_j^*$ , then the statistic given in part (a) will have the  $F$  distribution with 2 and  $n-p$  degrees of freedom when  $H_0$  is true and will tend to be larger when  $H_0$  is not true. Therefore, we should reject  $H_0$  if that statistic exceeds some constant  $C$ , where  $C$  can be chosen to obtain any specified level of significance  $\alpha_0$  ( $0 < \alpha_0 < 1$ ).

20. In this problem  $i = 2, j = 3, \beta_1^* = \beta_2^* = 0$  and, from the values found in Exercises 7 and 8,

$$W^2 = \frac{(0.014)(0.616)^2 + (0.421)(0.013)^2 + 2(0.074)(0.616)(0.13)}{[(0.421)(0.014) - (0.074)^2]\sigma^2} = \frac{16.7}{\sigma^2}.$$

Also,  $S^2 = 9.37$ , as found in the solution of Exercise 7. Hence, the value of the F statistic with 2 and 7 degrees of freedom is  $(7/2)(16.7/9.37) = 6.23$ . The corresponding tail area is between 0.025 and 0.05.

21. In this problem,  $i = 2, j = 3, \beta_1^* = 1, \beta_2^* = 0$  and from the values found in Exercises 12 and 13,

$$\begin{aligned} W^2 &= \frac{(0.0582)(0.4503 - 1)^2 + (0.1355)(0.1725)^2 + 2(0.0792)(0.4503 - 1)(0.1725)}{[(0.1355)(0.0582) - (0.0792)^2]\sigma^2} \\ &= \frac{4.091}{\sigma^2}. \end{aligned}$$

Also,  $S^2 = 8.865$ , as found in the solution of Exercise 12. Hence, the value of the F statistic with 2 and 7 degrees of freedom is  $(7/2)(4.091/8.865) = 1.615$ . The corresponding tail area is greater than 0.05.

22.  $S^2 = \sum_{i=1}^n (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i)^2$ . Since  $\hat{\beta}_0 = \bar{y}_n - \hat{\beta}_1 \bar{x}_n$ ,

$$\begin{aligned} S^2 &= \sum_{i=1}^n [(y_i - \bar{y}_n) - \hat{\beta}_1(x_i - \bar{x}_n)]^2 \\ &= \sum_{i=1}^n (y_i - \bar{y}_n)^2 - \hat{\beta}_1^2 \sum_{i=1}^n (x_i - \bar{x}_n)^2 - 2\hat{\beta}_1 \sum_{i=1}^n (x_i - \bar{x}_n)(y_i - \bar{y}_n). \end{aligned}$$

Since  $\hat{\beta}_1 = \frac{\sum_{i=1}^n (x_i - \bar{x}_n)(y_i - \bar{y}_n)}{\sum_{i=1}^n (y_i - \bar{y}_n)^2}$  and  $R^2 = 1 - \frac{S^2}{\sum_{i=1}^n (y_i - \bar{y}_n)^2}$ , the desired result can now be obtained.

23. We have the following relations:

$$\begin{aligned} E(\mathbf{X} + \mathbf{Y}) &= E \begin{bmatrix} X_1 + Y_1 \\ \vdots \\ X_n + Y_n \end{bmatrix} = \begin{bmatrix} E(X_1 + Y_1) \\ \vdots \\ E(X_n + Y_n) \end{bmatrix} = \begin{bmatrix} E(X_1) + E(Y_1) \\ \vdots \\ E(X_n) + E(Y_n) \end{bmatrix} \\ &= \begin{bmatrix} E(X_1) \\ \vdots \\ E(X_n) \end{bmatrix} + \begin{bmatrix} E(Y_1) \\ \vdots \\ E(Y_n) \end{bmatrix} = E(\mathbf{X}) + E(\mathbf{Y}). \end{aligned}$$

24. The element in row  $i$  and column  $j$  of the  $n \times n$  matrix  $\text{Cov}(\mathbf{X} + \mathbf{Y})$  is  $\text{Cov}(X_i + Y_i, X_j + Y_j) = \text{Cov}(X_i, X_j) + \text{Cov}(X_i, Y_j) + \text{Cov}(Y_i, X_j) + \text{Cov}(Y_i, Y_j)$ . Since  $\mathbf{X}$  and  $\mathbf{Y}$  are independent,  $\text{Cov}(X_i, Y_j) = 0$  and  $\text{Cov}(Y_i, X_j) = 0$ . Therefore, this element reduces to  $\text{Cov}(X_i, X_j) + \text{Cov}(Y_i, Y_j)$ . But  $\text{Cov}(X_i, X_j)$  is the element in row  $i$  and column  $j$  of  $\text{Cov}(\mathbf{X})$ , and  $\text{Cov}(Y_i, Y_j)$  is the corresponding element in  $\text{Cov}(\mathbf{Y})$ . Hence, the sum of these two covariances is the element in row  $i$  and column  $j$  of  $\text{Cov}(\mathbf{X}) + \text{Cov}(\mathbf{Y})$ . Thus, we have shown that the element in row  $i$  and column  $j$  of  $\text{Cov}(\mathbf{X} + \mathbf{Y})$  is equal to the corresponding element of  $\text{Cov}(\mathbf{X}) + \text{Cov}(\mathbf{Y})$ .

25. We know that  $\text{Var}(3Y_1 + Y_2 - 2Y_3 + 8) = \text{Var}(3Y_1 + Y_2 - 2Y_3)$ . By Theorem 11.5.2, with  $p = 1$ ,
- $$\text{Var}(3Y_1 + Y_2 - 2Y_3) = (3, 1, -2) \text{Cov}(\mathbf{Y}) \begin{pmatrix} 3 \\ 1 \\ -2 \end{pmatrix} = 87.$$

26. (a) We can see that  $\sum_{j=0}^{p-1} c_j \hat{\beta}_j$  is equal to  $\mathbf{c}'\hat{\beta}$ , where  $\mathbf{c}$  is defined in part (b) and  $\hat{\beta}$  is the least-squares regression coefficient vector. If  $\mathbf{Y}$  is the vector in Eq. (11.5.13), then we can write  $\mathbf{c}'\hat{\beta} = \mathbf{a}'\mathbf{Y}$ , where  $\mathbf{a}' = \mathbf{c}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}$ . It follows from Theorem 11.3.1 that  $\mathbf{a}'\mathbf{Y}$  has a normal distribution, and it follows from Theorem 11.5.2 that the mean of  $\mathbf{a}'\mathbf{Y}$  is  $\mathbf{c}'\beta$  and the variance is

$$\sigma^2 \mathbf{a}'\mathbf{a} = \sigma^2 \mathbf{c}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{c}. \quad (\text{S.11.3})$$

- (b) If  $H_0$  is true, then  $\mathbf{c}'\hat{\beta}$  has the normal distribution with mean  $c_*$  and variance given by (S.11.3). It follows that the following random variable  $Z$  has a standard normal distribution:

$$Z = \frac{\mathbf{c}'\hat{\beta} - c_*}{\sigma(\mathbf{c}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{c})^{1/2}}.$$

Also, recall that  $(n-p)\sigma'^2/\sigma^2$  has a  $\chi^2$  distribution with  $n-p$  degrees of freedom and is independent of  $Z$ . So, if we divide  $Z$  by  $\sigma'/\sigma$ , we get a random variable that has a  $t$  distribution with  $n-p$  degrees of freedom, which also happens to equal  $U$ .

- (c) To test  $H_0$  at level  $\alpha_0$ , we can reject  $H_0$  if  $|U| > T_{n-p}^{-1}(1 - \alpha_0/2)$ . If  $H_0$  is true,

$$\Pr(|U| > T_{n-p}^{-1}(1 - \alpha_0/2)) = \alpha_0,$$

so this test will have level  $\alpha_0$ .

27. In a simple linear regression,  $\hat{Y}_i$  is the same linear function of  $X_i$  for all  $i$ . If  $\hat{\beta}_1 > 0$ , then every unit increase in  $X$  corresponds to an increase of  $\hat{\beta}_1$  in  $\hat{Y}$ . So, a plot of residuals against  $\hat{Y}$  will look the same as a plot of residuals against  $X$  except that the horizontal axis will be labeled differently. If  $\hat{\beta}_1 < 0$ , then a unit increase in  $X$  corresponds to a decrease of  $-\hat{\beta}_1$  in  $\hat{Y}$ , so a plot of residuals against fitted values is a mirror image of a plot of residuals against  $X$ . (The plot is flipped horizontally around a vertical line.)
28. Since  $R^2$  is a decreasing function of the residual sum of squares, we shall show that the residual sum of squares is at least as large when using  $\mathbf{Z}'$  as when using  $\mathbf{Z}$ . Let  $\mathbf{Z}$  have  $p$  columns and let  $\mathbf{Z}'$  have  $q < p$  columns. Let  $\hat{\beta}_*$  be the least-squares coefficients that we get when using design matrix  $\mathbf{Z}'$ . For each column that was deleted from  $\mathbf{Z}$  to get  $\mathbf{Z}'$ , insert an additional coordinate equal to 0 into the  $q$ -dimensional vector  $\hat{\beta}_*$  to produce the  $p$ -dimensional vector  $\tilde{\beta}$ . This vector  $\tilde{\beta}$  is one of the possible vectors in the solution of the minimization problem to find the least-squares estimates with the design matrix  $\mathbf{Z}$ . Furthermore, since  $\tilde{\beta}$  has 0's for all of the extra columns that are in  $\mathbf{Z}$  but not in  $\mathbf{Z}'$ , it follows that the residual sum of squares when using  $\tilde{\beta}$  with design matrix  $\mathbf{Z}$  is identical to the residual sum of squares when using  $\hat{\beta}_*$  with design matrix  $\mathbf{Z}'$ . Hence the minimum residual sum of squares available with design matrix  $\mathbf{Z}$  must be no larger than the residual sum of squares using  $\tilde{\beta}$  with design matrix  $\mathbf{Z}'$ .

29. In Example 11.5.5, we are told that  $\sigma' = 352.9$ , so the residual sum of squares is 2864383. We can calculate  $\sum_{i=1}^n (y_i - \bar{y}_n)^2$  directly from the data in Table 11.13. It equals, 26844478. It follows that

$$R^2 = 1 - \frac{2864383}{26844478} = 0.893.$$

30. Use the notation in the solution of Exercise 26. Suppose that  $\mathbf{c}'\boldsymbol{\beta} = d$ . Then  $U$  has a noncentral  $t$  distribution with  $n-p$  degrees of freedom and noncentrality parameter  $(d-c)/[\sigma(\mathbf{c}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{c})^{1/2}]$ . The argument is the same as any of those in the book that derived noncentral  $t$  distributions.

## 11.6 Analysis of Variance

### Commentary

If one is using the software  $R$ , there is a more direct way to fit an analysis of variance model than to construct the design matrix. Let  $\mathbf{y}$  contain the observed responses arranged as in Eq. (11.6.1). Suppose also that  $\mathbf{x}$  is a vector of the same dimension as  $\mathbf{y}$ , each of whose values is the first subscript  $i$  of  $Y_{ij}$  in Eq. (11.6.1) so that the value of  $\mathbf{x}$  identifies which of the  $p$  sample each observation comes from. Specifically, the first  $n_1$  elements of  $\mathbf{x}$  would be 1, the next  $n_2$  would be 2, etc. Then `aovfit=lm(y~factor(x))` will fit the analysis of variance model. The function `factor` converts the vector of integers into category identifiers. Then `anova(aovfit)` will print the ANOVA table.

### Solutions to Exercises

1. By analogy with Eq. (11.6.2),

$$\mathbf{Z}'\mathbf{Z} = \begin{bmatrix} n_1 & 0 & \cdots & 0 \\ 0 & n_2 & \cdots & 0 \\ \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & n_p \end{bmatrix} \text{ and } (\mathbf{Z}'\mathbf{Z})^{-1} = \begin{bmatrix} 1/n_1 & 0 & \cdots & 0 \\ 0 & 1/n_2 & \cdots & 0 \\ \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & 1/n_p \end{bmatrix}$$

Also,

$$\mathbf{Z}'\mathbf{Y} = \begin{bmatrix} \left( \sum_{j=1}^{n_1} Y_{1j} \right) \\ \vdots \\ \left( \sum_{j=1}^{n_p} Y_{pj} \right) \end{bmatrix} \text{ and } (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y} = \begin{bmatrix} \bar{Y}_{1+} \\ \vdots \\ \bar{Y}_{p+} \end{bmatrix}.$$

2. Let  $\mathbf{A}$  be the orthogonal matrix whose first row is  $\mathbf{u}$  in the statement of the problem. Define

$$\mathbf{Y} = \begin{bmatrix} n_1^{1/2} \bar{Y}_{1+} \\ \vdots \\ n_p^{1/2} \bar{Y}_{p+} \end{bmatrix}.$$

Let  $\mathbf{v}'$  be a vector that is orthogonal to  $\mathbf{u}$  (like all the other rows of  $\mathbf{A}$ .) Then  $\mathbf{v}'\mathbf{X} = \mathbf{v}'\mathbf{Y}/\sigma$ . Define

$$\begin{aligned} \mathbf{U} &= \mathbf{AX} = (U_1, \dots, U_p)', \\ \mathbf{V} &= \mathbf{AY} = (V_1, \dots, V_p)'. \end{aligned}$$

We just showed that  $V_i/\sigma = U_i$  for  $i = 2, \dots, n$ . Now,

$$\begin{aligned} \mathbf{X}'\mathbf{X} &= (\mathbf{AX})'(\mathbf{AX}) = \sum_{i=1}^p U_i^2, \\ \mathbf{Y}'\mathbf{Y} &= (\mathbf{AY})'(\mathbf{AY}) = \sum_{i=1}^p V_i^2. \end{aligned}$$

Notice that  $V_1 = \sum_{i=1}^p n_i \bar{Y}_{i+} / n^{1/2} = n^{1/2} \bar{Y}_{++}$ , hence

$$\frac{S_{\text{Betw}}^2}{\sigma^2} = \frac{1}{\sigma^2} \sum_{i=1}^p n_i \bar{Y}_{i+}^2 - n \bar{Y}_{++}^2 = \frac{1}{\sigma^2} (\mathbf{Y}' \mathbf{Y} - V_1^2) = \sum_{i=2}^p \left( \frac{V_i}{\sigma} \right)^2 = \sum_{i=2}^p U_i^2.$$

Now, the coordinates of  $\mathbf{X}$  are i.i.d. standard normal random variables, so the coordinates of  $\mathbf{U}$  are also i.i.d. standard normal random variables. Hence  $\sum_{i=2}^p U_i^2 = S_{\text{Betw}}^2 / \sigma^2$  has a  $\chi^2$  distribution with  $p-1$  degrees of freedom.

3. Use the definitions of  $\bar{Y}_{i+}$  and  $\bar{Y}_{++}$  in the text to compute

$$\begin{aligned} \sum_{i=1}^p n_i (\bar{Y}_{i+} - \bar{Y}_{++})^2 &= \sum_{i=1}^p n_i \bar{Y}_{i+}^2 - n \bar{Y}_{++}^2 - 2 \bar{Y}_{++} \sum_{i=1}^p n_i \bar{Y}_{i+} \\ &= \sum_{i=1}^p n_i \bar{Y}_{i+}^2 + n \bar{Y}_{++}^2 - 2n \bar{Y}_{++}^2, \\ &= \sum_{i=1}^p n_i \bar{Y}_{i+}^2 - n \bar{Y}_{++}^2. \end{aligned}$$

4. (a) It is found that  $\bar{Y}_{1+} = 6.6$ ,  $\bar{Y}_{2+} = 9.0$ , and  $\bar{Y}_{3+} = 10.2$ . Also,

$$\sum_{j=1}^{n_1} (Y_{1j} - \bar{Y}_{1+})^2 = 1.90, \sum_{j=1}^{n_2} (Y_{2j} - \bar{Y}_{2+})^2 = 17.8, \sum_{j=1}^{n_3} (Y_{3j} - \bar{Y}_{3+})^2 = 5.54.$$

Hence, by Eq. (11.6.4),  $\hat{\sigma}^2 = (1.90 + 17.8 + 5.54)/13 = 1.942$ .

- (b) It is found that  $\bar{Y}_{++} = 8.538$ . Hence, by Eq. (11.6.9),  $U^2 = 10(24.591)/[2(25.24)] = 4.871$ . When  $H_0$  is true, the statistic  $U^2$  has the  $F$  distribution with 2 and 10 degrees of freedom. Therefore, the tail area corresponding to the value  $U^2 = 4.871$  is between 0.025 and 0.05.
5. In this problem  $n_i = 10$  for  $i = 1, 2, 3, 4$ , and  $\bar{Y}_{1+} = 105.7$ ,  $\bar{Y}_{2+} = 102.0$ ,  $\bar{Y}_{3+} = 93.5$ ,  $\bar{Y}_{4+} = 110.8$ , and  $\bar{Y}_{++} = 103$ .

$$\begin{aligned} \sum_{j=1}^{10} (Y_{1j} - \bar{Y}_{1+})^2 &= 303, \quad \sum_{j=1}^{10} (Y_{2j} - \bar{Y}_{2+})^2 = 544, \\ \sum_{j=1}^{10} (Y_{3j} - \bar{Y}_{3+})^2 &= 250, \quad \sum_{j=1}^{10} (Y_{4j} - \bar{Y}_{4+})^2 = 364. \end{aligned}$$

Therefore, by Eq. (11.6.9),

$$U^2 = \frac{36(1593.8)}{3(1461)} = 13.09.$$

When  $H_0$  is true, the statistic  $U^2$  has the  $F$  distribution with 3 and 36 degrees of freedom. The tail area corresponding to the value  $U^2 = 13.09$  is found to be less than 0.025.

6. The random variables  $Q_1, \dots, Q_p$  are independent, because each  $Q_i$  is a function of a different group of the observations in the sample. It is known that  $Q_i/\sigma^2$  has a  $\chi^2$  distribution with  $n_i - 1$  degrees of freedom. Therefore,  $(Q_1 + \dots + Q_p)/\sigma^2$  will have a  $\chi^2$  distribution with  $\sum_{i=1}^p (n_i - 1) = n - p$  degrees of freedom. Since  $Q_1$  and  $Q_p$  are independent,  $\frac{Q_i/[\sigma^2(n_i - 1)]}{Q_p/[\sigma^2(n_p - 1)]}$  will have the  $F$  distribution with  $n_1 - 1$  and  $n_p - 1$  degrees of freedom. In other words,  $(n_p - 1)Q_1/[(n_1 - 1)Q_p]$  will have that  $F$  distribution.
7. If  $U$  is defined by Eq. (9.6.3), then

$$U^2 = \frac{(m+n-2)(\bar{X}_m - \bar{Y}_n)^2}{\left(\frac{1}{m} + \frac{1}{n}\right)(S_x^2 + S_y^2)}.$$

The correspondence between the notation of Sec. 9.6 and our present notation is as follows:

Notation of Sec. 9.6	Present notation
$m$	$n_1$
$n$	$n_2$
$\bar{X}_m$	$\bar{Y}_{1+}$
$\bar{Y}_n$	$\bar{Y}_{2+}$
$S_X^2$	$\sum_{j=1}^{n_1} (Y_{1j} - \bar{Y}_{1+})^2$
$S_Y^2$	$\sum_{j=1}^{n_2} (Y_{2j} - \bar{Y}_{2+})^2$

Since  $p = 2$ ,  $\bar{Y}_{++} = n_1 \bar{Y}_{1+}/n + n_2 \bar{Y}_{2+}/n$ . Therefore,

$$\begin{aligned} & n_1(\bar{Y}_{1+} - \bar{Y}_{++})^2 + n_2(\bar{Y}_{2+} - \bar{Y}_{++})^2 \\ &= n_1 \left( \frac{n_2}{n} \right)^2 (\bar{Y}_{1+} - \bar{Y}_{2+})^2 + n_2 \left( \frac{n_1}{n} \right)^2 (\bar{Y}_{1+} - \bar{Y}_{2+})^2 \\ &= \frac{n_1 n_2}{n} (\bar{Y}_{1+} - \bar{Y}_{2+})^2, \quad \text{since } n_1 + n_2 = n. \end{aligned}$$

Also, since  $m + n$  in the notation of Sec. 9.6 is simply  $n$  in our present notation, we can now rewrite the expression for  $U^2$  as follows:

$$U^2 = \frac{(n-2) \frac{n}{n_1 n_2} \sum_{i=1}^2 n_i (\bar{Y}_{i+} - \bar{Y}_{++})^2}{\frac{n}{n_1 n_2} \sum_{i=1}^2 \sum_{j=1}^{n_i} (\bar{Y}_{ij} - \bar{Y}_{i+})^2}.$$

This expression reduces to the expression for  $U^2$  given in Eq. (11.6.9), with  $p = 2$ .

$$8. E \left[ \frac{1}{n-p} \sum_{i=1}^p \sum_{j=1}^{n_i} (\bar{Y}_{ij} - \bar{Y}_{i+})^2 \right] = \frac{1}{n-p} \sum_{i=1}^p E \left[ \sum_{j=1}^{n_i} (\bar{Y}_{ij} - \bar{Y}_{i+})^2 \right]$$

$$\begin{aligned}
&= \frac{1}{n-p} \sum_{i=1}^p (n_i - 1) \sigma^2, \text{ by the results of Sec. 8.7,} \\
&= \frac{1}{n-p} (n-p) \sigma^2 = \sigma^2.
\end{aligned}$$

9. Each of the three given random variables is a linear function of the independent random variables  $Y_{rs}$  ( $s = 1, \dots, n_r$  and  $r = 1, \dots, p$ ).

Let  $W_1 = \sum_{r,s} a_{rs} Y_{rs}$ ,  $W_2 = \sum_{r,s} b_{rs} Y_{rs}$ , and  $W_3 = \sum_{r,s} c_{rs} Y_{rs}$ . We have  $a_{ij} = 1 - \frac{1}{n_i}$ ,  $a_{is} = -\frac{1}{n_i}$  for  $s \neq j$ , and  $a_{rs} = 0$  for  $r \neq i$ . Also,  $b_{i's} = \frac{1}{n_{i'}} - \frac{1}{n}$  and  $b_{rs} = -\frac{1}{n}$  for  $r \neq i'$ . Finally,  $c_{rs} = \frac{1}{n}$  for all values of  $r$  and  $s$ .

$$\text{Now, } \text{Cov}(W_1, W_2) = \text{Cov} \left( \sum_{r,s} a_{rs} Y_{rs}, \sum_{r',s'} b_{r's'} Y_{r's'} \right) = \sum_{r,s} \sum_{r',s'} a_{rs} b_{r's'} \text{Cov}(Y_{rs}, Y_{r's'}).$$

But  $\text{Cov}(Y_{rs}, Y_{r's'}) = 0$  unless  $r = r'$  and  $s = s'$ , since any two distinct  $Y$ 's are independent. Also,  $\text{Cov}(Y_{rs}, Y_{rs}) = \text{Var}(Y_{rs}) = \sigma^2$ .

Therefore,  $\text{Cov}(W_1, W_2) = \sigma^2 \sum_{r,s} a_{rs} b_{rs}$ . If  $i = i'$ ,

$$\sum_{r,s} a_{rs} b_{rs} = a_{ij} b_{ij} + \sum_{s \neq j} a_{is} b_{is} + 0 = \left(1 - \frac{1}{n_i}\right) \left(\frac{1}{n_i} - \frac{1}{n}\right) + (n_i - 1) \left(-\frac{1}{n_i}\right) \left(\frac{1}{n_i} - \frac{1}{n}\right) = 0.$$

If  $i \neq i'$ ,

$$\sum_{r,s} a_{rs} b_{rs} = \left(1 - \frac{1}{n_i}\right) \left(-\frac{1}{n}\right) + (n_i - 1) \left(-\frac{1}{n_i}\right) \left(-\frac{1}{n}\right) = 0.$$

Similarly,

$$\text{Cov}(W_1, W_3) = \sigma^2 \sum_{r,s} a_{rs} c_{rs} = \sigma^2 \frac{1}{n} \left( a_{ij} + \sum_{s \neq j} a_{is} \right) = 0$$

Finally,

$$\text{Cov}(W_2, W_3) = \sigma^2 \sum_{r,s} b_{rs} c_{rs} = \sigma^2 \frac{1}{n} \sum_{r,s} b_{rs} = \sigma^2 \frac{1}{n} \left[ n_{i'} \left( \frac{1}{n_{i'}} - \frac{1}{n} \right) + (n - n_{i'}) \left( -\frac{1}{n} \right) \right] = 0.$$

10. (a) The three group averages are 825.8, 845.0, and 775.0. The residual sum of squares is 1671. The ANOVA table is then

Source of variation	Degrees of freedom	Sum of squares	Mean square
Between samples	2	15703	7851
Residuals	15	1671	111.4
Total	17	17374	

- (b) The  $F$  statistic is  $7851/111.4 = 70.48$ . Comparing this to the  $F$  distribution with 2 and 15 degrees of freedom, we get a  $p$ -value of essentially 0.
11. Write  $S_{\text{Betw}}^2 = \sum_{i=1}^p \bar{Y}_{i+}^2 - n\bar{Y}_{++}^2$ . Recall, that the mean of the square of a normal random variable with mean  $\mu$  and variance  $\sigma^2$  is  $\mu^2 + \sigma^2$ . The distribution of  $\bar{Y}_{i+}$  is the normal distribution with mean  $\mu_i$  and variance  $\sigma^2/n_i$ , while the distribution of  $\bar{Y}_{++}$  is the normal distribution with mean  $\bar{\mu}$  and variance  $\sigma^2/n$ . Hence the mean of  $S_{\text{Betw}}^2$  is

$$\sum_{i=1}^p n_i(\mu_i^2 + \sigma^2/n_i) - n(\bar{\mu}^2 + \sigma^2/n).$$

If we collect terms in this sum, we get  $(p-1)\sigma^2 + \sum_{i=1}^p n_i\mu_i^2 - n\bar{\mu}^2$ . This simplifies to the expression stated in the exercise.

12. If the null hypothesis is true, the likelihood is

$$(2\pi)^{-n/2} \sigma^{-n} \exp\left(-\frac{1}{2\sigma^2} \sum_{i=1}^p \sum_{j=1}^{n_i} (y_{ij} - \mu)^2\right).$$

This is maximized by choosing  $\mu = \bar{y}_{++}$  and

$$\sigma^2 = \frac{1}{n} \sum_{i=1}^p (y_{ij} - \bar{y}_{++})^2 = \frac{1}{n} S_{\text{Tot}}^2.$$

The resulting maximum value of the likelihood is

$$(2\pi)^{-n/2} \frac{n^{n/2}}{(S_{\text{Tot}}^2)^{n/2}} \exp\left(-\frac{n}{2}\right). \quad (\text{S.11.4})$$

If the null hypothesis is false, the likelihood is

$$(2\pi)^{-n/2} \sigma^{-n} \exp\left(-\frac{1}{2\sigma^2} \sum_{i=1}^p \sum_{j=1}^{n_i} (y_{ij} - \mu_i)^2\right).$$

This is maximized by choosing  $\mu_i = \bar{y}_{i+}$  and

$$\sigma^2 = \frac{1}{n} \sum_{i=1}^p (y_{ij} - \bar{y}_{i+})^2 = \frac{1}{n} S_{\text{Resid}}^2.$$

The resulting maximum value of the likelihood is

$$(2\pi)^{-n/2} \frac{n^{n/2}}{(S_{\text{Resid}}^2)^{n/2}} \exp\left(-\frac{n}{2}\right). \quad (\text{S.11.5})$$

The ratio of (S.11.5) to (S.11.4) is

$$\left(\frac{S_{\text{Tot}}^2}{S_{\text{Resid}}^2}\right)^{n/2} = \left(1 + \frac{S_{\text{Betw}}^2}{S_{\text{Resid}}^2}\right)^{n/2}.$$

Rejecting  $H_0$  when this ratio is greater than  $k$  is equivalent to rejecting when  $U^2 > k'$  for some other constant  $k'$ . In order for the test to have level  $\alpha_0$ ,  $k'$  must equal the  $1 - \alpha_0$  quantile of the distribution of  $U^2$  when  $H_0$  is true. We saw in the text that this distribution is the  $F$  distribution with  $p-1$  and  $n-p$  degrees of freedom.

13. We know that  $S_{\text{Tot}}^2 = S_{\text{Betw}}^2 + S_{\text{Resid}}^2$ . We also know that  $S_{\text{Betw}}^2/\sigma^2$  and  $S_{\text{Resid}}^2/\sigma^2$  are independent. If  $H_0$  is true then they both have  $\chi^2$  distributions, one with  $p - 1$  degrees of freedom (see Exercise 2) and the other with  $n - p$  degrees of freedom as in the text. The sum of two independent  $\chi^2$  random variables has  $\chi^2$  distribution with the sum of the degrees of freedom, in this case  $n - 1$ .
14. (a) (The exercise should have asked you to prove that  $\sum_{i=1}^p n_i \alpha_i = 0$ .) We see that  $\sum_{i=1}^p n_i \alpha_i = \sum_{i=1}^n n_i \mu_i - n\mu = 0$ .
- (b) The M.L.E. of  $\mu_i$  is  $\bar{Y}_{i+}$  and the M.L.E. of  $\mu$  is  $\bar{Y}_{++}$ , so the M.L.E. of  $\alpha_i$  is  $\bar{Y}_{i+} - \bar{Y}_{++}$ .
- (c) Notice that all of  $\mu_i$  equal each other if and only if they all equal  $\mu$ , if and only if all  $\alpha_i = 0$ .
- (d) This fact was proven in Exercise 11 with slightly different notation.

## 11.7 The Two-Way Layout

### Commentary

If one is using the software *R*, one can fit a two-way layout using `lm` with two `factor` variables. As in the Commentary to Sec. 11.6 above, let `y` contain the observed responses, and let `x1` and `x2` be two `factor` variables giving the levels of the two factors in the layout. Then `aovfit=lm(y~x1+x2)` will fit the model, and `anova(aovfit)` will print the ANOVA table.

### Solutions to Exercises

1. Write  $S_A^2 = J \sum_{i=1}^I \bar{Y}_{i+}^2 - IJ\bar{Y}_{++}^2$ . Recall, that the mean of the square of a normal random variable with mean  $\mu$  and variance  $\sigma^2$  is  $\mu^2 + \sigma^2$ . The distribution of  $\bar{Y}_{i+}$  is the normal distribution with mean  $\mu_i$  and variance  $\sigma^2/J$ , while the distribution of  $\bar{Y}_{++}$  is the normal distribution with mean  $\mu$  and variance  $\sigma^2/IJ$ . Hence the mean of  $S_A^2$  is  $J \sum_{i=1}^I (\mu_i^2 + \sigma^2/J) - IJ(\mu + \sigma^2/[IJ])$ . If we collect terms in this sum, we get

$$(I-1)\sigma^2 + J \sum_{i=1}^I \mu_i^2 - IJ\mu^2 = (I-1)\sigma^2 + J \sum_{i=1}^I (\mu_i - \mu)^2 = (I-1)\sigma^2 + J \sum_{i=1}^I \alpha_i^2.$$

2. In each part of this exercise, let  $\mu_{ij}$  denote the element in row  $i$  and column  $j$  of the given matrix.
- (a) The effects are not additive because  $\mu_{21} - \mu_{11} = 5 \neq \mu_{22} - \mu_{12} = 7$ .
- (b) The effects are additive because each element in the second row is 1 unit larger than the corresponding element in the first row. Alternatively, we could say that the effects are additive because each element in the second column is 3 units larger than the corresponding element in the first column.
- (c) The effects are additive because each element in the first row is 5 units smaller than the corresponding element in the second row and is 1 unit smaller than the corresponding element in the third row.
- (d) The effects are not additive because, for example,  $\mu_{21} - \mu_{11} = 1 \neq \mu_{22} - \mu_{12} = 2$ .

3. If the effects are additive, then there exist numbers  $\Theta_i$  and  $\Psi_j$  such that Eq. (11.7.1) is satisfied for  $i = 1, \dots, I$  and  $j = 1, \dots, J$ . Let  $\bar{\Theta} = \frac{1}{I} \sum_{i=1}^I \Theta_i$  and  $\bar{\Psi} = \frac{1}{J} \sum_{j=1}^J \Psi_j$ , and define.

$$\begin{aligned}\mu &= \bar{\Theta} + \bar{\Psi}, \\ \alpha_i &= \Theta_i - \bar{\Theta} \quad \text{for } i = 1, \dots, I, \\ \beta_j &= \Psi_j - \bar{\Psi} \quad \text{for } j = 1, \dots, J.\end{aligned}$$

Then it follows that Eqs. (11.7.2) and (11.7.3) will be satisfied.

It remains to be shown that no other set of values of  $\mu, \alpha_i$ , and  $\beta_j$  will satisfy Eqs. (11.7.2) and (11.7.3). Suppose that  $\mu', \alpha'_i$ , and  $\beta'_j$  are another such set of values. Then  $\mu + \alpha_i + \beta_j = \mu' + \alpha'_i + \beta'_j$  for all  $i$  and  $j$ . By summing both sides of this relation over  $i$  and  $j$ , we obtain the relation  $IJ\mu = IJ\mu'$ . Hence,  $\mu = \mu'$ . It follows, therefore, that  $\alpha_i + \beta_j = \alpha'_i + \beta'_j$  for all  $i$  and  $j$ . By summing both sides of this relation over  $j$ , we obtain the result  $\alpha_i = \alpha'_i$  for every value of  $i$ . Similarly, by summing both sides over  $i$ , we obtain the relation  $\beta_j = \beta'_j$  for every value of  $j$ .

4. If the effects are additive, so that Eq. (11.7.1) is satisfied, and we denote the elements of the matrix by  $\mu_{ij} = \Theta_i + \Psi_j$ , then  $\bar{\mu}_{++} = \bar{\Theta} + \bar{\Psi}$ ,  $\bar{\mu}_{i+} = \Theta_i + \bar{\Psi}$ , and  $\bar{\mu}_{+j} = \bar{\Theta} + \Psi_j$ . Therefore,  $\mu_{ij} = \bar{\mu}_{++} + (\bar{\mu}_{i+} - \bar{\mu}_{++}) + (\bar{\mu}_{+j} - \bar{\mu}_{++})$ . Hence, it can be verified that  $\mu = \bar{\mu}_{++}$ ,  $\alpha_i = \bar{\mu}_{i+} - \bar{\mu}_{++}$  and  $\beta_j = \bar{\mu}_{+j} - \bar{\mu}_{++}$ . In this exercise,

$$\begin{aligned}\bar{\mu}_{++} &= \frac{1}{4}(3 + 6 + 4 + 7) = 5, \\ \bar{\mu}_{1+} &= \frac{1}{2}(3 + 6) = 4.5, \bar{\mu}_{2+} = \frac{1}{2}(4 + 7) = 5.5, \\ \bar{\mu}_{+1} &= \frac{1}{2}(3 + 4) = 3.5, \bar{\mu}_{+2} = \frac{1}{2}(6 + 7) = 6.5.\end{aligned}$$

5. In this exercise,

$$\begin{aligned}\bar{\mu}_{++} &= \frac{1}{12} \sum_{i=1}^3 \sum_{j=1}^4 \mu_{ij} = \frac{1}{12}(39) = 3.25, \\ \bar{\mu}_{1+} &= \frac{5}{4} = 1.25, \bar{\mu}_{2+} = \frac{25}{4} = 6.35, \bar{\mu}_{3+} = \frac{9}{4} = 2.25, \\ \bar{\mu}_{+1} &= \frac{15}{3} = 5, \bar{\mu}_{+2} = \frac{3}{3} = 1, \bar{\mu}_{+3} = \frac{6}{3} = 2, \bar{\mu}_{+4} = \frac{15}{3} = 5.\end{aligned}$$

It follows that  $\alpha_1 = 1.25 - 3.25 = -2$ ,  $\alpha_2 = 6.35 - 3.25 = 3$ , and  $\alpha_3 = 2.25 - 3.25 = -1$ . Also,  $\beta_1 = 5 - 3.25 = 1.75$ ,  $\beta_2 = 1 - 3.25 = -2.25$ ,  $\beta_3 = 2 - 3.25 = -1.25$ , and  $\beta_4 = 5 - 3.25 = 1.75$ .

6.  $\sum_{i=1}^I \hat{\alpha}_i = \sum_{i=1}^I \bar{Y}_{i+} - I\bar{Y}_{++} = \frac{1}{J} \sum_{i=1}^I \sum_{j=1}^J Y_{ij} - \frac{1}{J} \sum_{i=1}^I \sum_{j=1}^J Y_{ij} = 0$ . A similar argument show that  $\sum_{j=1}^J \hat{\beta}_j = 0$ . Also, since  $E(Y_{ij}) = \mu + \alpha_i + \beta_j$ ,

$$\begin{aligned}E(\hat{\mu}) &= E(\bar{Y}_{++}) = \frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J E(Y_{ij}) = \frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J (\mu + \alpha_i + \beta_j) = \frac{1}{IJ} (IJ\mu + 0 + 0) = \mu, \\ E(\hat{\alpha}_i) &= E(\bar{Y}_{i+} - \bar{Y}_{++}) = E\left(\frac{1}{J} \sum_{j=1}^J Y_{ij}\right) - \mu = \frac{1}{J} \sum_{j=1}^J (\mu + \alpha_i + \beta_j) - \mu = \alpha_i.\end{aligned}$$

A similar argument shows that  $E(\hat{\beta}_j) = \beta_j$

$$7. \text{Var}(\hat{\mu}) = \text{Var}\left(\frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J Y_{ij}\right) = \frac{1}{I^2 J^2} \sum_{i=1}^I \sum_{j=1}^J \text{Var}(Y_{ij}) = \frac{1}{I^2 J^2} IJ\sigma^2 = \frac{1}{IJ}\sigma^2.$$

The estimator  $\hat{\alpha}_i$  is a linear function of the  $IJ$  independent random variables  $Y_{rs}$  ( $r = 1, \dots, I$  and  $s = 1, \dots, J$ ). If we let  $\hat{\alpha}_i = \sum_{r=1}^I \sum_{s=1}^J a_{rs} Y_{rs}$ , then it can be found that  $a_{is} = \frac{1}{J} - \frac{1}{IJ}$  for  $s = 1, \dots, J$  and  $a_{rs} = -\frac{1}{IJ}$  for  $r \neq i$ . Therefore,

$$\text{Var}(\hat{\alpha}_i) = \sum_{r=1}^I \sum_{s=1}^J a_{rs}^2 \sigma^2 = \sigma^2 \left[ J \left( \frac{1}{J} - \frac{1}{IJ} \right)^2 + (I-1)J \left( \frac{1}{IJ} \right)^2 \right] = \frac{I-1}{IJ} \sigma^2.$$

The value of  $\text{Var}(\hat{\beta}_j)$  can be found similarly.

8. If the square on the right of Eq. (11.7.9) is expanded and all the summations are then performed, we will obtain the right side of Eq. (11.7.8) provided that the summation of each of the cross product terms is 0. We shall now establish this result. Note that

$$\sum_{j=1}^J (Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++}) = J\bar{Y}_{i+} - J\bar{Y}_{i+} - J\bar{Y}_{++} + J\bar{Y}_{++} = 0.$$

Similarly,  $\sum_{j=1}^J (Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++}) = 0$ . Therefore,

$$\begin{aligned} \sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++})(\bar{Y}_{i+} - \bar{Y}_{++}) &= \sum_{i=1}^I (\bar{Y}_{i+} - \bar{Y}_{i+}) \sum_{j=1}^J (Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++}) = 0, \\ \sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++})(\bar{Y}_{+j} - \bar{Y}_{++}) &= \sum_{j=1}^J (\bar{Y}_{+j} - \bar{Y}_{+j}) \sum_{i=1}^I (Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++}) = 0. \end{aligned}$$

Finally,

$$\sum_{i=1}^I \sum_{j=1}^J (\bar{Y}_{i+} - \bar{Y}_{++})(\bar{Y}_{+j} - \bar{Y}_{++}) = \sum_{i=1}^I (\bar{Y}_{i+} - \bar{Y}_{++}) \sum_{j=1}^J (\bar{Y}_{+j} - \bar{Y}_{++}) = 0 \times 0.$$

9. Each of the four given random variables is a linear function of the independent random variables  $Y_{rs}$  ( $r = 1, \dots, I$  and  $s = 1, \dots, J$ ). Let

$$W_1 = \sum_{r=1}^I \sum_{s=1}^J a_{rs} Y_{rs},$$

$$W_2 = \sum_{r=1}^I \sum_{s=1}^J b_{rs} Y_{rs},$$

$$W_3 = \sum_{r=1}^I \sum_{s=1}^J c_{rs} Y_{rs}.$$

Then

$$\begin{aligned} a_{ij} &= 1 - \frac{1}{J} - \frac{1}{I} + \frac{1}{IJ}, a_{rj} = -\frac{1}{I} + \frac{1}{IJ} \quad \text{for } r \neq i, \\ a_{is} &= -\frac{1}{J} + \frac{1}{IJ} \quad \text{for } s \neq j, \quad \text{and} \quad a_{rs} = \frac{1}{IJ} \quad \text{for } r \neq i, \quad \text{and} \quad s \neq j. \end{aligned}$$

Also,

$$\begin{aligned} b_{i's} &= \frac{1}{J} - \frac{1}{IJ} \quad \text{and} \quad b_{rs} = -\frac{1}{IJ} \quad \text{for } r \neq i', \\ c_{rj'} &= \frac{1}{I} - \frac{1}{IJ} \quad \text{and} \quad c_{rs} = -\frac{1}{IJ} \quad \text{for } s \neq j'. \end{aligned}$$

As in Exercise 12 of Sec. 11.5,  $\text{Cov}(W_1, W_2) = \sigma^2 \sum_{r,s} a_{rs} b_{rs}$ . If  $i = i'$ ,

$$\begin{aligned} \sum_{r,s} a_{rs} b_{rs} &= \left(1 - \frac{1}{J} - \frac{1}{I} + \frac{1}{IJ}\right) \left(\frac{1}{J} - \frac{1}{IJ}\right) + (J-1) \left(-\frac{1}{J} + \frac{1}{IJ}\right) \left(\frac{1}{J} - \frac{1}{IJ}\right) \\ &\quad + (I-1) \left(-\frac{1}{I} + \frac{1}{IJ}\right) \left(-\frac{1}{IJ}\right) + (I-1)(J-1) \left(\frac{1}{IJ}\right) \left(-\frac{1}{IJ}\right) = 0. \end{aligned}$$

If  $i \neq i'$ ,

$$\begin{aligned} \sum_{r,s} a_{rs} b_{rs} &= \left(1 - \frac{1}{J} - \frac{1}{I} + \frac{1}{IJ}\right) \left(-\frac{1}{IJ}\right) \quad (i, j \text{ term}) \\ &\quad + (J-1) \left(-\frac{1}{J} + \frac{1}{IJ}\right) \left(-\frac{1}{IJ}\right) \quad (i, s \text{ terms for } s \neq j) \\ &\quad + \left(-\frac{1}{I} + \frac{1}{IJ}\right) \left(\frac{1}{J} - \frac{1}{IJ}\right) \quad (i', j \text{ term}) \\ &\quad + (J-1) \left(\frac{1}{IJ}\right) \left(\frac{1}{J} - \frac{1}{IJ}\right) \quad (i', j \text{ terms for } s \neq j) \\ &\quad + (I-2) \left(-\frac{1}{I} + \frac{1}{IJ}\right) \left(-\frac{1}{IJ}\right) \quad (r, j \text{ terms for } r \neq i, i') \\ &\quad + (I-2)(J-1) \left(\frac{1}{IJ}\right) \left(-\frac{1}{IJ}\right) \quad (r, s \text{ terms for } r \neq i, i' \text{ and } s \neq j). \\ &= 0. \end{aligned}$$

Similarly, the covariance between any other pair of the four variances can be shown to be 0.

$$10. \sum_{i=1}^I (\bar{Y}_{i+} - \bar{Y}_{++})^2 = \sum_{i=1}^I \bar{Y}_{i+}^2 - 2\bar{Y}_{++} \sum_{i=1}^I \bar{Y}_{i+} - I\bar{Y}_{++}^2 = \sum_{i=1}^I \bar{Y}_{i+}^2 - 2I\bar{Y}_{++}^2 + I\bar{Y}_{++}^2 = \sum_{i=1}^I \bar{Y}_{i+}^2 - I\bar{Y}_{++}^2.$$

The other part of this exercise is proved similarly.

$$\begin{aligned} 11. \sum_{i=1}^I \sum_{j=1}^J (Y_{ij} - \bar{Y}_{i+} - \bar{Y}_{+j} + \bar{Y}_{++})^2 &= \sum_i \sum_j Y_{ij}^2 + J \sum_i \bar{Y}_{i+}^2 + I \sum_j \bar{Y}_{+j}^2 + IJ\bar{Y}_{++}^2 \\ &\quad - 2 \sum_i \sum_j Y_{ij} \bar{Y}_{i+} - 2 \sum_j \sum_i Y_{ij} \bar{Y}_{+j} + 2\bar{Y}_{++} \sum_i \sum_j Y_{ij} \\ &\quad + 2 \sum_i \sum_j \bar{Y}_{i+} \bar{Y}_{+j} - 2J\bar{Y}_{++} \sum_i \bar{Y}_{i+} - 2I\bar{Y}_{++} \sum_j \bar{Y}_{+j} \end{aligned}$$

$$\begin{aligned}
&= \sum_i \sum_j Y_{ij}^2 + J \sum_i \bar{Y}_{i+}^2 + I \sum_i \bar{Y}_{+j}^2 + IJ\bar{Y}_{++}^2 \\
&\quad - 2J \sum_i \bar{Y}_{i+}^2 - 2I \sum_j \bar{Y}_{+j}^2 + 2IJ\bar{Y}_{++}^2 \\
&\quad + 2IJ\bar{Y}_{++}^2 - 2IJ\bar{Y}_{++}^2 - 2IJ\bar{Y}_{++}^2 \\
&= \sum_i \sum_j Y_{ij}^2 - J \sum_i \bar{Y}_{i+}^2 - I \sum_j \bar{Y}_{+j}^2 + IJ\bar{Y}_{++}^2.
\end{aligned}$$

12. It is found that  $\bar{Y}_{1+} = 17.4$ ,  $\bar{Y}_{2+} = 15.94$ ,  $\bar{Y}_{3+} = 17.08$ ,  $\bar{Y}_{+1} = 15.1$ ,  $\bar{Y}_{+2} = 14.6$ ,  $\bar{Y}_{+3} = 15.5333$ ,  $\bar{Y}_{+4} = 19.5667$ ,  $\bar{Y}_{+5} = 19.2333$ ,  $\bar{Y}_{++} = 16.8097$ . The values of  $\hat{\mu}$ ,  $\hat{\alpha}_i$  for  $i = 1, 2, 3$ , and  $\hat{\beta}_j$  for  $j = 1, \dots, 5$ , can now be obtained from Eq. (11.7.6).
13. The estimate of  $E(Y_{ij})$  is  $\hat{\mu} + \hat{\alpha}_i + \hat{\beta}_j$ . From the values given in the solution of Exercise 12, we therefore obtain the following table of estimated expectations:

	1	2	3	4	5
1	15.6933	15.1933	16.1267	20.16	19.8267
2	14.2333	13.7333	14.6667	18.7	18.3667
3	15.3733	14.8733	15.8067	19.84	19.5067

Furthermore, Theorem 11.7.1 says that the M.L.E. of  $\sigma^2$  is

$$\hat{\sigma}^2 = \frac{1}{15}(29.470667) = 1.9647.$$

14. It is found from Eq. (11.7.12) that

$$U_A^2 = \frac{20(1.177865)}{(29.470667)} = 0.799.$$

When the null hypothesis is true,  $U_A^2$  will have the  $F$  distribution with  $I - 1 = 2$  and  $(I - 1)(J - 1) = 8$  degrees of freedom. The tail area corresponding to the value just calculated is found to be greater than 0.05.

15. It is found from Eq. (11.7.13) that

$$U_B^2 = \frac{6(22.909769)}{(29.470667)} = 4.664.$$

When the null hypothesis is true,  $U_B^2$  will have the  $F$  distribution with  $J - 1 = 4$  and  $(I - 1)(J - 1) = 8$  degrees of freedom. The tail area corresponding to the value just calculated is found to be between 0.025 and 0.05.

16. If the null hypothesis in (11.7.15) is true, then all  $Y_{ij}$  have the same mean  $\mu$ . The random variables  $S_A^2/\sigma^2$ ,  $S_B^2/\sigma^2$ , and  $S_{Resid}^2/\sigma^2$  are independent, and their distributions are  $\chi^2$  with  $I - 1$ ,  $J - 1$ , and  $(I - 1)(J - 1)$  degrees of freedom respectively. Hence  $S_A^2 + S_B^2$  has the  $\chi^2$  distribution with  $I + J - 2$  degrees of freedom and is independent of  $\sigma'$ . The conclusion now follows directly from the definition of the  $F$  distribution.

## 11.8 The Two-Way Layout with Replications

### Commentary

This section is optional. There is reference to some of the material in this section in Chapter 12. In particular, Example 12.3.4 shows how to use simulation to compute the size of the two-stage test procedure that is described in Sec. 11.8.

If one is using the software *R*, and if one has **factor** variables **x1** and **x2** (as in the Commentary to Sec. 11.7) giving the levels of the two factors in a two-way layout with replication, then the following commands will fit the model and print the ANOVA table:

```
aovfit=lm(y~x1*x2)
anova(aovfit)
```

### Solutions to Exercises

- Let  $\mu = \bar{\Theta}_{++}$ ,  $\alpha_i = \bar{\Theta}_{i+} - \bar{\Theta}_{++}$ ,  $\beta_j = \bar{\Theta}_{+j} - \bar{\Theta}_{++}$ , and  $\gamma_{ij} = \Theta_{ij} - \bar{\Theta}_{i+} - \bar{\Theta}_{+j} + \bar{\Theta}_{++}$  for  $i = 1, \dots, I$  and  $j = 1, \dots, J$ . Then it can be verified that Eqs. (11.8.4) and (11.8.5) are satisfied. It remains to be shown that no other set of values of  $\mu, \alpha_i, \beta_j$ , and  $\gamma_{ij}$  will satisfy Eqs. (11.8.4) and (11.8.5).

Suppose that  $\mu', \alpha'_i, \beta'_j$ , and  $\gamma'_{ij}$  are another such set of values. Then, for all values of  $i$  and  $j$ ,

$$\mu + \alpha_i + \beta_j + \gamma_{ij} = \mu' + \alpha'_i + \beta'_j + \gamma'_{ij}$$

By summing both sides of this equation over  $i$  and  $j$ , we obtain the relation  $IJ\mu = IJ\mu'$ . Hence,  $\mu = \mu'$ . It follows, therefore, that for all values of  $i$  and  $j$ ,

$$\alpha_i + \beta_j + \gamma_{ij} = \alpha'_i + \beta'_j + \gamma'_{ij}.$$

By summing both sides of this equation over  $j$ , we obtain the relation  $J\alpha_i = J\alpha'_i$ . By summing both sides of this equation over  $i$ , we obtain the relation  $I\beta_j = I\beta'_j$ . Hence,  $\alpha_i = \alpha'_i$  and  $\beta_j = \beta'_j$ . It also follows, therefore, that  $\gamma_{ij} = \gamma'_{ij}$ .

- Since  $\bar{Y}_{ij+}$  is the M.L.E. of  $\theta_{ij}$  for each  $i$  and  $j$ , it follows from the definitions in Exercise 1 that the M.L.E.'s of the various linear functions defined in Exercise 1 are the corresponding linear functions of  $\bar{Y}_{ij+}$ . These are precisely the values in (11.8.6) and (11.8.7).
- The values of  $\mu, \alpha_i, \beta_j$ , and  $\gamma_{ij}$  can be determined in each part of this problem from the given values of  $\Theta_{ij}$  by applying the definitions given in the solution of Exercise 1.

$$4. \quad \sum_{i=1}^I \hat{\alpha}_i = \sum_{i=1}^I (\bar{Y}_{i++} - \bar{Y}_{+++}) = I\bar{Y}_{+++} - I\bar{Y}_{+++} = 0,$$

$$\sum_{i=1}^I \hat{\gamma}_{ij} = \sum_{i=1}^I (\bar{Y}_{ij+} - \bar{Y}_{i++} - \bar{Y}_{+j+} + \bar{Y}_{+++}) = I\bar{Y}_{+j+} - I\bar{Y}_{+++} - I\bar{Y}_{+j+} + I\bar{Y}_{+++} = 0.$$

The proofs that  $\sum_{j=1}^J \hat{\beta}_j = 0$  and  $\sum_{j=1}^J \hat{\gamma}_{ij} = 0$  are similar.

5.  $E(\hat{\mu}) = \frac{1}{IJK} \sum_{i,j,k} E(Y_{ijk}) = \frac{1}{IJK} \sum_{i,j,k} \Theta_{ij} = \frac{1}{IJ} \sum_{i,j} \Theta_{ij} = \bar{\Theta}_{++} = \mu$ , by Exercise 1;

$$\begin{aligned} E(\hat{\alpha}_i) &= \frac{1}{JK} \sum_{j,k} E(Y_{ijk}) - E(\bar{Y}_{+++}) \\ &= \frac{1}{JK} \sum_{j,k} \Theta_{ij} - \bar{\Theta}_{++}, \text{ by the first part of this exercise} \end{aligned}$$

$$= \frac{1}{J} \sum_j \Theta_{ij} - \bar{\Theta}_{++} = \bar{\Theta}_{i+} - \bar{\Theta}_{++} = \alpha_i, \text{ by Exercise 1};$$

$$E(\hat{\beta}_j) = \beta_j, \text{ by a similar argument};$$

$$E(\hat{\gamma}_{ij}) = \frac{1}{K} \sum_k E(Y_{ijk}) - E(\hat{\mu} + \hat{\alpha}_i + \hat{\beta}_j), \text{ by Eq. (11.8.7)}$$

$$= \Theta_{ij} - \bar{\Theta}_{i+} - \bar{\Theta}_{+J} + \bar{\Theta}_{++}, \text{ by the previous parts of this exercise,}$$

$$= \gamma_{ij}, \text{ by Exercise 1.}$$

6. The  $IJK$  random variables  $Y_{ijk}$  are independent and each has variance  $\sigma^2$ . Hence,

$$\text{Var}(\hat{\mu}) = \text{Var} \left( \frac{1}{IJK} \sum_{i,j,k} Y_{ijk} \right) = \frac{1}{(IJK)^2} \sum_{i,j,k} \text{Var}(Y_{ijk}) = \frac{1}{(IJK)^2} IJK \sigma^2 = \frac{\sigma^2}{IJK}.$$

The estimator  $\hat{\alpha}_i$  is a linear function of the observations  $Y_{ijk}$  of the form  $\hat{\alpha}_i = \sum_{r,s,t} a_{rst} Y_{rst}$ , where

$$a_{ist} = \frac{1}{JK} - \frac{1}{IJK} = \frac{I-1}{IJK}, \quad \text{and} \quad a_{rst} = -\frac{1}{IJK},$$

for  $r \neq i$ . Hence,

$$\text{Var}(\hat{\alpha}_i) = \sum_{r,s,t} a_{rst}^2 \sigma^2 = \left[ JK \left( \frac{I-1}{IJK} \right)^2 + (I-1)JK \left( -\frac{1}{IJK} \right)^2 \right] \sigma^2 = \frac{I-1}{IJK} \sigma^2.$$

$\text{Var}(\hat{\beta}_j)$  can be determined similarly. Finally, if we represent  $\hat{\gamma}_{ij}$  in the form  $\hat{\gamma}_{ij} = \sum_{r,s,t} c_{rst} Y_{rst}$ , then it follows from Eq. (11.8.7) that

$$\begin{aligned} c_{ijt} &= \frac{1}{K} - \frac{1}{JK} - \frac{1}{IK} + \frac{1}{IJK} \text{ for } t = 1, \dots, K, \\ c_{rjt} &= -\frac{1}{IK} + \frac{1}{IJK} \text{ for } r \neq i \text{ and } t = 1, \dots, K, \\ c_{ist} &= -\frac{1}{JK} + \frac{1}{IJK} \text{ for } s \neq j \text{ and } t = 1, \dots, K, \\ c_{rst} &= \frac{1}{IJK} \text{ for } r \neq i, s \neq j, \text{ and } t = 1, \dots, K. \end{aligned}$$

Therefore,

$$\text{Var}(\hat{\gamma}_{ij}) = \sum_{r,s,t} c_{rst}^2 \sigma^2$$

$$\begin{aligned}
&= \left[ K \left( \frac{1}{K} - \frac{1}{JK} - \frac{1}{IK} + \frac{1}{IJK} \right)^2 + (I-1)K \left( -\frac{1}{IK} + \frac{1}{IJK} \right)^2 \right. \\
&\quad \left. + (J-1)K \left( -\frac{1}{JK} + \frac{1}{IJK} \right)^2 + (I-1)(J-1)K \left( \frac{1}{IJK} \right)^2 \right] \sigma^2 \\
&= \frac{(I-1)(J-1)}{IJK} \sigma^2.
\end{aligned}$$

7. First, write  $S_{\text{Tot}}^2$  as

$$\sum_{i,j,k} [(Y_{ijk} - \bar{Y}_{ij+}) + (\bar{Y}_{ij+} - \bar{Y}_{i++} - \bar{Y}_{+j+} + \bar{Y}_{+++}) + (\bar{Y}_{i++} - \bar{Y}_{+++}) + (\bar{Y}_{+j+} - \bar{Y}_{+++})]^2. \quad (\text{S.11.6})$$

The sums of squares of the grouped terms in the summation in (S.11.6) are  $S_{\text{Resid}}^2$ ,  $S_{\text{Int}}^2$ ,  $S_A^2$ , and  $S_B^2$ . Hence, to verify Eq. (11.8.9), it must be shown that the sum of each of the pairs of cross-products of the grouped terms is 0. This is verified in a manner similar to what was done in the solution to Exercise 8 in Sec. 11.7. Each of the sums of  $(Y_{ijk} - \bar{Y}_{ij+})$  times one of the other terms is 0 by summing over  $k$  first. The sum of the product of the last two grouped terms is 0 because the sum factors into sums of  $i$  and  $j$  that are each 0. The other two sums are similar, and we shall illustrate this one:

$$\sum_{i,j,k} (\bar{Y}_{ij+} - \bar{Y}_{i++} - \bar{Y}_{+j+} + \bar{Y}_{+++})(\bar{Y}_{i++} - \bar{Y}_{+++}).$$

Summing over  $j$  first produces 0 in this sum. For the other one, sum over  $i$  first.

8. Each of the five given random variables is a linear function of the IJK independent observations  $Y_{rst}$ . Let

$$\begin{aligned}
\hat{\alpha}_{i_1} &= \sum_{r,s,t} a_{rst} Y_{rst}, \\
\hat{\beta}_{j_1} &= \sum_{r,s,t} b_{rst} Y_{rst}, \\
\hat{\gamma}_{i_2 j_2} &= \sum_{r,s,t} c_{rst} Y_{rst} \\
Y_{ijk} - \bar{Y}_{ij+} &= \sum_{r,s,t} d_{rst} Y_{rst}.
\end{aligned}$$

Of course,  $\hat{\mu} = \sum_{r,s,t} Y_{rst}/[IJK]$ . The value of  $a_{rst}$ ,  $b_{rst}$ , and  $c_{rst}$  were given in the solution of Exercise 6, and

$$\begin{aligned}
d_{ijk} &= 1 - \frac{1}{K}, \\
d_{ijt} &= -\frac{1}{K} \quad \text{for } t \neq k, \\
d_{rst} &= 0 \quad \text{otherwise.}
\end{aligned}$$

To show that  $\hat{\alpha}_{i_1}$  and  $\hat{\beta}_{j_1}$  are uncorrelated, for example, it must be shown, as in Exercise 9 of Sec. 11.7, that  $\sum_{r,s,t} a_{rst} b_{rst} = 0$ . We have

$$\sum_{r,s,t} a_{rst} b_{rst} = K \left( \frac{I-1}{IJK} \right) \left( \frac{J-1}{IJK} \right) + (J-1)K \left( \frac{I-1}{IJK} \right) \left( -\frac{1}{IJK} \right)$$

$$\begin{aligned}
& + (I-1)K \left( -\frac{1}{IJK} \right) \left( \frac{J-1}{IJK} \right) + (I-1)(J-1)K \left( -\frac{1}{IJK} \right) \left( -\frac{1}{IJK} \right) \\
= & 0.
\end{aligned}$$

Similarly, to show that  $Y_{ijk} - \bar{Y}_{ij+}$  and  $\hat{\gamma}_{i_2 j_2}$  are uncorrelated, it must be shown that  $\sum_{r,s,t} c_{rst} d_{rst} = 0$ . Suppose first that  $i = i_2$  and  $j = j_2$ . Then

$$\begin{aligned}
\sum_{r,s,t} c_{rst} d_{rst} &= \left( \frac{1}{K} - \frac{1}{JK} - \frac{1}{IK} + \frac{1}{IJK} \right) \left( 1 - \frac{1}{K} \right) \\
&\quad + (K-1) \left( \frac{1}{K} - \frac{1}{JK} - \frac{1}{IK} + \frac{1}{IJK} \right) \left( -\frac{1}{K} \right) = 0.
\end{aligned}$$

Suppose next that  $i = i_2$  and  $j \neq j_2$ . Then

$$\sum_{r,s,t} c_{rst} d_{rst} = \left( -\frac{1}{JK} + \frac{1}{IJK} \right) \left( 1 - \frac{1}{K} \right) + (K-1) \left( -\frac{1}{JK} + \frac{1}{IJK} \right) \left( -\frac{1}{K} \right) = 0.$$

The other cases can be treated similarly, and it can be shown that the five given random variables are uncorrelated with one another regardless of whether any of the values  $j, j_1$  and  $j_2$  are equal.

9. We shall first show that the numerators are equal:

$$\begin{aligned}
\sum_{i,j} (\bar{Y}_{ij+} - \bar{Y}_{i++} - \bar{Y}_{+j+} + \bar{Y}_{+++})^2 &= \sum_{i,j} (\bar{Y}_{ij+}^2 + \bar{Y}_{i++}^2 + \bar{Y}_{+j+}^2 + \bar{Y}_{+++}^2 - 2\bar{Y}_{ij+}\bar{Y}_{i++} \\
&\quad - 2\bar{Y}_{ij+}\bar{Y}_{+j+} + 2\bar{Y}_{ij+}\bar{Y}_{+++} + 2\bar{Y}_{i++}\bar{Y}_{+j+} \\
&\quad - 2\bar{Y}_{i++}\bar{Y}_{+++} - 2\bar{Y}_{+j+}\bar{Y}_{+++}) \\
&= \sum_{i,j} \bar{Y}_{ij+}^2 + J \sum_i \bar{Y}_{i++}^2 + I \sum_j \bar{Y}_{+j+}^2 + IJ\bar{Y}_{+++}^2 \\
&\quad - 2J \sum_i \bar{Y}_{i++} - 2I \sum_j \bar{Y}_{+j+}^2 + 2IJ\bar{Y}_{+++}^2 \\
&\quad + 2IJ\bar{Y}_{+++}^2 - 2IJ\bar{Y}_{+++}^2 - 2IJ\bar{Y}_{+++}^2 \\
&= \sum_{i,j} \bar{Y}_{ij+}^2 - J \sum_i \bar{Y}_{i++}^2 - I \sum_j \bar{Y}_{+j+}^2 + IJ\bar{Y}_{+++}^2.
\end{aligned}$$

Next, we shall show that the denominators are equal:

$$\begin{aligned}
\sum_{i,j,k} (\bar{Y}_{ijk} - \bar{Y}_{ij+})^2 &= \sum_{i,j,k} (Y_{ijk}^2 - 2Y_{ijk}\bar{Y}_{ij+} + \bar{Y}_{ij+}^2) \\
&= \sum_{i,j} \left( \sum_k Y_{ijk}^2 - 2K\bar{Y}_{ij+}^2 + K\bar{Y}_{ij+}^2 \right) \\
&= \sum_{i,j,k} Y_{ijk}^2 - K \sum_{i,j} \bar{Y}_{ij+}^2.
\end{aligned}$$

10. In this problem,  $I = 3$ ,  $J = 4$ , and  $K = 2$ . The values of the estimates can be calculated directly from Eqs. (11.8.6), (11.8.7), and (11.8.3).

11. It is found from Eq. (11.8.12) that  $U_{AB}^2 = 0.7047$ . When the hypothesis is true,  $U_{AB}^2$  has the  $F$  distribution with  $(I-1)(J-1) = 6$  and  $IJ(K-1) = 12$  degrees of freedom. The tail area corresponding to the value just calculated is found to be greater than 0.05.
12. Since the hypothesis in Exercise 11 was not rejected, we proceed to test the hypotheses (11.8.13). It is found from Eq. (11.8.14) that  $U_A^2 = 7.5245$ . When the hypothesis is true,  $U_A^2$  has the  $F$  distribution with  $(I-1)J = 8$  and 12 degrees of freedom. The tail area corresponding to the value just calculated is found to be less than 0.025.
13. It is found from Eq. (11.8.18) that  $U_B^2 = 9.0657$ . When the hypothesis is true,  $U_B^2$  has the  $F$  distribution with  $I(J-1) = 9$  and 12 degrees of freedom. The tail area corresponding to the value just calculated is found to be less than 0.025.
14. The estimator  $\hat{\mu}$  has the normal distribution with mean  $\mu$  and, by Exercise 6, variance  $\sigma^2/24$ . Also,  $\sum_{i,j,k} (Y_{ijk} - \bar{Y}_{ij+})^2 / \sigma^2$  has a  $\chi^2$  distribution with 12 degrees of freedom, and these two random variables are independent. Therefore, when  $H_0$  is true, the following statistic  $V$  will have the  $t$  distribution with 12 degrees of freedom:

$$V = \frac{\sqrt{24}(\hat{\mu} - 8)}{\left[ \frac{1}{12} \sum_{i,j,k} (Y_{ijk} - \bar{Y}_{ij+})^2 \right]^{1/2}}.$$

We could test the given hypotheses by carrying out a two-sided  $t$  test using the statistic  $V$ . Equivalently, as described in Sec. 9.7,  $V^2$  will have the  $F$  distribution with 1 and 12 degrees of freedom. It is found that

$$V^2 = \frac{24(0.7708)^2}{\frac{1}{12}(10.295)} = 16.6221.$$

The corresponding tail area is less than 0.025.

15. The estimator  $\hat{\alpha}_2$  has the normal distribution with mean  $\alpha_2$  and, by Exercise 6, variance  $\sigma^2/12$ . Hence, as in the solution of Exercise 14, when  $\alpha_2 = 1$ , the following statistic  $V$  will have the  $t$  distribution with 12 degrees of freedom:

$$V = \frac{\sqrt{12}(\hat{\alpha}_2 - 1)}{\left[ \frac{1}{12} \sum_{i,j,k} (Y_{ijk} - \bar{Y}_{ij+})^2 \right]^{1/2}}$$

The null hypothesis  $H_0$  should be rejected if  $V \geq c$ , where  $c$  is an appropriate constant. It is found that

$$V = \frac{\sqrt{12}(0.7667)}{\left[ \frac{1}{12}(10.295) \right]^{1/2}} = 2.8673$$

The corresponding tail area is between 0.005 and 0.01.

16. Since  $E(Y_{ijk}) = \mu + \alpha_i + \beta_j + \gamma_{ij}$ , then  $E(\bar{Y}_{ij+}) = \mu + \alpha_i + \beta_j + \gamma_{ij}$ . The desired results can now be obtained from Eq. (11.8.19) and Eq. (11.8.5).

17.  $\sum_{i=1}^I \hat{\alpha}_i = \frac{1}{J} \sum_{i=1}^I \sum_{j=1}^J \bar{Y}_{ij+} - I\hat{\mu} = I\hat{\mu} - I\hat{\mu} = 0$  and

$$\sum_{i=1}^I \hat{\gamma}_{ij} = \left( \sum_{i=1}^I \bar{Y}_{ij+} - I\hat{\mu} \right) - \sum_{i=1}^I \hat{\alpha}_i - I\hat{\beta}_j = I\hat{\beta}_j - 0 - I\hat{\beta}_j = 0.$$

It can be shown similarly that

$$\sum_{j=1}^J \hat{\beta}_j = 0 \quad \text{and} \quad \sum_{j=1}^J \hat{\gamma}_{ij} = 0.$$

18. Both  $\hat{\mu}$  and  $\hat{\alpha}_i$  are linear functions of the  $\sum_{i=1}^I \sum_{j=1}^J K_{ij}$  independent random variables  $Y_{ijk}$ . Let  $\hat{\mu} = \sum_{r,s,t} m_{rst} Y_{rst}$  and  $\hat{\alpha}_i = \sum_{r,s,t} a_{rst} Y_{rst}$ . Then it is found from Eq. (11.8.19) that

$$M_{rst} = \frac{1}{IJK_{rs}} \quad \text{for all values of } r, s, \text{ and } t,$$

and

$$\begin{aligned} a_{ist} &= \frac{1}{JK_{is}} - \frac{1}{IJK_{is}}, \\ a_{rst} &= -\frac{1}{IJK_{rs}} \quad \text{for } r \neq i. \end{aligned}$$

As in the solution of Exercise 8,

$$\begin{aligned} \text{Cov}(\hat{\mu}, \hat{\alpha}_i) &= \sigma^2 \sum_{r,s,t} m_{rst} a_{rst} \\ &= \sigma^2 \left[ \sum_{s=1}^J \sum_{t=1}^{K_{is}} \frac{1}{IJK_{is}} \left( \frac{1}{JK_{is}} - \frac{1}{IJK_{is}} \right) + \sum_{r \neq i} \sum_{s=1}^J \sum_{t=1}^{K_{rs}} \left( \frac{1}{IJK_{rs}} \right) \left( -\frac{1}{IJK_{rs}} \right) \right] \\ &= \sigma^2 \left[ \frac{I-1}{I^2 J^2} \sum_{s=1}^J \frac{1}{K_{is}} - \frac{1}{I^2 J^2} \sum_{r \neq i} \sum_{s=1}^J \frac{1}{K_{rs}} \right] \\ &= \frac{\sigma^2}{I^2 J^2} \left[ (I-1) \sum_{s=1}^J \frac{1}{K_{is}} - \left( \sum_{r=1}^I \sum_{s=1}^J \frac{1}{K_{rs}} - \sum_{s=1}^J \frac{1}{K_{is}} \right) \right] \\ &= \frac{\sigma^2}{I^2 J^2} \left[ I \sum_{s=1}^J \frac{1}{K_{is}} - \sum_{r=1}^I \sum_{s=1}^J \frac{1}{K_{rs}} \right]. \end{aligned}$$

19. Notice that we cannot reject the second null hypothesis unless we accept the first null hypothesis, since we don't even test the second hypothesis if we reject the first one. The probability that the two-stage procedure rejects at least one of the two hypotheses is then

$$\Pr(\text{reject first null hypothesis})$$

$$+ \Pr(\text{reject second null hypothesis and accept first null hypothesis}).$$

The first term above is  $\alpha_0$ , and the second term can be rewritten as

$$\begin{aligned} & \Pr(\text{reject second null hypothesis} | \text{accept first null hypothesis}) \\ & \quad \times \Pr(\text{accept first null hypothesis}). \end{aligned}$$

This product equals  $\beta_0(1 - \alpha_0)$ , hence the overall probability is  $\alpha_0 + \beta_0(1 - \alpha_0)$ .

20. (a) The three additional cell averages are 822.5, 821.7, and 770. The ANOVA table for the combined samples is

Source of variation	Degrees of freedom	Sum of squares	Mean square
Main effects of filter	1	1003	1003
Main effects of size	2	25817	12908
Interactions	2	739	369.4
Residuals	30	1992	66.39
Total	35	29551	

- (b) The  $F$  statistic for the test of no interaction is  $369.4/66.39 = 5.56$ . Comparing this to the  $F$  distribution with 2 and 30 degrees of freedom, we get a  $p$ -value of 0.009.
- (c) If we use the one-stage test procedure in which both the main effects and interactions are hypothesized to be 0 together, we get an  $F$  statistic equal to  $[(25817 + 739)/4]/66.39 = 100$  with 3 and 30 degrees of freedom. The  $p$ -value is essentially 0.
- (d) If we use the one-stage test procedure in which both the main effects and interactions are hypothesized to be 0 together, we get an  $F$  statistic equal to  $[(1003 + 739)/3]/66.39 = 8.75$  with 3 and 30 degrees of freedom. The  $p$ -value is 0.0003.

## 11.9 Supplementary Exercises

### Solutions to Exercises

1. The necessary calculations were done in Example 11.3.6. The least-squares coefficients are  $\hat{\beta}_0 = -0.9709$  and  $\hat{\beta}_1 = 0.0206$ , with  $\sigma' = 8.730 \times 10^{-3}$ , and  $n = 17$ . We also can compute  $s_x^2 = 530.8$  and  $\bar{x}_n = 203.0$ .
- (a) A 90% confidence interval for  $\beta_1$  is  $\hat{\beta}_1 \pm T_{n-2}^{-1}(0.95)\sigma'/s_x$ . This becomes  $(0.01996, 0.02129)$ .
- (b) Since 0 is not in the 90% interval in part (a), we would reject  $H_0$  at level  $\alpha_0 = 0.1$ .
- (c) A 90% prediction interval for log-pressure at boiling-point equal to  $x$  is

$$\hat{\beta}_0 + x\hat{\beta}_1 \pm T_{n-2}^{-1}(0.95)\sigma' \left( 1 + \frac{1}{n} + \frac{(x - \bar{x}_n)^2}{s_x^2} \right)^{1/2}.$$

With the data we have, this gives  $[3.233, 3, 264]$ . Converting this to pressure gives  $(25.35, 26.16)$ .

2. This result follows directly from the expressions for  $\hat{\rho}$ ,  $\hat{\sigma}_1$ , and  $\hat{\sigma}_2$  given in Exercise 24 of Sec. 7.6 and the expression for  $\hat{\beta}_1$  given in Exercise 2a of Sec. 11.1.
3. The conditional distribution of  $Y_i$  given  $X_i = x_i$  has mean  $\beta_0 + \beta_1 x_i$ , where

$$\beta_0 = \mu_2 - \frac{\rho\sigma_2}{\sigma_1}\mu_1 \quad \text{and} \quad \beta_1 = \frac{\rho\sigma_2}{\sigma_1},$$

and variance  $(1 - \rho^2)\sigma_2^2$ . Since  $T = \hat{\beta}_1$ , as given in Exercise 2b of Sec. 11.1, it follows that  $E(T) = \beta_1 = \rho\sigma_2/\sigma_1$  and

$$\text{Var}(T) = \frac{(1 - \rho^2)\sigma_2^2}{\sum_{i=1}^n (x_i - \bar{x}_n)^2}.$$

4. The least squares estimates will be the values of  $\theta_1, \theta_2$ , and  $\theta_3$  that minimize  $Q = \sum_{i=1}^3 (y_i - \theta_i)^2$ , where  $\theta_3 = 180 - \theta_1 - \theta_2$ . If we solve the equations  $\partial Q/\partial\theta_1 = 0$  and  $\partial Q/\partial\theta_2 = 0$ , we obtain the relations

$$y_1 - \theta_1 = y_2 - \theta_2 = y_3 - \theta_3.$$

Since  $\sum_{i=1}^3 y_i = 186$  and  $\sum_{i=1}^3 \theta_i = 180$ , it follows that  $\hat{\theta}_i = y_i - 2$  for  $i = 1, 2, 3$ . Hence  $\hat{\theta}_1 = 81$ ,  $\hat{\theta}_2 = 45$ , and  $\hat{\theta}_3 = 54$ .

5. This result can be established from the formulas for the least squares line given in Sec. 11.1 or directly from the following reasoning: Let  $x_1 = a$  and  $x_2 = b$ . The data contain one observation  $(a, y_1)$  at  $x = a$  and  $n - 1$  observations  $(b, y_2), \dots, (b, y_n)$  at  $x = b$ . Let  $u$  denote the average of the  $n - 1$  values  $y_2, \dots, y_n$ , and let  $h_a$  and  $h_b$  denote the height of the least square line at  $x = a$  and  $x = b$ , respectively. Then the value of  $Q$ , as given by Eq. (11.1.2), is

$$Q = (y_1 - h_a)^2 + \sum_{j=2}^n (y_j - h_b)^2.$$

The first term is minimized by taking  $h_a = y_1$  and the summation is minimized by taking  $h_b = u$ . Hence,  $Q$  is minimized by passing the straight line through the two points  $(a, y_1)$  and  $(b, u)$ . But  $(a, y_1)$  is the point  $(x_1, y_1)$ .

6. The first line is the usual least squares line  $y = \hat{\beta}_0 + \hat{\beta}_1 x$ , where  $\hat{\beta}_1$  is given in Exercise 2a of Sec. 11.1. In the second line, the roles of  $x$  and  $y$  are interchanged, so it is  $x = \hat{\alpha}_1 + \hat{\alpha}_2 y$ , where

$$\hat{\alpha}_2 = \frac{\sum_{i=1}^n (x_i - \bar{x}_n)(y_i - \bar{y}_n)}{\sum_{i=1}^n (y_i - \bar{y}_n)^2}.$$

Both lines pass through the point  $(\bar{x}_n, \bar{y}_n)$ , so they will coincide if and only if they have the same slope; i.e., if and only if  $\hat{\beta}_1 = 1/\hat{\alpha}_2$ . This condition reduces to the condition that  $\hat{\rho}^2 = 1$ , where  $\hat{\rho}$  is given in Exercise 24 of Sec. 7.6 and is the sample correlation coefficient. But  $\hat{\rho}^2 = 1$  if and only if the  $n$  points lie exactly on a straight line. Hence, the two least squares lines will coincide if and only if all  $n$  points lie exactly on a straight line.

7. It is found from standard calculus texts that the sum of the squared distances from the points to the line is

$$Q = \frac{\sum_{i=1}^n (y_i - \beta_1 - \beta_2 x_i)^2}{1 + \beta_2^2}.$$

The equation  $\partial Q/\partial\beta_1 = 0$  reduces to the relation  $\beta_1 = \bar{y}_n - \beta_2\bar{x}_n$ . If we replace  $\beta_1$  in the equation  $\partial Q/\partial\beta_2 = 0$  by this quantity, we obtain the relation:

$$(1 + \beta_2^2) = \sum_{i=1}^n [(y_i - \bar{y}_n) - \beta_2(x_i - \bar{x}_n)]x_i + \beta_2 \sum_{i=1}^n [(y_i - \bar{y}_n) - \beta_2(x_i - \bar{x}_n)]^2 = 0.$$

Note that we can replace the factor  $x_i$  in the first summation by  $x_i - \bar{x}_n$  without changing the value of the summation. If we then let  $x'_i = x_i - \bar{x}_n$  and  $y'_i = y_i - \bar{y}_n$ , and expand the final squared term, we obtain the following relation after some algebra:

$$(\beta_2^2 - 1) \sum_{i=1}^n x'_i y'_i + \beta_2 \sum_{i=1}^n (x'^2_i - y'^2_i) = 0.$$

Hence

$$\beta_2 = \frac{\sum_{i=1}^n (y'^2_i - x'^2_i) \pm \left[ \left( \sum_{i=1}^n (y'^2_i - x'^2_i) \right)^2 + 4 \left( \sum_{i=1}^n x'_i y'_i \right)^2 \right]^{1/2}}{2 \sum_{i=1}^n x'_i y'_i}.$$

Either the plus sign or the minus sign should be used, depending on whether the optimal line has positive or negative slope.

8. This phenomenon was discussed in Exercise 19 of Sec. 11.2. The conditional expectation  $E(X_2|X_1)$  of the sister's score  $X_2$  given the first twin's score  $X_1$  can be derived from Eq. (5.10.6) with  $\mu_1 = \mu_2 = \mu$  and  $\sigma_1 = \sigma_2 = \sigma$ . Hence,

$$E(X_2|X_1) = \mu + \rho(X_1 - \mu) = (1 - \rho)\mu + \rho X_1,$$

which is between  $\mu$  and  $X_1$ . The same holds with subscripts 1 and 2 switched.

9.

$$\begin{aligned} v^2 &= \frac{1}{n} \sum_{i=1}^k \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_{i+} + \bar{x}_{i+} - \bar{x}_{++})^2 \\ &= \frac{1}{n} \sum_{i=1}^k \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_{i+})^2 + \frac{1}{n} \sum_{i=1}^k n_i (\bar{x}_{i+} - \bar{x}_{++})^2 \\ &= \frac{1}{n} \sum_{i=1}^k n_i [v_i^2 + (\bar{x}_{i+} - \bar{x}_{++})^2]. \end{aligned}$$

10. In the notation of Sec. 11.5, the design matrix is

$$\mathbf{Z} = \begin{bmatrix} w_1 & x_1 \\ \vdots & \vdots \\ w_n & x_n \end{bmatrix}.$$

For  $t = w, x, Y$  and  $u = w, x, Y$ , let  $S_{tu} = \sum_{i=1}^n t_i u_i$ . Then

$$\begin{aligned}\mathbf{Z}'\mathbf{Z} &= \begin{bmatrix} S_{ww} & S_{wx} \\ S_{wx} & S_{xx} \end{bmatrix}, \\ (\mathbf{Z}'\mathbf{Z})^{-1} &= \frac{1}{S_{ww}S_{xx} - S_{wx}^2} \begin{bmatrix} S_{xx} & -S_{wx} \\ -S_{wx} & S_{ww} \end{bmatrix}, \\ \mathbf{Z}'\mathbf{Y} &= \begin{bmatrix} S_{wY} \\ S_{xY} \end{bmatrix}.\end{aligned}$$

Hence,

$$(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y} = \frac{1}{S_{ww}S_{xx} - S_{wx}^2} \begin{bmatrix} S_{xx}S_{wY} - S_{wx}S_{xY} \\ S_{ww}S_{xY} - S_{wx}S_{wY} \end{bmatrix}.$$

The first component on the right side of this equation is  $\hat{\beta}_0$  and the second is  $\hat{\beta}_1$ .

11. It was shown in Sec. 11.8 that the quantity  $S_{\text{Resid}}^2/\sigma^2$  given in Eq. (11.8.10) has a  $\chi^2$  distribution with  $IJ(K-1)$  degrees of freedom. Hence, the random variable  $S_{\text{Resid}}^2/[IJ(K-1)]$  is an unbiased estimator of  $\sigma^2$ .
12. It follows from Table 11.23 that if  $\alpha_i = \beta_j = 0$  for  $i = 1, \dots, I$  and  $j = 1, \dots, J$ , and  $Q = S_A^2 + S_B^2$  then  $Q/\sigma^2$  will have a  $\chi^2$  distribution with  $(I-1) + (J-1) = I+J-2$  degrees of freedom. Furthermore, regardless of the values of  $\alpha_i$  and  $\beta_j$ ,  $R = S_{\text{Resid}}^2/\sigma^2$  will have a  $\chi^2$  distribution with  $(I-1)(J-1)$  degrees of freedom, and  $Q$  and  $R$  will be independent. Hence, under  $H_0$ , the statistic

$$U = \frac{(I-1)(J-1)Q}{(I+J-2)R}$$

will have the  $F$  distribution with  $I+J-2$  and  $(I-1)(J-1)$  degrees of freedom. The null hypothesis  $H_0$  should be rejected if  $U \geq c$ .

13. Suppose that  $\alpha_i = \beta_j = \gamma_{ij} = 0$  for all values of  $i$  and  $j$ . Then it follows from Table 11.28 that  $(S_A^2 + S_B^2 + S_{\text{Int}}^2)/\sigma^2$  will have a  $\chi^2$  distribution with  $(I-1) + (J-1) + (I-1)(J-1) = IJ-1$  degrees of freedom. Furthermore, regardless of the values of  $\alpha_i, \beta_j$  and  $\gamma_{ij}$ ,  $S_{\text{Resid}}^2/\sigma^2$  will have a  $\chi^2$  distribution with  $IJ(K-1)$  degrees of freedom, and  $S_A^2 + S_B^2 + S_{\text{Int}}^2$  and  $S_{\text{Resid}}^2$  will be independent. Hence, under  $H_0$ , the statistic

$$U = \frac{IJ(K-1)(S_A^2 + S_B^2 + S_{\text{Int}}^2)}{(IJ-1)S_{\text{Resid}}^2}$$

will have the  $F$  distribution with  $IJ-1$  and  $IJ(K-1)$  degrees of freedom. The null hypothesis  $H_0$  should be rejected if  $U \geq c$ .

14. The design in this exercise is a two-way layout with two levels of each factor and  $K$  observations in each cell. The hypothesis  $H_0$  is precisely the hypothesis  $H_0$  given in (11.8.11) that the effects of the two factors are additive and all interactions are 0. Hence,  $H_0$  should be rejected if  $U_{AB}^2 > c$ , where  $U_{AB}^2$  is given by (11.8.12) with  $I = J = 2$ , and  $U_{AB}^2$  has an  $F$  distribution with 1 and  $4(K-1)$  degrees of freedom when  $H_0$  is true.

15. Let  $Y_1 = W_1$ ,  $Y_2 = W_2 - 5$ , and  $Y_3 = \frac{1}{2}W_3$ . Then the random vector

$$\mathbf{Y} = \begin{bmatrix} Y_1 \\ Y_2 \\ Y_3 \end{bmatrix}$$

satisfies the conditions of the general linear model as described in Sec. 11.5 with

$$\mathbf{Z} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \\ 1 & -1 \end{bmatrix}, \quad \boldsymbol{\beta} = \begin{bmatrix} \theta_1 \\ \theta_2 \end{bmatrix}.$$

Thus,

$$\mathbf{Z}'\mathbf{Z} = \begin{bmatrix} 3 & 1 \\ 1 & 3 \end{bmatrix}, \quad (\mathbf{Z}'\mathbf{Z})^{-1} = \begin{bmatrix} 3/8 & -1/8 \\ -1/8 & 3/8 \end{bmatrix},$$

and

$$\hat{\boldsymbol{\beta}} = \begin{bmatrix} \hat{\theta}_1 \\ \hat{\theta}_2 \end{bmatrix} = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y} = \begin{bmatrix} \frac{1}{4}Y_1 + \frac{1}{4}Y_2 + \frac{1}{2}Y_3 \\ \frac{1}{4}Y_1 + \frac{1}{4}Y_2 - \frac{1}{2}Y_3 \end{bmatrix}.$$

Also,

$$\begin{aligned} \hat{\sigma}^2 &= \frac{1}{3}(\mathbf{Y} - \mathbf{Z}\hat{\boldsymbol{\beta}})'(\mathbf{Y} - \mathbf{Z}\hat{\boldsymbol{\beta}}) \\ &= \frac{1}{3}[(Y_1 - \hat{\theta}_1 - \hat{\theta}_2)^2 + (Y_2 - \hat{\theta}_1 - \hat{\theta}_2)^2 + (Y_3 - \hat{\theta}_1 + \hat{\theta}_2)^2]. \end{aligned}$$

The following distributional properties of these M.L.E.'s are known from Sec. 11.5:  $(\hat{\theta}_1, \hat{\theta}_2)$  and  $\hat{\sigma}^2$  are independent;  $(\hat{\theta}_1, \hat{\theta}_2)$  has a bivariate normal distribution with mean vector  $(\theta_1, \theta_2)$  and covariance matrix

$$\sigma^2(\mathbf{Z}'\mathbf{Z})^{-1} = \begin{bmatrix} 3/8 & -1/8 \\ -1/8 & 3/8 \end{bmatrix} \sigma^2;$$

$3\hat{\sigma}^2/\sigma^2$  has a  $\chi^2$  distribution with one degree of freedom.

16. Direct application of the theory of least squares would require choosing  $\alpha$  and  $\beta$  to minimize

$$Q_1 = \sum_{i=1}^n (y_i - \alpha x_i^\beta)^2.$$

This minimization must be carried out numerically since the solution cannot be found in closed form. However, if we express the required curve in the form  $\log y = \log \alpha + \beta \log x$ , and then apply the method of least squares, we must choose  $\beta_0$  and  $\beta_1$  to minimize

$$Q_2 = \sum_{i=1}^n (\log y_i - \beta_0 - \beta_1 \log x_i)^2,$$

where  $\beta_0 = \log \alpha$  and  $\beta_1 = \beta$ . The least squares estimates  $\hat{\beta}_0$  and  $\hat{\beta}_1$  can now be found as in Sec. 11.1, based on the values of  $\log y_i$  and  $\log x_i$ . Estimates of  $\alpha$  and  $\beta$  can then be obtained from the relations  $\log \hat{\alpha} = \hat{\beta}_0$  and  $\hat{\beta} = \hat{\beta}_1$ . It should be emphasized that these values will not be the same as the least squares estimates found by minimizing  $Q_1$  directly.

The appropriateness of each of these methods depends on the appropriateness of minimizing  $Q_1$  and  $Q_2$ . The first method is appropriate if  $Y_i = \alpha x_i^\beta + \varepsilon_i$ , where  $\varepsilon_i$  has a normal distribution with mean 0 and variance  $\sigma^2$ . The second method is appropriate if  $Y_i = \alpha x_i^\beta \varepsilon_i$ , where  $\log \varepsilon_i$  has the normal distribution just described.

17. It follows from the expressions for  $\hat{\beta}_0$  and  $\hat{\beta}_1$  given by Eqs. (11.1.1) and (11.2.7) that

$$\begin{aligned} e_i &= Y_i - (\bar{Y}_n - \bar{x}_n \hat{\beta}_1) - \hat{\beta}_1 x_i \\ &= Y_i - \bar{Y}_n + \frac{(\bar{x}_n - x_i) \sum_{j=1}^n (x_j - \bar{x}_n) Y_j}{s_x^2} \\ &= Y_i \left[ 1 - \frac{1}{n} - \frac{(x_i - \bar{x}_n)^2}{s_x^2} \right] \\ &\quad - \sum_{j \neq i} Y_j \left[ \frac{1}{n} + \frac{(x_i - \bar{x}_n)(x_j - \bar{x}_n)}{s_x^2} \right] \end{aligned}$$

where  $s_x^2 = \sum_{j=1}^n (x_j - \bar{x}_n)^2$ . Since  $Y_1, \dots, Y_n$  are independent and each has variance  $\sigma^2$ , it follows that

$$\text{Var}(e_i) = \sigma^2 \left[ 1 - \frac{1}{n} - \frac{(x_i - \bar{x}_n)^2}{s_x^2} \right]^2 + \sigma^2 \sum_{j \neq i} \left[ \frac{1}{n} + \frac{(x_i - \bar{x}_n)(x_j - \bar{x}_n)}{s_x^2} \right]^2.$$

Let  $Q_i = \frac{1}{n} + \frac{(x_i - \bar{x}_n)^2}{s_x^2}$ . Then

$$\begin{aligned} \text{Var}(e_i) &= \sigma^2 (1 - Q_i)^2 + \sigma^2 \sum_{j=1}^n \left[ \frac{1}{n} + \frac{(x_i - \bar{x}_n)(x_j - \bar{x}_n)}{s_x^2} \right]^2 - \sigma^2 Q_i^2 \\ &= \sigma^2 [(1 - Q_i)^2 + Q_i - Q_i^2] \\ &= \sigma^2 (1 - Q_i). \end{aligned}$$

(This result could also have been obtained from the more general result to be obtained next in Exercise 18.) Since  $Q_i$  is an increasing function of  $(x_i - \bar{x}_n)^2$ , it follows that  $\text{Var}(e_i)$  is a decreasing function of  $(x_i - \bar{x}_n)^2$  and, hence, of the distance between  $x_i$  and  $\bar{x}_n$ .

18. (a) Since  $\hat{\beta}$  has the form given in Eq. (11.5.10), it follows directly that  $\mathbf{Y} - \mathbf{Z}\hat{\beta}$  has the specified form.  
(b) Let  $\mathbf{A} = \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$ . It can be verified directly that  $\mathbf{A}$  is idempotent, i.e.,  $\mathbf{A}\mathbf{A} = \mathbf{A}$ . Since  $\mathbf{D} = \mathbf{I} - \mathbf{A}$ , it now follows that

$$\mathbf{DD} = (\mathbf{I} - \mathbf{A})(\mathbf{I} - \mathbf{A}) = \mathbf{II} - \mathbf{AI} - \mathbf{IA} + \mathbf{AA} = \mathbf{I} - \mathbf{A} - \mathbf{A} + \mathbf{A} = \mathbf{I} - \mathbf{A} = \mathbf{D}.$$

- (c) As stated in Eq. (11.5.15),  $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$ . Hence, by Theorem 11.5.2,  $\text{Cov}(\mathbf{W}) = \text{Cov}(\mathbf{D}\mathbf{Y}) = \mathbf{D}\text{Cov}(\mathbf{Y})\mathbf{D}' = \mathbf{D}(\sigma^2 \mathbf{I})\mathbf{D} = \sigma^2(\mathbf{D}\mathbf{D}') = \sigma^2 \mathbf{D}$ .

19. Let  $\bar{\theta} = \sum_{i=1}^I v_i \theta_i / v_+$  and  $\bar{\psi} = \sum_{j=1}^J w_j \psi_j / w_+$ , and define  $\mu = \bar{\theta} + \bar{\psi}$ ,  $\alpha_i = \theta_i - \bar{\theta}$ , and  $\beta_j = \psi_j - \bar{\psi}$ . Then  $E(Y_{ij}) = \theta_i + \psi_j = \mu + \alpha_i + \beta_j$  and  $\sum_{i=1}^I v_i \alpha_i = \sum_{j=1}^J w_j \beta_j = 0$ . To establish uniqueness, suppose that  $\mu'$ ,  $\alpha'_i$ , and  $\beta'_j$  are another set of values satisfying the required conditions. Then

$$\mu + \alpha_i + \beta_j = \mu' + \alpha'_i + \beta'_j \quad \text{for all } i \text{ and } j.$$

If we multiply both sides by  $v_i w_j$  and sum over  $i$  and  $j$ , we find that  $\mu = \mu'$ . Hence,  $\alpha_i + \beta_j = \alpha'_i + \beta'_j$ . If we now multiply both sides by  $v_i$  and sum over  $i$ , we find that  $\beta_j = \beta'_j$ . Similarly, if we multiply both sides by  $w_j$  and sum over  $j$ , we find that  $\alpha_i = \alpha'_i$ .

20. The value of  $\mu$ ,  $\alpha_i$ , and  $\beta_j$  must be chosen to minimize

$$Q = \sum_{i=1}^I \sum_{j=1}^J \sum_{k=1}^{K_{ij}} (Y_{ijk} - \mu - \alpha_i - \beta_j)^2.$$

The equation  $\partial Q / \partial \mu = 0$  reduces to

$$Y_{+++} - n\mu - \sum_{i=1}^I K_{i+} \alpha_i - \sum_{j=1}^J K_{+j} \beta_j = 0,$$

where  $n = K_{++}$  is the total number of observations in the two-way layout. Next we shall calculate  $\frac{\partial Q}{\partial \alpha_i}$  for  $i = 1, \dots, I-1$ , keeping in mind that  $\sum_{i=1}^I K_{i+} \alpha_i = 0$ . Hence,  $\partial \alpha_I / \partial \alpha_i = -K_{i+} / K_{I+}$ . It can be found that the equation  $\partial Q / \partial \alpha_i = 0$  reduces to the following equation for  $i = 1, \dots, I-1$ :

$$Y_{i++} - K_{i+} \mu - K_{i+} \alpha_i - \sum_j K_{ij} \beta_j = \frac{K_{i+}}{K_{I+}} (Y_{I++} - K_{I+} \mu - K_{I+} \alpha_I - \sum_j K_{IJ} \beta_j).$$

In other words, the following quantity must have the same value for  $i = 1, \dots, I$ :

$$\frac{1}{K_{i+}} \left( Y_{i++} - K_{i+} \mu - K_{i+} \alpha_i - \sum_j K_{ij} \beta_j \right).$$

Similarly, the set of equations  $\partial Q / \partial \beta_j = 0$  for  $j = 1, \dots, J-1$  reduces to the requirement that the following quantity have the same value for  $j = 1, \dots, J$ :

$$\frac{1}{K_{+j}} \left( Y_{+j+} - K_{+j} \mu - \sum_i K_{ij} \alpha_i - K_{+j} \beta_j \right).$$

It can be verified by direct substitution that the values of  $\hat{\mu}$ ,  $\hat{\alpha}_i$ , and  $\hat{\beta}_j$  given in the exercise satisfy all these requirements and, hence, are the least squares estimators.

21. As in the solution of Exercise 18 of Sec. 11.8, let

$$\begin{aligned} \hat{\mu} &= \sum_{r,s,t} m_{rst} Y_{rst}, \\ \hat{\alpha}_i &= \sum_{r,s,t} a_{rst} Y_{rst}, \\ \hat{\beta}_j &= \sum_{r,s,t} b_{rst} Y_{rst}. \end{aligned}$$

To show that  $\text{Cov}(\hat{\mu}, \hat{\alpha}_i) = 0$ , we must show that  $\sum_{r,s,t} m_{rst} a_{rst} = 0$ . But  $m_{rst} = \frac{1}{n}$  for all  $r, s, t$ , and

$$a_{rst} = \begin{cases} \frac{1}{K_{i+}} - \frac{1}{n} & \text{for } r = i, \\ -\frac{1}{n} & \text{for } r \neq i. \end{cases}$$

Hence, it is found that  $\sum m_{rst} a_{rst} = 0$ . Similarly,

$$b_{rst} = \begin{cases} \frac{1}{K_{+j}} - \frac{1}{n} & \text{for } s = j, \\ -\frac{1}{n} & \text{for } s \neq j. \end{cases}$$

and  $\sum m_{rst} b_{rst} = 0$ , so  $\text{Cov}(\hat{\mu}, \hat{\beta}_j) = 0$ .

22. We must show that  $\sum a_{rst} b_{rst} = 0$ , where  $a_{rst}$  and  $b_{rst}$  are given in the solution of Exercise 21:

$$\begin{aligned} \sum_{r,s,t} a_{rst} b_{rst} &= \sum_{k=1}^{K_{ij}} \left( \frac{1}{K_{i+}} - \frac{1}{n} \right) \left( \frac{1}{K_{+j}} - \frac{1}{n} \right) - \frac{1}{n} \sum_{s \neq j} \sum_{k=1}^{K_{is}} \left( \frac{1}{K_{i+}} - \frac{1}{n} \right) - \frac{1}{n} \sum_{r \neq i} \sum_{k=1}^{K_{rj}} \left( \frac{1}{K_{+j}} - \frac{1}{n} \right) \\ &\quad + \frac{1}{n^2} \sum_{r \neq i} \sum_{s \neq j} K_{rs}. \end{aligned}$$

Since  $nK_{ij} = K_{i+}K_{+j}$ , it can be verified that this sum is 0.

23. Consider the expression for  $\theta_{ijk}$  given in this exercise. If we sum both sides of this expression over  $i$ ,  $j$ , and  $k$ , then it follows from the constraints on the  $\alpha$ 's,  $\beta$ 's, and  $\gamma$ 's, that  $\mu = \bar{\theta}_{+++}$ . If we substitute this value for  $\mu$  and sum both sides of the expression over  $j$  and  $k$ , we can solve the result for  $\alpha_i^A$ . Similarly,  $\alpha_j^B$  can be found by summing over  $i$  and  $k$ , and  $\alpha_k^C$  by summing over  $i$  and  $j$ . After these values have been found, we can determine  $\beta_{ij}^{AB}$  by summing both sides over  $k$ , and determine  $\beta_{ik}^{AC}$  and  $\beta_{jk}^{BC}$  similarly. Finally,  $\gamma_{ijk}$  is determined by taking its value to be whatever is necessary to satisfy the required expression for  $\theta_{ijk}$ . In this way, we obtain the following values:

$$\begin{aligned} \mu &= \bar{\theta}_{+++}, \\ \alpha_i^A &= \bar{\theta}_{i++} - \bar{\theta}_{+++}, \\ \alpha_j^B &= \bar{\theta}_{+j+} - \bar{\theta}_{+++}, \\ \alpha_k^C &= \bar{\theta}_{++k} - \bar{\theta}_{+++}, \\ \beta_{ij}^{AB} &= \bar{\theta}_{ij+} - \bar{\theta}_{i++} - \bar{\theta}_{+j+} + \bar{\theta}_{+++}, \\ \beta_{ik}^{AC} &= \bar{\theta}_{i+k} - \bar{\theta}_{i++} - \bar{\theta}_{++k} + \bar{\theta}_{+++}, \\ \beta_{jk}^{BC} &= \bar{\theta}_{+jk} - \bar{\theta}_{+j+} - \bar{\theta}_{++k} + \bar{\theta}_{+++}, \\ \gamma_{ijk} &= \theta_{ijk} - \bar{\theta}_{ij+} - \bar{\theta}_{i+k} - \bar{\theta}_{+jk} + \bar{\theta}_{i++} + \bar{\theta}_{+j+} + \bar{\theta}_{++k} - \bar{\theta}_{+++}. \end{aligned}$$

It can be verified that these quantities satisfy all the specified constraints. They are unique by the method of their construction, since they were derived as the only values that could possibly satisfy the constraints.

24. (a) The plot of Buchanan vote against total county vote is in Fig. S.11.3. Palm Beach county is plotted with the symbol P.

Figure S.11.3: Figure for Exercise 24a in Sec. 11.9.

- (b) The summary of the fitted regression is  $\hat{\beta}_0 = 83.69$ ,  $\hat{\beta}_1 = 0.00153$ ,  $\bar{x}_n = 8.254 \times 10^4$ ,  $s_x^2 = 1.035 \times 10^{12}$ ,  $n = 67$ , and  $\sigma' = 120.1$ .
- (c) The plot of residuals is in Fig. S.11.4. Notice that the residuals are much more spread out at the

Figure S.11.4: Figure for Exercise 24c in Sec. 11.9.

right side of the plot than at the left. There also appears to be a bit of a curve to the plot.

- (d) The summary of the fitted regression is  $\hat{\beta}_0 = -2.746$ ,  $\hat{\beta}_1 = 0.7263$ ,  $\bar{x}_n = 10.32$ ,  $s_x^2 = 151.5$ ,  $n = 67$ , and  $\sigma' = 0.4647$ .
- (e) The new residual plot is in Fig. S.11.5. The spread is much more uniform from right to left and the curve is no longer evident.
- (f) The quantile we need is  $T_{65}^{-1}(0.995) = 2.654$ . The logarithm of total vote for Palm Beach county is 12.98. prediction interval for logarithm of Buchanan vote when  $X = 12.98$  is

$$\begin{aligned}
 & -2.746 + 12.98 \times 0.7263 \pm 2.654 \times 0.4647 \left( 1 + \frac{1}{67} + \frac{(12.98 - 10.32)^2}{151.5} \right)^{1/2} \\
 & = [5.419, 7.942].
 \end{aligned}$$

Figure S.11.5: Figure for Exercise 24e in Sec. 11.9.

Converting to Buchanan vote, we take  $e$  to the power of each endpoint and get the interval [225.6, 2812].

- (g) The official Gore total was 2912253, while the official Bush total was 2912790. Suppose that 2812 people in Palm Beach county had actually voted for Buchanan and the other  $3411 - 2812 = 599$  had voted for Gore. Then the Gore total would have been 2912852, enough to make him the winner.

# Chapter 12

## Simulation

All exercises that involve simulation will produce different answers when run with repeatedly. Hence, one cannot expect numerical results to match perfectly with any answers given here.

For all exercises that require simulation, students will need access to software that will do some of the work for them. At a minimum they will need software to simulate uniform pseudo-random numbers on the interval  $[0, 1]$ . Some of the exercises require software to simulate all of the famous distributions and compute the c.d.f.'s and quantile functions of the famous distributions.

Some of the simulations require a nonnegligible programming effort. In particular, Markov chain Monte Carlo (MCMC) requires looping through all of the coordinates inside of the iteration loop. Assessing convergence and simulation standard error for a MCMC result requires running several chains in parallel. Students who do not have a lot of programming experience might need some help with these exercises.

If one is using the software *R*, the function `runif` will return uniform pseudo-random numbers, the argument is how many you want. For other named distributions, as mentioned earlier in this manual, one can use the functions `rbinom`, `rhyper`, `rpois`, `rnbnom`, `rgeom`, `rnorm`, `rlnorm`, `rgamma`, `rexp`, `rbeta`, and `rmultinom`.

Most simulations require calculation of averages and sample variances. The functions `mean`, `median`, and `var` compute the average, sample median, and sample variance respectively of their first argument. Each of these has an optional argument `na.rm`, which can be set either to `TRUE` or to `FALSE` (the default). If true, `na.rm` causes missing values to be ignored in the calculation. Missing values in simulations should be rare if calculations are being done correctly. Other useful functions for simulations are `sort` and `sort.list`. They both take a vector argument. The first returns its argument sorted algebraically from smallest to largest (or largest to smallest with optional argument `decreasing=TRUE`.) The second returns a list of integers giving the locations (in the vector) of the ordered values of its argument. The functions `min` and `max` give the smallest and largest values of their argument.

For looping, one can use

```
for(i in 1:n){ ... }
```

to perform all of the functions between `{` and `}` once for each value of `i` from `1` to `n`. For an indeterminate number of iterations, one can use

```
while(expression){ ... }
```

where `expression` stands for a logical expression that changes value from `TRUE` to `FALSE` at some point during the iterations.

A long series of examples appears at the end.

## 12.1 What is Simulation?

### Solutions to Exercises

1. Simulate a large number of exponential random variables with parameter 1, and take their average.
2. We would expect that every so often one of the simulated random variables would be much larger than the others and the sample average would go up significantly when that random variable got included in the average. The more simulations we do, the more such large observations we would expect, and the average should keep getting larger.
3. We would expect to get a lot of very large positive observations and a lot of very large negative observations. Each time we got one, the average would either jump up (when we get a positive one) or jump down (when we get a negative one). As we sampled more and more observations, the average should bounce up and down quite a bit and never settle anywhere.
4. We could count how many Bernoulli's we had to sample to get a success (1) and call that the first observation of a geometric random variable. Starting with the next Bernoulli, start counting again until the next 1, and call that the second geometric, etc. Average all the observed geometrics to approximate the mean.
5. (a) Simulate three exponentials at a time. Call the sum of the first two  $X$  and call the third one  $Y$ . For each triple, record whether  $X < Y$  or not. The proportion of times that  $X < Y$  in a large sample of triples approximates  $\Pr(X < Y)$ .
- (b) Let  $Z_1, Z_2, Z_3$  be i.i.d. having the exponential distribution with parameter  $\beta$ , and let  $W_1, W_2, W_3$  be i.i.d. having the exponential distribution with parameter 1. Then  $Z_1 + Z_2 < Z_3$  if and only if  $\beta Z_1 + \beta Z_2 < \beta Z_3$ . But  $(\beta Z_1, \beta Z_2, \beta Z_3)$  has precisely the same joint distribution as  $(W_1, W_2, W_3)$ . So, the probability that  $Z_1 + Z_2 < Z_3$  is the same as the probability that  $W_1 + W_2 < W_3$ , and it doesn't matter which parameter we use for the exponential distribution. All simulations will approximate the same quantity as we would approximate using parameter 1.
- (c) We know that  $X$  and  $Y$  are independent and that  $X$  has the gamma distribution with parameters 2 and 0.4. The joint p.d.f. is

$$f(x, y) = 0.4^2 x \exp(-0.4x) 0.4 \exp(-0.4y), \text{ for } x, y > 0.$$

The integral to compute the probability is

$$\Pr(X < Y) = \int_0^\infty \int_x^\infty 0.4^3 x \exp(-0.4[x+y]) dy dx.$$

There is also a version with the  $x$  integral on the inside.

$$\Pr(X < Y) = \int_0^\infty \int_0^y 0.4^3 x \exp(-0.4[x+y]) dx dy.$$

## 12.2 Why Is Simulation Useful?

### Commentary

This section introduces the fundamental concepts of simulation and illustrates the basic calculations that underlie almost all simulations. Instructors should stress the need for assessing the variability in a simulation result. For complicated simulations, it can be difficult to assess variability, but students need to be aware that a highly variable simulation may be no better than an educated guess.

The lengthy examples (12.2.13 and 12.2.14) at the end of the section and the exercises (15 and 16) that go with them are mainly illustrative of the power of simulation. These would only be covered in course that devoted a lot of time to simulation.

### Solutions to Exercises

1. Since  $E(Z) = \mu$ , the Cheybshev inequality says that  $\Pr(|Z - \mu| \leq \epsilon) \geq \epsilon^2 / \text{Var}(Z)$ . Since  $Z$  is the average of  $v$  independent random variables with variance  $\sigma^2$ ,  $\text{Var}(Z) = \sigma^2/v$ . It follows that

$$\Pr(|Z - \mu| \leq \epsilon) \geq \frac{\epsilon^2 v}{\sigma^2}.$$

Now, suppose that  $v \geq \sigma^2/[\epsilon^2(1 - \gamma)]$ , then

$$\frac{\epsilon^2 v}{\sigma^2} \geq 1 - \gamma.$$

2. In Example 12.2.11, we are approximating  $\sigma$  by 0.3892. According to Eq. (12.2.6), we need

$$v \geq \frac{0.3892^2}{0.01^2 \times .01} = 151476.64$$

So,  $v$  must be at least 151477.

3. We could simulate a lot (say  $v_0$ ) standard normal random variables  $W_1, \dots, W_{v_0}$  and let  $X_i = 7W_i + 2$ . Then each  $X_i$  has the distribution of  $X$ . Let  $W_i = \log(|X_i| + 1)$ . We could then compute  $Z$  equal to the average of the  $W_i$ 's as an estimate of  $E(\log(|X| + 1))$ . If we needed our estimate to be close to  $E(\log(|X| + 1))$  with high probability, we could estimate the variance of  $W_i$  by the sample variance and then use (12.2.5) to choose a possibly larger simulation size.
4. Simulate 15 random variables  $U_1, \dots, U_{15}$  with uniform distribution on the interval  $[0, 1]$ . For  $i = 1, \dots, 13$ , let  $X_i = 2(U_i - 0.5)$  and for  $i = 14, 15$ , let  $X_i = 20(U_i - 0.5)$ . Then  $X_1, \dots, X_{15}$  have the desired distribution. In most of my simulations, the median or the sample average was the closest to 0. The first simulation led to the following six values:

Estimator	Trimmed mean					
	Average	$k = 1$	$k = 2$	$k = 3$	$k = 4$	Median
Estimate	0.5634	0.3641	0.2205	0.2235	0.2359	0.1836

5. (a) In my ten samples, the sample median was closest to 0 nine times, and the  $k = 3$  trimmed mean was closest to 0 one time.  
(b) Although the  $k = 2$  trimmed mean was never closest to 0, it was also never very far from 0, and it had the smallest average squared distance from 0. The  $k = 3$  trimmed mean was a close second. Here are the six values for my first 10 simulations:

Estimator	Trimmed mean					
	Average	$k = 1$	$k = 2$	$k = 3$	$k = 4$	Median
M.S.E.	0.4425	0.1354	0.0425	0.0450	0.0509	0.0508

These rankings were also reflected in a much larger simulation.

6. (a) Simulate lots (say  $v_0$ ) of random variables  $X_1, \dots, X_{v_0}$  and  $Y_1, \dots, Y_{v_0}$  with  $X_i$  have the beta distribution with parameters 3.5 and 2.7 while  $Y_i$  have the beta distribution with parameters 1.8 and 4.2. Let  $Z_i = X_i/(X_i + Y_i)$ . The sample average of  $Z_1, \dots, Z_{v_0}$  should be close to the mean of  $X/(X + Y)$  if  $v_0$  is large enough.
- (b) We could calculate the sample variance of  $Z_1, \dots, Z_{v_0}$  and use this as an estimate of  $\sigma^2$  in Eq. (12.2.5) with  $\gamma = 0.98$  and  $\epsilon = 0.01$  to obtain a new simulation size.
7. (a) The distribution of  $X$  is the contaminated normal distribution with p.d.f. given in Eq. (10.7.2) with  $\sigma = 1$ ,  $\mu = 0$ .
- (b) To calculate a number in Table 10.40, we should simulate lots of samples of size 20 from the distribution in part (a) with the desired  $\epsilon$  (0.05 in this case). For each sample, compute the desired estimator (the sample median in this case). Then compute the average of the squares of the estimators (since  $\mu = 0$  in our samples) and multiply by 20. As an example, we did two simulations of size 10000 each and got 1.617 and 1.621.
8. (a) The description is the same as in Exercise 7(b) with “sample median” replaced by “trimmed mean for  $k = 2$ ” and 0.05 replaced by 0.1.
- (b) We did two simulations of size 10000 each and got 2.041 and 2.088. It would appear that this simulation is slightly more variable than the one in Exercise 7.
9. The marginal p.d.f. of  $X$  is

$$\int_0^\infty \frac{\mu^3}{2} \exp(-\mu(x+1)) d\mu = \frac{3}{(x+1)^4},$$

for  $x > 0$ . The c.d.f. of  $X$  is then

$$F(x) = \int_0^x \frac{3}{(t+1)^4} dt = 1 - \left(\frac{1}{x+1}\right)^3,$$

for  $x > 0$ , and  $F(x) = 0$  for  $x \leq 0$ . The median is that  $x$  such that  $F(x) = 1/2$ , which is easily seen to be  $2^{1/3} - 1 = 0.2599$ .

10. (a) The c.d.f. of each  $X_i$  is  $F(x) = 1 - \exp(-\lambda x)$ , for  $x > 0$ . The median is  $\log(2)/\lambda$ .
- (b) Let  $Y_i = X_i\lambda$ , and let  $M'$  be the sample median of  $Y_1, \dots, Y_{21}$ . Then the  $Y_i$ 's have the exponential distribution with parameter 1, the median of  $Y_i$  is  $\log(2)$ , and  $M' = M\lambda$ . The M.S.E. of  $M$  is then

$$\begin{aligned} E\left[\left(M - \frac{\log(2)}{\lambda}\right)^2\right] &= \frac{1}{\lambda^2} E[(M\lambda - \log(2))^2] \\ &= \frac{1}{\lambda^2} E[(M' - \log(2))^2] \\ &= \frac{\theta}{\lambda^2}. \end{aligned}$$

- (c) Simulate a lot (say  $21v_0$ ) of random variables  $X_1, \dots, X_{21v_0}$  having the exponential distribution with parameter 1. For  $i = 1, \dots, v_0$ , let  $M_i$  be the sample median of  $X_{21(i-1)+1}, \dots, X_{21i}$ . Let  $Y_i = (M_i - \log(2))^2$ , and compute the sample average  $Z = \frac{1}{v_0} \sum_{i=1}^{v_0} Y_i$  as an estimate of  $\theta$ . If you want to see how good an estimate it is, compute the simulation standard error.

11. In Example 12.2.4,  $\mu_x$  and  $\mu_y$  are independent with  $(\mu_x - \mu_{x1})/(\beta_{x1}/[\alpha_{x1}\lambda_{x1}])^{1/2}$  having the  $t$  distribution with  $2\alpha_{x1}$  degrees of freedom and  $(\mu_y - \mu_{y1})/(\beta_{y1}/[\alpha_{y1}\lambda_{y1}])^{1/2}$  having the  $t$  distribution with  $2\alpha_{y1}$  degrees of freedom. We should simulate lots (say  $v$ ) of  $t$  random variables  $T_x^{(1)}, \dots, T_x^{(v)}$  with  $2\alpha_{x1}$  degrees of freedom and just as many  $t$  random variables  $T_y^{(1)}, \dots, T_y^{(v)}$  with  $2\alpha_{y1}$  degrees of freedom. Then let

$$\begin{aligned}\mu_x^{(i)} &= \mu_{x1} + T_x^{(i)} \left( \frac{\beta_{x1}}{\alpha_{x1}\lambda_{x1}} \right)^{1/2}, \\ \mu_y^{(i)} &= \mu_{y1} + T_y^{(i)} \left( \frac{\beta_{y1}}{\alpha_{y1}\lambda_{y1}} \right)^{1/2},\end{aligned}$$

for  $i = 1, \dots, v$ . Then the values  $\mu_x^{(i)} - \mu_y^{(i)}$  form a sample from the posterior distribution of  $\mu_x - \mu_y$ .

12. To the level of approximation in Eq. (12.2.7), we have

$$Z = g(E(Y), E(W)) + g_1(E(Y), E(W))[Y - E(Y)] + g_2(E(Y), E(W))[W - E(W)].$$

The variance of  $Z$  would then be

$$\begin{aligned}g_1(E(Y), E(W))^2 \text{Var}(Y) + g_2(E(Y), E(W))^2 \text{Var}(W) \\ + 2g_1(E(Y), E(W))g_2(E(Y), E(W)) \text{Cov}(Y, W).\end{aligned}\tag{S.12.1}$$

Now substitute the entries of  $\Sigma$  for the variances and covariance.

13. The function  $g$  in this exercise is  $g(y, w) = w - y^2$  with partial derivatives

$$\begin{aligned}g_1(y, w) &= 2y, \\ g_2(y, w) &= 1.\end{aligned}$$

In the formula for  $\text{Var}(Z)$  given in Exercise 12, make the following substitutions:

Exercise 12	This exercise
$E(Y)$	$\bar{Y}$
$E(W)$	$\bar{W}$
$\sigma_{yy}$	$Z/v$
$\sigma_{ww}$	$V/v$
$\sigma_{yw}$	$C/v$ ,

where  $Z$ ,  $V$ , and  $C$  are defined in Example 12.2.10. The result is  $[(2\bar{Y})^2 Z + V + 4\bar{Y}C]/v$ , which simplifies to (12.2.3).

14. Let  $Y_1, \dots, Y_v$  be a large sample from the distribution of  $Y$ . Let  $\bar{Y}$  be the sample average, and let  $V$  be the sample variance. For each  $i$ , define  $W_i = (Y_i - \bar{Y})^3/V$ . Estimate the skewness by the sample average of the  $W_i$ 's. Use the sample variance to compute a simulation standard error to see if the simulation size is large enough.

15. (a) Since  $S_u = S_0 \exp(\alpha u + W_u)$ , we have that

$$E(S_u) = S_0 \exp(\alpha u) E(\exp(W_u)) = S_0 \exp(\alpha u) \psi(1).$$

In order for this mean to be  $S_0 \exp(ru)$ , it is necessary and sufficient that  $\psi(1) = \exp(u[r - \alpha])$ , or equivalently,  $\alpha = r - \log(\psi(1))/u$ .

- (b) First, simulate lots (say  $v$ ) of random variables  $W^{(1)}, \dots, W^{(v)}$  with the distribution of  $W_u$ . Define the function  $h(s)$  as in Example 12.2.13. Define  $Y^{(i)} = \exp(-ru)h(S_0 \exp[\alpha u + W^{(i)}])$ , where  $r$  is the risk free interest rate and  $\alpha$  is the number found in part (a). The sample average of the  $Y^{(i)}$ 's would estimate the appropriate price for the option. One should compute a simulation standard error to see if the simulation size is large enough.
16. We can model our solution on Example 12.2.14. We should simulate a large number of operations of the queue up to time  $t$ . For each simulated operation of the queue, count how many customers are in the queue (including any being served). In order to simulate one instance of the queue operation up to time  $t$ , we can proceed as follows. Simulate interarrival times  $X_1, X_2, \dots$  as exponential random variables with parameter  $\lambda$ . Define  $T_j = \sum_{i=1}^j T_i$  for  $j = 1, 2, \dots$ . Stop simulating at the first  $k$  such that  $T_k > t$ . Start the queue with  $W_0 = 0$ , where  $W_j$  stands for the time that customer  $j$  leaves the queue. In what follows,  $S_j \in \{1, 2\}$  will stand for which server serves customer  $j$ , and  $Z_j$  will stand for the time at which customer  $j$  begins being served.

For  $j = 1, \dots, k - 1$  and each  $i < j$ , define

$$U_{i,j} = \begin{cases} 1 & \text{if } W_i \geq T_j, \\ 0 & \text{otherwise.} \end{cases}$$

The number of customers in the queue when customer  $j$  arrives is  $r = \sum_{i=0}^{j-1} U_{i,j}$ .

- If  $r = 0$ , simulate  $U$  with a uniform distribution on the interval  $[0, 1]$ . Set  $S_j = 1$  if  $U < 1/2$  and  $S_j = 2$  if  $U \geq 1/2$ . Set  $Z_j = T_j$ .
- If  $r = 1$ , find the value  $i$  such that  $W_i \geq T_j$  and set  $S_j = 2 - S_i$  so that customer  $j$  goes to the other server. Set  $Z_j = T_j$ .
- If  $r \geq 2$ , simulate  $U$  with a uniform distribution on the interval  $[0, 1]$ , and let customer  $j$  leave if  $U < p_r$ . If customer  $j$  leaves, set  $W_j = T_j$ . If customer  $j$  does not leave, find the second highest value  $W_{i'}$  out of  $W_1, \dots, W_{j-1}$  and set  $S_j = S_{i'}$  and  $Z_j = W_{i'}$ .

For each customer that does not leave, simulate a service time  $Y_j$  having an exponential distribution with parameter  $\mu_{S_j}$ , and set  $W_j = Z_j + Y_j$ . The number of customers in the queue at time  $t$  is the number of  $j \in \{1, \dots, k - 1\}$  such that  $W_j \geq t$ .

## 12.3 Simulating Specific Distributions

### Commentary

This section is primarily of mathematical interest. Most distributions with which students are familiar can be simulated directly with existing statistical software. Instructors who wish to steer away from the theoretical side of simulation should look over the examples before skipping this section in case they contain some points that they would like to make. For example, a method is given for computing simulation standard error when the simulation result is an entire sample c.d.f. (see page 811). This relies on results from Sec. 10.6.

### Solutions to Exercises

1. (a) Here we are being asked to perform the simulation outlined in the solution to Exercise 10 in Sec. 12.2 with  $v_0 = 2000$  simulations. Each  $Y_i$  (in the notation of that solution) can be simulated

by taking a random variable  $U_i$  having uniform distribution on the interval  $[0, 1]$  and setting  $Y_i = -\log(1 - U_i)$ . In addition to the run whose answers are in the back of the text, here are the results of two additional simulations: Approximation = 0.0536, sim. std. err. = 0.0023 and Approximation = 0.0492, sim. std. err. = 0.0019.

- (b) For the two additional simulations in part (a), the value of  $v$  to achieve the desired goal are 706 and 459.
- 2. Let  $V_i = a + (b - a)U_i$ . Then the p.d.f. of  $V_i$  is easily seen to be  $1/(b - a)$  for  $a \leq v \leq b$ , so  $V_i$  has the desired uniform distribution.
- 3. The c.d.f. corresponding to  $g_1$  is

$$G_1(x) = \int_0^x \frac{1}{2t^{1/2}} dt = x^{1/2}, \text{ for } 0 \leq x \leq 1.$$

The quantile function is then  $G_1^{-1}(p) = p^2$  for  $0 < p < 1$ . To simulate a random variable with the p.d.f.  $g_1$ , simulate  $U$  with a uniform distribution on the interval  $[0, 1]$  and let  $X = U^2$ . The c.d.f. corresponding to  $g_2$  is

$$G_2(x) = \int_0^x \frac{1}{2(1-t)^{1/2}} dt = 1 - (1-x)^{1/2}, \text{ for } 0 \leq x \leq 1.$$

The quantile function is then  $G_2^{-1}(p) = 1 - (1-p)^2$  for  $0 < p < 1$ . To simulate a random variable with the p.d.f.  $g_2$ , simulate  $U$  with a uniform distribution on the interval  $[0, 1]$  and let  $X = 1 - (1-U)^2$ .

- 4. The c.d.f. of a Cauchy random variable is

$$F(x) = \int_{-\infty}^x \frac{dt}{\pi(1+t^2)} = \frac{1}{\pi} \left[ \arctan(x) + \frac{\pi}{2} \right].$$

The quantile function is  $F^{-1}(p) = \tan(\pi[p - 1/2])$ . So, if  $U$  has a uniform distribution on the interval  $[0, 1]$ , then  $\tan(\pi[U - 1/2])$  has a Cauchy distribution.

- 5. The probability of acceptance on each attempt is  $1/k$ . Since the attempts (trials) are independent, the number of failures  $X$  until the first acceptance is a geometric random variable with parameter  $1/k$ . The number of iterations until the first acceptance is  $X + 1$ . The mean of  $X$  is  $(1 - 1/k)/(1/k) = k - 1$ , so the mean of  $X + 1$  is  $k$ .

- 6. (a) The c.d.f. of the Laplace distribution is

$$F(x) = \int_{-\infty}^x \frac{1}{2} \exp(-|t|) dt = \begin{cases} \frac{1}{2} \exp(x) & \text{if } x < 0, \\ 1 - \frac{1}{2} \exp(-x) & \text{if } x \geq 0. \end{cases}$$

The quantile function is then

$$F^{-1}(p) = \begin{cases} \log(2p) & \text{if } 0 < p < 1/2, \\ -\log(2[1-p]) & \text{if } 1/2 \leq p < 1. \end{cases}$$

Simulate a uniform random variable  $U$  on the interval  $[0, 1]$  and let  $X = F^{-1}(U)$ .

(b) Define

$$\begin{aligned} f(x) &= \frac{1}{(2\pi)^{1/2}} \exp(-x^2/2), \\ g(x) &= \frac{1}{2} \exp(-|x|). \end{aligned}$$

We need to find a constant  $k$  such that  $kg(x) \geq f(x)$  for all  $x$ . Equivalently, we need a constant  $c$  such that

$$c \geq \frac{\exp(-x^2/2)}{\exp(-|x|)}, \quad (\text{S.12.2})$$

for all  $x$ . Then we can set  $k = c(2/\pi)^{1/2}$ . The smallest  $c$  that satisfies (S.12.2) is the supremum of  $\exp(|x| - x^2/2)$ . This function is symmetric around 0, so we can look for  $\sup_{x \geq 0} \exp(x - x^2/2)$ . To maximize this, we can maximize  $x - x^2/2$  instead. The maximum of  $x - x^2/2$  occurs at  $x = 1$ , so  $c = \exp(1/2)$ . Now, use acceptance/rejection with  $k = \exp(1/2)(2/\pi)^{1/2} = 1.315$ .

7. Simulate a random sample  $X_1, \dots, X_{11}$  from the standard normal distribution. Then  $\sum_{i=1}^4 X_i^2$  has the  $\chi^2$  distribution with 4 degrees of freedom and is independent of  $\sum_{i=5}^{11} X_i^2$ , which has the  $\chi^2$  distribution with 7 degrees of freedom. It follows that

$$\frac{7 \sum_{i=1}^4 X_i^2}{4 \sum_{i=5}^{11} X_i^2}$$

the  $F$  distribution with 4 and 7 degrees of freedom.

8. (a) I did five simulations of the type requested and got the estimates 1.325, 1.385, 1.369, 1.306, and 1.329. There seems to be quite a bit of variability if we want three significant digits.
- (b) The five variance estimates were 1.333, 1.260, 1.217, 1.366, and 1.200.
- (c) The required sample sizes varied from 81000 to 91000, suggesting that we do not yet have a very precise estimate.
9. The simplest acceptance/rejection algorithm would use a uniform distribution on the interval  $[0, 2]$ . That is, let  $g(x) = 0.5$  for  $0 < x < 2$ . Then  $(4/3)g(x) \geq f(x)$  for all  $x$ , i.e.  $k = 4/3$ . We could simulate  $U$  and  $V$  both having a uniform distribution on the interval  $[0, 1]$ . Then let  $X = 2V$  if  $2f(2V) \geq (4/3)U$  and reject otherwise.
10. Using the prior distribution stated in the exercise, the posterior distributions for the probabilities of no relapse in the four treatment groups are

Group	Beta with parameters	
	$\alpha$	$\beta$
Imipramine	23	19
Lithium	26	15
Combination	17	22
Placebo	11	25

We then simulate 5000 vectors of four beta random variables with the above parameters. Then we see what proportion of those 5000 vectors have the imipramine parameter the largest. We did five such simulations and got the proportions 0.1598, 0.1626, 0.1668, 0.1650, and 0.1650. The sample sizes required to achieve the desired accuracy are all around 5300.

11. The  $\chi^2$  distribution with  $m$  degrees of freedom is the same as the gamma distribution with parameters  $m/2$  and  $1/2$ . So, we should simulate  $Y^{(i)}$  having the  $\chi^2$  distribution with  $n - p$  degrees of freedom and set  $\tau^{(i)} = Y^{(i)}/S_{\text{Resid}}^2$ .
12. We did a simulation of size  $v = 2000$ .
  - (a) The plot of the sample c.d.f. of the  $|\mu_x^{(i)} - \mu_y^{(i)}|$  values is in Fig. S.12.1.

Figure S.12.1: Sample c.d.f. of  $|\mu_x^{(i)} - \mu_y^{(i)}|$  values for Exercise 12a in Sec. 12.3.

- (b) The histogram of the ratios of calcium supplement precision to placebo precision is given in Fig. S.12.2. Only 12% of the simulated  $\log(\tau_x^{(i)}/\tau_y^{(i)})$  were positive and 37% were less than  $-1$ .

Figure S.12.2: Histogram of  $\log(\tau_x^{(i)}/\tau_y^{(i)})$  values for Exercise 12b in Sec. 12.3.

There seems to be a sizeable probability that the two precisions (hence the variances) are unequal.

13. Let  $X = F^{-1}(U)$ , where  $F^{-1}$  is defined in Eq. (12.3.7) and  $U$  has a uniform distribution on the interval  $[0, 1]$ . Let  $G$  be the c.d.f. of  $X$ . We need to show that  $G = F$ , where  $F$  is defined in Eq. (12.3.6). Since  $F^{-1}$  only takes the values  $t_1, \dots, t_n$ , it follows that  $G$  has jumps at those values and is flat everywhere else. Since  $F$  also has jumps at  $t_1, \dots, t_n$  and is flat everywhere else, we only need to show that  $F(x) = G(x)$  for  $x \in \{t_1, \dots, t_n\}$ . Let  $q_n = 1$ . Then  $X \leq t_i$  if and only if  $U \leq q_i$  for  $i = 1, \dots, n$ . Since  $\Pr(U \leq q_i) = q_i$ , it follows that  $G(t_i) = q_i$  for  $i = 1, \dots, n$ . That is,  $G(x) = F(x)$  for  $x \in \{t_1, \dots, t_n\}$ .

14. First, establish the Bonferroni inequality. Let  $A_1, \dots, A_k$  be events. Then

$$\Pr\left(\bigcap_{i=1}^k A_i\right) = 1 - \Pr\left(\bigcup_{i=1}^k A_i^c\right) \geq 1 - \sum_{i=1}^k \Pr(A_i^c) = 1 - \sum_{i=1}^k [1 - \Pr(A_i)].$$

Now, let  $k = 3$  and

$$A_i = \{|G_{v,i}(x) - G_i(x)| \leq 0.0082, \text{ for all } x\},$$

for  $i = 1, 2, 3$ . The event stated in the exercise is  $\cap_{i=1}^3 A_i$ . According to the arguments in Sec. 10.6,

$$\Pr\left(60000^{1/2}|G_{v,i}(x) - G_i(x)| \leq 2, \text{ for all } x\right) \approx 0.9993.$$

Since  $2/60000^{1/2} = 0.0082$ , we have  $\Pr(A_i) \approx 0.9993$  for  $i = 1, 2, 3$ . The Bonferroni inequality then says that  $\Pr(\cap_{i=1}^3 A_i) \approx 0.9979$  or more.

15. The proof is exactly what the hint says. All joint p.d.f.'s should be considered joint p.f./p.d.f.'s and the p.d.f.'s of  $X$  and  $Y$  should be considered p.f.'s instead. The only integral over  $x$  in the proof is in the second displayed equation in the proof. The outer integral in that equation should be replaced by a sum over all possible  $x$  values. The rest of the proof is identical to the proof of Theorem 12.3.1.

16. Let  $p_i = \exp(-\theta)\theta^i/(i!)$  for  $i = 0, 1, \dots$  and let  $q_k = \sum_{i=1}^k p_i$ . Let  $U$  have a uniform distribution on the interval  $[0, 1]$ . Let  $Y$  be the smallest  $k$  such that  $U \leq q_k$ . Then  $Y$  has a Poisson distribution with mean  $\theta$ .
17. Let  $\{x_1, \dots, x_m\}$  be the set of values that have positive probability under at least one of  $g_1, \dots, g_n$ . That is, for each  $j = 1, \dots, m$  there is at least one  $i$  such that  $g_i(x_j) > 0$  and for each  $i = 1, \dots, n$ ,  $\sum_{j=1}^m g_i(x_j) = 1$ . Then, the law of total probability says that

$$\Pr(X = x_j) = \sum_{i=1}^n \Pr(X = x_j | I = i) \Pr(I = i).$$

Since  $\Pr(I = i) = 1/n$  for  $i = 1, \dots, n$  and  $\Pr(X = x_j | I = i) = g_i(x_j)$ , it follows that

$$\Pr(X = x_j) = \sum_{i=1}^n \frac{1}{n} g_i(x_j). \tag{S.12.3}$$

Since  $x_1, \dots, x_m$  are the only values that  $X$  can take, Eq. (S.12.3) specifies the entire p.f. of  $X$  and we see that Eq. (S.12.3) is the same as Eq. (12.3.8).

18. The Poisson probabilities with mean 5 from the table in the text are

$x$	0	1	2	3	4	5	6	7	8
$\Pr(X = x)$	.0067	.0337	.0842	.1404	.1755	.1755	.1462	.1044	.0653
$x$	9	10	11	12	13	14	15	16	
$\Pr(X = x)$	.0363	.0181	.0082	.0034	.0013	.0005	.0002	.0001	

where we have put the remainder probability under  $x = 16$ . In this case we have  $n = 17$  different possible values. Since  $1/17 = .0588$ , we can use  $x_1 = 0$  and  $y_1 = 2$ . Then  $g_1(0) = .1139$  and  $g_1(2) = .8861$ . Then  $f_1^*(2) = .8042 - (1 - .1139)/17 = .0321$ . Next, take  $x_2 = 1$  and  $y_2 = 3$ . Then  $g_2(1) = .5729$  and  $g_2(3) = .4271$ . This makes  $f_2^*(3) = .1153$ . Next, take  $x_3 = 2$  and  $y_3 = 3$  so that  $g_3(2) = .5453$ ,  $g_3(3) = .4547$ , and  $f_3^*(3) = .0885$ . Next, take  $x_4 = 9$  and  $y_4 = 3$ , etc. The result of 16 such iterations is summarized in Table S.12.1.

Table S.12.1: Result of alias method in Exercise 18 of Sec. 12.3

$i$	$x_i$	$g_i(x_i)$	$y_i$	$g_i(y_i)$	$i$	$x_i$	$g_i(x_i)$	$y_i$	$g_i(y_i)$
1	0	.1139	2	.8861	10	13	.0221	5	.9779
2	1	.5729	3	.4271	11	14	.0085	5	.9915
3	2	.5453	3	.4547	12	5	.6246	6	.3754
4	9	.6171	3	.3829	13	15	.0034	6	.9966
5	10	.3077	3	.6923	14	16	.0017	6	.9983
6	3	.4298	4	.5702	15	6	.1151	7	.8849
7	11	.1394	4	.8606	16	7	.8899	8	.1101
8	12	.0578	4	.9422	17	8	1		
9	4	.6105	5	.3895					

The alias method is not unique. For example, we could have started with  $x_1 = 1$  and  $y_1 = 3$  or many other possible combinations. Each choice would lead to a different version of Table S.12.1.

19. For  $k = 1, \dots, n$ ,  $I = k$  if and only if  $k \leq nY + 1 < k + 1$ . Hence

$$\Pr(I = k) = \Pr\left(\frac{k-1}{n} \leq Y \leq \frac{k}{n}\right) = \frac{1}{n}.$$

The conditional c.d.f. of  $U$  given  $I = k$  is

$$\begin{aligned} \Pr(U \leq t | I = k) &= \Pr(nY + 1 - I \leq t | I = k) \\ &= \frac{\Pr(nY + 1 - k \leq t, I = k)}{\Pr(I = k)} \\ &= \frac{\Pr\left(Y \leq \frac{t+k-1}{n}, \frac{k-1}{n} \leq Y \leq \frac{k}{n}\right)}{1/n} \\ &= n \Pr\left(\frac{k-1}{n} \leq Y < \frac{t+k-1}{n}\right) \\ &= t, \end{aligned}$$

for  $0 < t < 1$ . So, the conditional distribution of  $U$  given  $I = k$  is uniform on the interval  $[0, 1]$  for all  $k$ . Since the conditional distribution is the same for all  $k$ ,  $U$  and  $I$  are independent and the marginal distribution of  $U$  is uniform on the interval  $[0, 1]$ .

## 12.4 Importance Sampling

### Commentary

Users of importance sampling might forget to check whether the importance function leads to a finite variance estimator. If the ratio of the function being integrated to the importance function is not bounded, one might have an infinite variance estimator. This doesn't happen in the examples in the text, but students should be made aware of the possibility. This section ends with an introduction to stratified importance sampling. This is an advanced topic that is quite useful, but might be skipped in a first pass. The last five exercises in this section introduce two additional variance reduction techniques, control variates and antithetic variates. These can be useful in many types of simulation problems, but those problems can be difficult to identify.

### Solutions to Exercises

1. We want to approximate the integral  $\int_a^b g(x)dx$ . Suppose that we use importance sampling with  $f$  being the p.d.f. of the uniform distribution on the interval  $[a, b]$ . Then  $g(x)/f(x) = (b - a)g(x)$  for  $a < x < b$ . Now, (12.4.1) is the same as (12.4.2).
2. First, we shall describe the second method in the exercise. We wish to approximate the integral  $\int g(x)f(x)dx$  using importance sampling with importance function  $f$ . We should then simulate values  $X^{(i)}$  with p.d.f.  $f$  and compute

$$Y^{(i)} = \frac{g(X^{(i)})f(X^{(i)})}{f(X^{(i)})} = g(X^{(i)}).$$

The importance sampling estimate is the average of the  $Y^{(i)}$  values. Notice that this is precisely the same as the first method in the exercise.

3. (a) This is a distribution for which the quantile function is easy to compute. The c.d.f. is  $F(x) = 1 - (c/x)^{n/2}$  for  $x > c$ , so the quantile function is  $F^{-1}(p) = c/(1-p)^{2/n}$ . So, simulate  $U$  having a uniform distribution on the interval  $[0, 1]$  and let  $X = c/(1-U)^{2/n}$ . Then  $X$  has the p.d.f.  $f$ .
- (b) Let

$$a = \frac{\Gamma\left[\frac{1}{2}(m+n)\right] m^{m/2} n^{n/2}}{\Gamma\left(\frac{1}{2}m\right) \Gamma\left(\frac{1}{2}n\right)}.$$

Then the p.d.f. of  $Y$  is  $g(x) = ax^{(m/2)-1}/(mx + n)^{(m+n)/2}$ , for  $x > 0$ . Hence,

$$\Pr(Y > c) = \int_c^\infty a \frac{x^{(m/2)-1}}{(mx + n)^{(m+n)/2}} dx.$$

We could approximate this by sampling lots of values  $X^{(i)}$  with the p.d.f.  $f$  from part (a) and then averaging the values  $g(X^{(i)})/f(X^{(i)})$ .

- (c) The ratio  $g(x)/f(x)$  is, for  $x > c$ ,

$$\frac{g(x)}{f(x)} = \frac{ax^{(m+n)/2}}{c^{n/2}(n/2)(mx + n)^{(m+n)/2}} = \frac{a}{c^{n/2}(n/2)(m + n/x)^{(m+n)/2}}.$$

This function is fairly flat for large  $x$ . Since we are only interested in  $x > c$  in this exercise, importance sampling will have us averaging random variables  $g(X^{(i)})/f(X^{(i)})$  that are nearly constant, hence the average should have small variance.

4. (a) If our 10000 exponentials are  $X^{(1)}, \dots, X^{(10000)}$ , then our approximation is the average of the values  $\log(1 + X^{(i)})$ . In two example simulations, I got averages of 0.5960 and 0.5952 with simulation standard errors of 0.0042 both times.
- (b) Using importance sampling with the importance function being the gamma p.d.f. with parameters 1.5 and 1, I got estimates of 0.5965 and 0.5971 with simulation standard errors of 0.0012 both times.
- (c) The reason that the simulations in part (b) have smaller simulation standard error is that gamma importance function is a constant times  $x^{1/2} \exp(-x)$ . The ratio of the integrand to the importance function is a constant times  $\log(1 + x)x^{-1/2}$ , which is nearly constant itself.
5. Let  $U$  have a uniform distribution on the interval  $[0, 1]$ , and let  $W$  be defined by Eq. (12.4.6). The inverse transformation is

$$u = \frac{\Phi\left(\frac{w - \mu_2}{\sigma_2}\right)}{\Phi\left(\frac{c_2 - \mu_2}{\sigma_2}\right)}.$$

The derivative of the inverse transformation is

$$\frac{1}{(2\pi)^{1/2} \sigma_2 \Phi\left(\frac{c_2 - \mu_2}{\sigma_2}\right)} \exp\left(-\frac{1}{2\sigma_2^2}(w - \mu_2)^2\right). \quad (\text{S.12.4})$$

Since the p.d.f. of  $U$  is constant, the p.d.f. of  $W$  is (S.12.4), which is the same as (12.4.5).

6. (a) We can simulate truncated normals as follows. If  $U$  has a uniform distribution on the interval  $[0, 1]$ , then  $X = \Phi^{-1}(\Phi(1) + U[1 - \Phi(1)])$  has the truncated normal distribution in the exercise. If  $X^{(1)}, \dots, X^{(1000)}$  are our simulated values, then the estimate is the average of the  $(1 - \Phi(1))X^{(i)}$  values. Three simulations of size 1000 each produced the estimates 0.4095, 0.3878, and 0.4060.
- (b) If  $Y$  has an exponential distribution with parameter 0.5, and  $X = (1 + Y)^{1/2}$ , then we can find the p.d.f. of  $X$ . The inverse transformation is  $y = x^2 - 1$  with derivative  $2x$ . The p.d.f. of  $X$  is then  $2x0.5 \exp(-0.5x^2 + 0.5)$ . If  $X^{(1)}, \dots, X^{(1000)}$  are our simulated values, then the estimate is the average of the  $X^{(i)} \exp(-0.5)/(2\pi)^{1/2}$  values. Three simulations of size 1000 each produced the estimates 0.3967, 0.3980, and 0.4016.
- (c) The simulation standard errors of the simulations in part (a) were close to 0.008, while those from part (b) were about 0.004, half as large. The reason is that the random variables averaged in part (b) are closer to constant than those in part (a) since  $x$  is closer to constant than  $x^2$ .
7. (a) We can simulate bivariate normals by simulating one of the marginals first and then simulating the second coordinate conditional on the first one. For example, if we simulate  $X_1^{(i)}, U^{(i)}$  as independent normal random variables with mean 0 and variance 1, we can simulate  $X_2^{(i)} = 0.5X_1^{(i)} + U^{(i)}.75^{1/2}$ . Three simulations of size 10000 each produced estimates of 0.8285, 0.8308, and 0.8316 with simulation standard errors of 0.0037 each time.
- (b) Using the method of Example 12.4.3, we did three simulations of size 10000 each and got estimates of 0.8386, 0.8387, and 0.8386 with simulation standard errors of about  $3.4 \times 10^{-5}$ , about 0.01 as large as those from part (a). Also, notice how much closer the three simulations are in part (b) compared to the three in part (a).

8. The random variables that are averaged to compute the importance sampling estimator are  $Y^{(i)} = g(X^{(i)})/f(X^{(i)})$  where the  $X^{(i)}$ 's have the p.d.f.  $f$ . Since  $g/f$  is bounded,  $Y^{(i)}$  has finite variance.
9. The inverse transformation is  $v = F(x)$  with derivative  $f(x)$ . So, the p.d.f. of  $X$  is  $f(x)/(b-a)$  for those  $x$  that can arise as values of  $F^{-1}(V)$ , namely  $F^{-1}(a) < x < F^{-1}(b)$ .
10. For part (a), the stratified importance samples can be found by replacing  $U$  in the formula used in Exercise 6(a) by  $a + U(b-a)$  where  $(a,b)$  is one of the pairs  $(0,.2)$ ,  $(.2,.4)$ ,  $(.4,.6)$ ,  $(.6,.8)$ , or  $(.8,1)$ . For part (b), replace  $Y$  by  $-\log(1 - [a + U(b-a)])$  in the formula  $X = (1+Y)^{1/2}$  using the same five  $(a,b)$  pairs. Three simulations using five intervals with 200 samples each produced estimates of 0.4018, 0.4029, and 0.2963 in part (a) and 0.4022, 0.4016, and 0.4012 in part (b). The simulation standard errors were about 0.0016 in part (a) and 0.0006 in part (b). Both parts have simulation standard errors about  $1/5$  or  $1/6$  the size of those in Exercise 6.
11. Since the conditional p.d.f. of  $X^*$  given  $J = j$  is  $f_j$ , the marginal p.d.f. of  $X^*$  is

$$f^*(x) = \sum_{j=1}^k f_j(x) \Pr(J=j) = \frac{1}{k} \sum_{j=1}^k f_j(x).$$

Since  $f_j(x) = kf(x)$  for  $q_{j-1} \leq x < q_j$ , for each  $x$  there is one and only one  $f_j(x) > 0$ . Hence,  $f^*(x) = f(x)$  for all  $x$ .

12. (a) The m.g.f. of a Laplace distribution with parameters 0 and  $\sigma$  is

$$\psi(t) = \int_{-\infty}^{\infty} \exp(tx) \frac{1}{2\sigma} \exp(-|x|/\sigma) dx.$$

The integral from  $-\infty$  to 0 is finite if and only if  $t > -1/\sigma$ . The integral from 0 to  $\infty$  is finite if and only if  $t < 1/\sigma$ . So the integral is finite if and only if  $-1/\sigma < t < 1/\sigma$ . The value of the integral is

$$\frac{1}{2\sigma} \left[ \frac{1}{t+1/\sigma} + \frac{1}{-t+1/\sigma} \right] = \frac{1}{1-t^2\sigma^2}.$$

Plugging  $\sigma^2 = u/100$  into this gives the expression in the exercise.

- (b) With  $u = 1$ ,  $\psi(1) = 1/0.99$ . With  $r = 0.06$ , we get  $\alpha = 0.06 + \log(0.99) = 0.04995$ . We ran three simulations of size 100000 each using the method described in the solution to Exercise 15 in Sec. 12.2. The estimated prices were  $S_0$  times 0.0844, 0.0838, and 0.0843. The simulation standard errors were all about  $3.6S_0 \times 10^{-4}$ .
- (c)  $S_u > S_0$  if and only if  $W_u > -\alpha u$ , in this case  $\alpha u = 0.04995$ . The conditional c.d.f. of  $W_u$  given that  $W_n > -0.04995$  is

$$F(w) = 1.4356 \begin{cases} 0.5[\exp(10w) - 0.6068] & \text{if } -0.04995 < w \leq 0, \\ 1 - 0.5[\exp(-10w) + 0.6068] & \text{if } w > 0. \end{cases}$$

The quantile function is then

$$F^{-1}(p) = \begin{cases} 0.1 \log(1.3931p + 0.6068) & \text{if } 0 < p < 0.2822, \\ -0.1 \log(2[1 - 0.6966p] - 0.6068) & \text{if } 0.2822 \leq p < 1. \end{cases}$$

When we use samples from this conditional distribution, we need to divide the average by 1.4356, which is the ratio of the conditional p.d.f. to the unconditional p.d.f. We ran three more simulations of size 100000 each and got estimates of  $S_0$  times 0.0845, 0.0846, and 0.0840 with simulation standard errors of about  $2.66S_0 \times 10^{-4}$ . The simulation standard error is only a little smaller than it was in part (b).

13. (a)  $E(Z) = E(Y^{(i)}) + kc = E(W^{(i)}) - kE(V^{(i)}) + kc$ . By the usual importance sampling argument,  $E(W^{(i)}) = \int g(x)dx$  and  $E(V^{(i)}) = c$ , so  $E(Z) = \int g(x)dx$ .
- (b)  $\text{Var}(Z) = [\sigma_W^2 + k^2\sigma_V^2 - 2k\rho\sigma_W\sigma_V]$ . This is a quadratic in  $k$  that is minimized when  $k = \rho\sigma_W/\sigma_V$ .

14. (a) We know that  $\int_0^1 (1+x^2)^{-1}dx = \pi/4$ . We shall use  $f(x) = \exp(-x)/(1-\exp(-1))$  for  $0 < x < 1$ . We shall simulate  $X^{(1)}, \dots, X^{(10000)}$  with this p.d.f. and compute

$$\begin{aligned} W^{(i)} &= \frac{1 - \exp(-1)}{1 + X^{(i)2}}, \\ V^{(i)} &= \frac{\exp[X^{(i)}](1 - \exp(-1))}{1 + X^{(i)2}}. \end{aligned}$$

We ran three simulations of 10000 each and got estimates of the integral equal to 0.5248, 0.5262, and 0.5244 with simulation standard errors around 0.00135. This compares to 0.00097 in Example 12.4.1. We shall see what went wrong in part (b).

- (b) We use the samples in our simulation to estimate  $\sigma_W$  at 0.0964,  $\sigma_Z$  at 0.0710, and  $\rho$  at  $-0.8683$ . Since the correlation appears to be negative, we should have used a negative value of  $k$  to multiply our control variate. Based on our estimates, we might use  $k = -1.1789$ . Additional simulations using this value of  $k$  produce simulation standard errors around  $4.8 \times 10^{-4}$ .
15. (a) Since  $U^{(i)}$  and  $1 - U^{(i)}$  both have uniform distributions on the interval  $[0, 1]$ ,  $X^{(i)} = F^{-1}(U^{(i)})$  and  $T^{(i)} = F^{-1}(1 - U^{(i)})$  have the same distribution.
- (b) Since  $X^{(i)}$  and  $T^{(i)}$  have the same distribution, so do  $W^{(i)}$  and  $V^{(i)}$ , so the means of  $W^{(i)}$  and  $V^{(i)}$  are both the same and they are both  $\int g(x)dx$ , according to the importance sampling argument.
- (c) Since  $F^{-1}$  is a monotone increasing function, we know that  $X^{(i)}$  and  $T^{(i)}$  are decreasing functions of each other. If  $g(x)/f(x)$  is monotone, then  $W^{(i)}$  and  $V^{(i)}$  will also be decreasing functions of each other. As such they ought to be negatively correlated since one is small when the other is large.
- (d)  $\text{Var}(Z) = \text{Var}(Y^{(i)})/v$ , and

$$\text{Var}(Y^{(i)}) = 0.25[\text{Var}(W^{(i)}) + \text{Var}(V^{(i)}) + 2\text{Cov}(W^{(i)}, V^{(i)})] = 0.5(1 + \rho)\text{Var}(W^{(i)}).$$

Without antithetic variates, we get a variance of  $\text{Var}(W^{(i)})/[2v]$ . If  $\rho < 0$ , then  $0.5(1 + \rho) < 0.5$  and  $\text{Var}(Z)$  is smaller than we get without antithetic variates.

16. Using the method outlined in Exercise 15, we did three simulations of size 5000 each and got estimates of 0.5250, 0.5247, and 0.5251 with estimates of  $\text{Var}(Y^{(i)})^{1/2}$  of about 0.0238, approximately 1/4 of  $\hat{\sigma}_3$  from Example 12.4.1.
17. In Exercise 3(c),  $g(x)/f(x)$  is a monotone function of  $x$ , so antithetic variates should help. In Exercise 4(b), we could use control variates with  $h(x) = \exp(-x)$ . In Exercises 6(a) and 6(b) the ratios  $g(x)/f(x)$  are monotone, so antithetic variates should help. Control variates with  $h(x) = x \exp(-x^2/2)$  could also help in Exercise 6(a). Exercise 10 involves the same function, so the same methods could also be used in the stratified versions.

## 12.5 Markov Chain Monte Carlo

### Commentary

Markov chain Monte Carlo (MCMC) is primarily used to simulate parameters in a Bayesian analysis. Implementing Gibbs sampling in all but the simplest problems is generally a nontrivial programming task. Instructors should keep this in mind when assigning exercises. The less experience students have had with programming, the more help they will need in implementing Gibbs sampling. The theoretical justification given in the text relies on the material on Markov chains from Sec. 3.10, which might have been skipped earlier in the course. This material is not necessary for actually performing MCMC.

If one is using the software *R*, there is no substitute for old-fashioned programming. (There is a package called *BUGS*:

<http://www.mrc-bsu.cam.ac.uk/bugs/> but I will not describe it here.) After the solutions, there is *R* code to do the calculations in Examples 12.5.6 and 12.5.7 in the text.

### Solutions to Exercises

1. The conditional p.d.f. of  $X_2$  given  $X_2 = x_2$  is

$$g_1(x_1|x_2) = \frac{f(x_1, x_2)}{f_2(x_2)} = \frac{cg(x_1, x_2)}{f_2(x_2)} = \frac{c}{f_2(x_2)} h_2(x_1).$$

Let  $c_2 = c/f_2(x_2)$ , which does not depend on  $x_1$ .

2. Let  $f_2(x_2) = \int f(x_1, x_2) dx_1$  stand for the marginal p.d.f. of  $X_2$ , and let  $g_1(x_1|x_2) = f(x_1, x_2)/f_2(x_2)$  stand for the conditional p.d.f. of  $X_1^{(i)}$  given  $X_2^{(i)} = x_2$ . We are supposing that  $X_2^{(i)}$  has the marginal distribution with p.d.f.  $f_2$ . In step 2 of the Gibbs sampling algorithm, after  $X_2^{(i)} = x_2$  is observed,  $X_1^{(i+1)}$  is sampled from the distribution with p.d.f.  $g_a(x_1|x_2)$ . Hence, the joint p.d.f. of  $(X_1^{(i+1)}, X_2^{(i)})$  is  $f_2(x_2)g_1(x_1, x_2) = f(x_1, x_2)$ . In particular  $X_1^{(i+1)}$  has the same marginal distribution as  $X_1$ , and the same argument we just gave (with subscripts 1 and 2 switched and applying step 3 instead of 2 in the Gibbs sampling algorithm) shows that  $(X_1^{(i+1)}, X_2^{(i+1)})$  has the same joint distribution as  $(X_1^{(i)}, X_2^{(i)})$ .
3. Let  $h(z)$  stand for the p.f. or p.d.f. of the stationary distribution and let  $g(z|z')$  stand for the conditional p.d.f. or p.f. of  $Z_{i+1}$  given  $Z_i = z'$ , which is assumed to be the same for all  $i$ . Suppose that  $Z_i$  has the stationary distribution for some  $i$ , then  $(Z_i, Z_{i+1})$  has the joint p.f. or p.d.f.  $h(z_i)g(z_{i+1}|z_i)$ . Since  $Z_1$  does have the stationary distribution,  $(Z_1, Z_2)$  has the joint p.f. or p.d.f.  $h(z_1)g(z_2|z_1)$ . Hence,  $(Z_1, Z_2)$  has the same distribution as  $(Z_i, Z_{i+1})$  whenever  $Z_i$  has the stationary distribution. The proof is complete if we can show that  $Z_i$  has the stationary distribution for every  $i$ . We shall show this by induction. We know that it is true for  $i = 1$  (that is,  $Z_1$  has the stationary distribution). Assume that each of  $Z_1, \dots, Z_k$  has the stationary distribution, and prove that  $Z_{k+1}$  has the stationary distribution. Since  $h$  is the p.d.f. or p.f. of the stationary distribution, it follows that the marginal p.d.f. or p.f. of  $Z_{k+1}$  is  $\int h(z_k)g(z_{k+1}|z_k)dz_k$  or  $\sum_{\text{All } z_k} h(z_k)g(z_{k+1}|z_k)$ , either of which is  $h(z_{k+1})$  by the definition of stationary distribution. Hence  $Z_{k+1}$  also has the stationary distribution, and the induction proof is complete.
4.  $\text{Var}(\bar{X}) = \sigma^2/n$  and

$$\text{Var}(\bar{Y}) = \frac{\sigma^2}{n} + \frac{1}{n^2} \sum \sum_{i \neq j} \text{Cov}(Y_i, Y_j).$$

Since  $\text{Cov}(Y_i, Y_j) > 0$ ,  $\text{Var}(\bar{Y}) > \sigma^2/n = \text{Var}(\bar{X})$ .

5. The sample average of all 30 observations is 1.442, and the value of  $s_n^2$  is 2.671. The posterior hyperparameters are then

$$\alpha_1 = 15.5, \lambda_1 = 31, \mu_1 = 1.4277, \text{ and } \beta_1 = 1.930.$$

The method described in Example 12.5.1 says to simulate values of  $\mu$  having the normal distribution with mean 1.4277 and variance  $(31\tau)^{-1}$  and to simulate values of  $\tau$  having the gamma distribution with parameters 16 and  $1.930 + 0.5(\mu - 1.4277)^2$ . In my particular simulation, I used five Markov chains with the following starting values for  $\mu$ : 0.4, 1.0, 1.4, 1.8, and 2.2. The convergence criterion was met very quickly, but we did 100 burn-in anyway. The estimated mean of  $(\sqrt{\tau}\mu)^{-1}$  was 0.2542 with simulation standard error  $4.71 \times 10^{-4}$ .

6. The data summaries that we need to follow the pattern of Example 12.5.4 are the following:

$$\begin{aligned} \bar{x}_1 &= 12.5 & \bar{x}_2 &= 47.89 & \bar{y} &= 2341.4 \\ s_{11} &= 5525 & s_{12} &= 16737 & s_{22} &= 61990.47 \\ s_{1y} &= 927865 & s_{2y} &= 3132934 & s_{yy} &= 169378608, \end{aligned}$$

and  $n = 26$ .

- (a) The histogram of  $|\beta_1^{(\ell)}|$  values is in Fig. S.12.3.

Figure S.12.3: Sample c.d.f. of  $|\beta_1^{(\ell)}|$  values for Exercise 6a in Sec. 12.5.

- (b) i. The histogram of  $\beta_0^{(\ell)} + 26\beta_1^{(\ell)} + 67.2\beta_2^{(\ell)}$  values is in Fig. S.12.4.  
ii. Let  $\mathbf{z}' = (1, 26, 67.2)$  as in Example 11.5.7 of the text. To create the predictions, we take each of the values in the histogram in Fig. S.12.4 and add a pseudo-random normal variable to each with mean 0 and variance

$$\left[1 + \mathbf{z}'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{z}\right]^{1/2} \tau^{(\ell)-1/2}.$$

We then use the sample 0.05 and 0.95 quantiles as the endpoints of our interval. In three separate simulations, I got the following intervals (3652, 5107), (3650, 5103), and (3666, 5131). These are all slightly wider than the interval in Example 11.5.7.

Figure S.12.4: Histogram of  $\beta_0^{(\ell)} + 26\beta_1^{(\ell)} + 67.2\beta_2^{(\ell)}$  values for Exercise6(b)i in Sec. 12.5.

Figure S.12.5: Histogram of predicted values for 1986 sales in Exercise 6(b)iii in Sec. 12.5.

- iii. The histogram of the sales figures used in Exercise 6(b)ii is in Fig. S.12.5. This histogram has more spread in it than the one in Fig. S.12.4 because the 1986 predictions equal the 1986 parameters plus independent random variables (as described in part (b)ii). The addition of the independent random variables increases the variance.
7. There are  $n_i = 6$  observations in each of  $p = 3$  groups. The sample averages are 825.83, 845.0, and 775.0. The  $w_i$  values are 570.83, 200.0, and 900.0. In three separate simulations of size 10000 each, I got the following three vectors of posterior mean estimates: (826.8, 843.2, 783.3), (826.8, 843.2, 783.1), and (826.8, 843.2, 783.2).
8. (a) To prove that the two models are the same, we need to prove that we get Model 1 when we integrate  $\tau_1, \dots, \tau_n$  out of Model 2. Since the  $\tau_i$ 's are independent, the  $Y_i$ 's remain independent after integrating out the  $\tau_i$ 's. In Model 2,  $[Y_i - (\beta_0 + \beta_1 x_i)]\tau_i^{1/2}$  has the standard normal distribution given  $\tau_i$ , and is therefore independent of  $\tau_i$ . Also,  $\tau_i a\sigma^2$  has the  $\chi^2$  distribution with  $a$  degrees of

freedom, so

$$\frac{[Y_i - (\beta_0 + \beta_1 x_i)]\tau_i^{1/2}}{\tau_i^{1/2}\sigma}$$

has the  $t$  distribution with  $a$  degrees of freedom, which is the same as Model 1.

- (b) The prior p.d.f. is a constant times

$$\eta^{b/2-1} \exp(-f\eta/2) \prod_{i=1}^n \left[ \tau_i^{a/2-1} \eta^{a/2} \exp(-a\eta\tau_i/2) \right],$$

while the likelihood is

$$\prod_{i=1}^n \left[ \tau_i^{1/2} \exp(-[y_i - \beta_0 - \beta_1 x_i]^2 \tau_i/2) \right].$$

The product of these two produces Eq. (12.5.4).

- (c) As a function of  $\eta$ , we have  $\eta$  to the power  $(na+b)/2 - 1$  times  $e$  to the power of  $-\eta/2$  times  $f + a \sum_{i=1}^n \tau_i$ . This is, aside from a constant factor, the p.d.f. of the gamma distribution with parameters  $(na+b)/2$  and  $(f+a \sum_{i=1}^n \tau_i)/2$ . As a function of  $\tau_i$ , we have  $\tau_i$  to the power  $(a+1)/2 - 1$  times  $e$  to the power  $-\tau_i[a\eta + (y_i - \beta_0 - \beta_1 x_i)^2]/2$ , which is (aside from a constant factor) the p.d.f. of the gamma distribution with parameters  $(a+1)/2$  and  $[a\eta + (y_i - \beta_0 - \beta_1 x_i)^2]/2$ . As a function of  $\beta_0$ , we have a constant times  $e$  to the power

$$-\sum_{i=1}^n \tau_i(\beta_0 - [y_i - \beta_1 x_i])^2/2 = -\frac{1}{2} \sum_{i=1}^n \tau_i \left( \beta_0 - \frac{\sum_{i=1}^n \tau_i(y_i - \beta_1 x_i)}{\sum_{i=1}^n \tau_i} \right)^2 + c,$$

where  $c$  does not depend on  $\beta_0$ . (Use the method of completing the square.) This is a constant times the p.d.f. of the normal distribution stated in the exercise. Completing the square as a function of  $\beta_1$  produces the result stated for  $\beta_1$  in the exercise.

9. In three separate simulations of size 10000 each I got posterior mean estimates for  $(\beta_0, \beta_1, \eta)$  of  $(-0.9526, 0.02052, 1.124 \times 10^{-5})$ ,  $(-0.9593, 0.02056, 1.143 \times 10^{-5})$ , and  $(-0.9491, 0.02050, 1.138 \times 10^{-5})$ . It appears we need more than 10000 samples to get a good estimate of the posterior mean of  $\beta_0$ . The estimated posterior standard deviations from the three simulations were  $(1.503 \times 10^{-2}, 7.412 \times 10^{-5}, 7.899 \times 10^{-6})$ ,  $(2.388 \times 10^{-2}, 1.178 \times 10^{-4}, 5.799 \times 10^{-6})$ , and  $(2.287 \times 10^{-2}, 1.274 \times 10^{-4}, 6.858 \times 10^{-6})$ .
  10. Let the proper prior have hyperparameters  $\mu_0$ ,  $\lambda_0$ ,  $\alpha_0$ , and  $\beta_0$ . Conditional on the  $Y_i$ 's, those  $X_i$ 's that have  $Y_i = 1$  are an i.i.d. sample of size  $\sum_{i=1}^n Y_i$  from the normal distribution with mean  $\mu$  and precision  $\tau$ .
    - (a) The conditional distribution of  $\mu$  given all else is the normal distribution with mean equal to  $\frac{\mu_0 + \sum_{i=1}^n Y_i X_i}{\lambda_0 + \sum_{i=1}^n Y_i}$ , and precision equal to  $\tau \sum_{i=1}^n Y_i$ .
    - (b) The conditional distribution of  $\tau$  given all else is the gamma distribution with parameters  $\alpha_0 + \sum_{i=1}^n Y_i/2 + 1/2$  and
- $$\beta_0 + \frac{1}{2} \left[ \lambda_0(\mu - \mu_0)^2 + \sum_{i=1}^n Y_i(X_i - \mu)^2 \right].$$

- (c) Given everything except  $Y_i$ ,

$$\Pr(Y_i = 1) = \frac{\tau^{1/2} \exp\left(-\frac{\tau}{2}[X_i - \mu]^2\right)}{\tau^{1/2} \exp\left(-\frac{\tau}{2}[X_i - \mu]^2\right) + \exp\left(-\frac{1}{2}X_i^2\right)}.$$

- (d) To use Gibbs sampling, we need starting values for all but one of the unknowns. For example, we could randomly assign the data values to the two distributions with probabilities 1/2 each or randomly split the data into two equal-sized subsets. Given starting values for the  $Y_i$ 's, we could start  $\mu$  and  $\tau$  at their posterior means given the observations that came from the distribution with unknown parameters. We would then cycle through simulating random variables with the distributions in parts (a)–(c). After burn-in and a large simulation run, estimate the the posterior means by the averages of the sample parameters in the large simulation run.
- (e) The posterior mean of  $Y_i$  is the posterior probability that  $Y_i = 1$ . Since  $Y_i = 1$  is the same as the event that  $X_i$  came from the distribution with unknown mean and variance, the posterior mean of  $Y_i$  is the posterior probability that  $X_i$  came from the distribution with unknown mean and variance.
11. For this exercise, I ran five Markov chains for 10000 iterations each. For each iteration, I obtain a vector of 10  $Y_i$  values. Our estimated probability that  $X_i$  came from the distribution with unknown mean and variance equals the average of the 50000  $Y_i$  values for each  $i = 1, \dots, 10$ . The ten estimated probabilities for each of my three runs are listed below:
- | Run | Estimated Probabilities |       |       |       |       |       |       |       |       |       |
|-----|-------------------------|-------|-------|-------|-------|-------|-------|-------|-------|-------|
| 1   | 0.291                   | 0.292 | 0.302 | 0.339 | 0.370 | 0.281 | 0.651 | 0.374 | 0.943 | 0.816 |
| 2   | 0.285                   | 0.286 | 0.302 | 0.339 | 0.375 | 0.280 | 0.656 | 0.371 | 0.945 | 0.819 |
| 3   | 0.283                   | 0.286 | 0.301 | 0.340 | 0.373 | 0.280 | 0.651 | 0.370 | 0.945 | 0.820 |
12. Note that  $\gamma_0$  should be the precision rather than the variance of the prior distribution of  $\mu$ .
- (a) The prior p.d.f. times the likelihood equals a constant times
- $$\tau^{n/2} \exp\left(-\frac{\tau}{2}\left\{n[\bar{x}_n - \mu]^2 + s_n^2\right\}\right) \exp\left(-\frac{\gamma_0}{2}[\mu - \mu_0]^2\right) \tau^{\alpha_0-1} \exp\left(-\frac{\tau\beta_0}{2}\right),$$
- where  $s_n^2 = \sum_{i=1}^n (x_i - \bar{x}_n)^2$ . As a function of  $\tau$  this looks like the p.d.f. of the gamma distribution with parameters  $\alpha_0 + n/2$  and  $[n(\bar{x}_n - \mu)^2 + s_n^2 + \beta_0]/2$ . As a function of  $\mu$ , (by completing the square) it looks like the p.d.f. of the normal distribution with mean  $(n\tau\bar{x}_n + \mu_0\gamma_0)/(n\tau + \gamma_0)$  and variance  $1/(n\tau + \gamma_0)$ .
- (b) The data summaries are  $n = 18$ ,  $\bar{x}_n = 182.17$ , and  $s_n^2 = 88678.5$ . I ran five chains of length 10000 each for three separate simulations. For each simulation, I obtained 50000 parameter pairs. To obtain the interval, I sorted the 50000  $\mu$  values and chose the 1250th and 48750th values. For the three simulations, I got the intervals (154.2, 216.2), (154.6, 216.5), and (154.7, 216.2).
13. In part (a), the exponent in the displayed formula should have been  $-1/2$ .
- (a) The conditional distribution of  $(\mu - \mu_0)\gamma^{1/2}$  given  $\gamma$  is standard normal, hence it is independent of  $\gamma$ . Also, the distribution of  $2b_0\gamma$  is the  $\chi^2$  distribution with  $2a_0$  degrees of freedom. It follows that  $(\mu - \mu_0)/(b_0/a_0)^{1/2}$  has the  $t$  distribution with  $2a_0$  degrees of freedom.

- (b) The marginal prior distributions of  $\tau$  are in the same form with the same hyperparameters in Exercise 12 and in Sec. 8.6. The marginal prior distributions of  $\mu$  are in the same form also, but the hyperparameters are not identical. We need  $a_0 = \alpha_0$  to make the degrees of freedom match, and we need  $b_0 = \beta_0/\lambda_0$  in order to make the scale factor match.
- (c) The prior p.d.f. times the likelihood equals a constant times
- $$\tau^{\alpha_0+n/2-1} \gamma^{a_0+1/2-1} \exp\left(-\frac{\tau}{2}\left\{n[\bar{x}_n - \mu]^2 + s_n^2 + \beta_0\right\} - \frac{\gamma}{2}[\mu - \mu_0]^2 + \gamma b_0\right).$$
- As a function of  $\tau$  this is the same as in Exercise 12. As a function of  $\mu$ , it is also the same as Exercise 12 if we replace  $\gamma_0$  by  $\gamma$ . As a function of  $\gamma$ , it looks like the p.d.f. of the gamma distribution with parameters  $a_0 + 1/2$  and  $b_0 + (\mu - \mu_0)/2$ .
- (d) This time, I ran 10 chains of length 10000 each for three different simulations. The three intervals are found by sorting the  $\mu$  values and using the 2500th and 97500th values. The interval are (154.4, 216.3), (154.6, 215.8), and (154.4, 215.9).
14. The exercise should have included that the prior hyperparameters are  $\alpha_0 = 0.5$ ,  $\mu_0 = 0$ ,  $\lambda_0 = 1$ , and  $\beta_0 = 0.5$ .
- (a) I used 10 chains of length 10000 each.
  - (b) The histogram of predicted values is in Fig. S.12.6. There are two main differences between this

Figure S.12.6: Histogram of Log-arsenic predictions for Exercise 14b in Sec. 12.5.

- histogram and the one in Fig. 12.10 in the text. First, the distribution of log-arsenic is centered at slightly higher values in this histogram. Second, the distribution is much less spread out in this histogram. (Notice the difference in horizontal scales between the two figures.)
- (c) The median of predicted arsenic concentration is 1.525 in my simulation, compared to the smaller value 1.231 in Example 12.5.8, about 24% higher.
15. (a) For each censored observation  $X_{n+i}$ , we observe only that  $X_{n+i} \leq c$ . The probability of  $X_{n+i} \leq c$  given  $\theta$  is  $1 - \exp(-c\theta)$ . The likelihood times prior is a constant times

$$\theta^{n+\alpha-1} [1 - \exp(-c\theta)]^m \exp\left(-\theta \sum_{i=1}^n x_i\right). \quad (\text{S.12.5})$$

We can treat the unobserved values  $X_{n+1}, \dots, X_{n+m}$  as parameters. The conditional distribution of  $X_{n+i}$  given  $\theta$  and given that  $X_{n+i} \leq c$  has the p.d.f.

$$g(x|\theta) = \frac{\theta \exp(-\theta x)}{1 - \exp(-\theta c)}, \text{ for } 0 < x < c. \quad (\text{S.12.6})$$

If we multiply the conditional p.d.f. of  $(X_{n+1}, \dots, X_{n+m})$  given  $\theta$  times Eq. (S.12.5), we get

$$\theta^{n+m+\alpha-1} \exp\left(-\theta \sum_{i=1}^{n+m} x_i\right),$$

for  $\theta > 0$  and  $0 < x_i < c$  for  $i = n+1, \dots, n+m$ . As a function of  $\theta$ , this looks like the p.d.f. of the gamma distribution with parameters  $n+m+\alpha$  and  $\sum_{i=1}^{n+m} x_i$ . As a function of  $X_{n+i}$ , it looks like the p.d.f. in Eq. (S.12.6). So, Gibbs sampling can work as follows. Pick a starting value for  $\theta$ , such as one over the average of the uncensored values. Then simulate the censored observations with p.d.f. (S.12.6). This can be done using the quantile function

$$G^{-1}(p) = -\frac{\log(1 - p[1 - \exp(-c\theta)])}{\theta}.$$

Then, simulate a new  $\theta$  from the gamma distribution mentioned above to complete one iteration.

- (b) For each censored observation  $X_{n+i}$ , we observe only that  $X_{n+i} \geq c$ . The probability of  $X_{n+i} \geq c$  given  $\theta$  is  $\exp(-c\theta)$ . The likelihood times prior is a constant times

$$\theta^{n+\alpha-1} \exp\left(-\theta \left[mc + \sum_{i=1}^n x_i\right]\right). \quad (\text{S.12.7})$$

We could treat the unobserved values  $X_{n+1}, \dots, X_{n+m}$  as parameters. The conditional distribution of  $X_{n+i}$  given  $\theta$  and given that  $X_{n+i} \geq c$  has the p.d.f.

$$g(x|\theta) = \theta \exp(-\theta[x - c]), \text{ for } x > c. \quad (\text{S.12.8})$$

If we multiply the conditional p.d.f. of  $(X_{n+1}, \dots, X_{n+m})$  given  $\theta$  times Eq. (S.12.7), we get

$$\theta^{n+m+\alpha-1} \exp\left(-\theta \sum_{i=1}^{n+m} x_i\right),$$

for  $\theta > 0$  and  $x_i > c$  for  $i = n+1, \dots, n+m$ . As a function of  $\theta$ , this looks like the p.d.f. of the gamma distribution with parameters  $n+m+\alpha$  and  $\sum_{i=1}^{n+m} x_i$ . As a function of  $X_{n+i}$ , it looks like the p.d.f. in Eq. (S.12.8). So, Gibbs sampling can work as follows. Pick a starting value for  $\theta$ , such as the M.L.E.,  $\frac{n+m}{mc + \sum_{i=1}^n x_i}$ . Then simulate the censored observations with p.d.f. (S.12.8).

This can be done using the quantile function

$$G^{-1}(p) = c - \frac{\log(1 - p)}{\theta}.$$

Then, simulate a new  $\theta$  from the gamma distribution mentioned above to complete one iteration. In this part of the exercise, Gibbs sampling is not really needed because the posterior distribution of  $\theta$  is available in closed form. Notice that (S.12.7) is a constant times the p.d.f. of the gamma distribution with parameters  $n+\alpha$  and  $mc + \sum_{i=1}^n x_i$ , which is then the posterior distribution of  $\theta$ .

16. (a) The joint p.d.f. of  $(X_i, Z_i)$  can be found from the joint p.d.f. of  $(X_i, Y_i)$  and the transformation  $h(x, y) = (x, x + y)$ . The joint p.d.f. of  $(X_i, Y_i)$  is  $f(x, y) = \lambda\mu \exp(-x\lambda - y\mu)$  for  $x, y > 0$ . The inverse transformation is  $h^{-1}(x, z) = (x, z - x)$ , with Jacobian equal to 1. So, the joint p.d.f. of  $(X_i Z_i)$  is

$$g(x, z) = f(x, z - x) = \lambda\mu \exp(-x[\lambda - \mu] - z\mu), \text{ for } 0 < x < z, z > 0.$$

The marginal p.d.f. of  $Z_i$  is the integral of this over  $x$ , namely

$$g_2(z) = \frac{\lambda\mu}{\lambda - \mu} [1 - \exp(-z[\lambda - \mu])] \exp(-z\mu),$$

for  $z > 0$ . The conditional p.d.f. of  $X_i$  given  $Z_i = z$  is the ratio

$$\frac{g(x, z)}{g_2(z)} = \frac{\lambda - \mu}{1 - \exp(-z[\lambda - \mu])} \exp(-x[\lambda - \mu]), \text{ for } 0 < x < z. \quad (\text{S.12.9})$$

The conditional c.d.f. of  $X_i$  given  $Z_i = z$  is the integral of this, which is the formula in the text.

- (b) The likelihood times prior is

$$\frac{\lambda^{n+a-1}\mu^{n+b-1}}{(\lambda - \mu)^{n-k}} \exp\left(-\lambda \sum_{i=1}^k x_i - \mu \sum_{i=1}^k y_i\right) \prod_{i=k+1}^n [1 - \exp(-[\lambda - \mu]z_i)]. \quad (\text{S.12.10})$$

We can treat the unobserved pairs  $(X_i, Y_i)$  for  $i = k + 1, \dots, n$  as parameters. Since we observe  $X_i + Y_i = Z_i$ , we shall just treat  $X_i$  as a parameter. The conditional p.d.f. of  $X_i$  given the other parameters and  $Z_i$  is in (S.12.9). Multiplying the product of those p.d.f.'s for  $i = k + 1, \dots, n$  times (S.12.10) gives

$$\lambda^{n+a-1}\mu^{n+b-1} \exp\left(-\lambda \sum_{i=1}^n x_i - \mu \left[\sum_{i=1}^k y_i + \sum_{i=k+1}^n (z_i - x_i)\right]\right), \quad (\text{S.12.11})$$

where  $0 < x_i < z_i$  for  $i = k + 1, \dots, n$ . As a function of  $\lambda$ , (S.12.11) looks like the p.d.f. of the gamma distribution with parameters  $n + a$  and  $\sum_{i=1}^n x_i$ . As a function of  $\mu$  it looks like the p.d.f. of the gamma distribution with parameters  $n + b$  and  $\sum_{i=1}^n y_i$ . As a function of  $x_i$  ( $i = k + 1, \dots, n$ ), it looks like the p.d.f. in (S.12.9). So, Gibbs sampling can work as follows. Pick starting values for  $\mu$  and  $\lambda$ , such as one over the averages of the observed values of the  $X_i$ 's and  $Y_i$ 's. Then simulate the unobserved  $X_i$  values for  $i = k + 1, \dots, n$  using the probability integral transform. Then simulate new  $\lambda$  and  $\mu$  values using the gamma distributions mentioned above to complete one iteration.

## 12.6 The Bootstrap

### Commentary

The bootstrap has become a very popular technique for solving non-Bayesian problems that are not amenable to analysis. The nonparametric bootstrap can be implemented without much of the earlier material in this chapter. Indeed, one need only know how to simulate from a discrete uniform distribution (Example 12.3.11) and compute simulation standard errors (Sec. 12.2).

The software *R* has a function `boot` that is available after issuing the command `library(boot)`. The first three arguments to `boot` are a vector `data` containing the original sample, a function `f` to compute the statistic whose distribution is being bootstrapped, and the number of bootstrap samples to create. For the nonparametric bootstrap, the function `f` must have at least two arguments. The first will always be `data`, and

the second will be a vector `inds` of integers of the same dimension as `data`. This vector `inds` will choose the bootstrap sample. The function should return the desired statistic computed from the sample `data[inds]`. Any additional arguments to `f` can be passed to `boot` by setting them explicitly at the end of the argument list. For the parametric bootstrap, `boot` needs the optional arguments `sim="parametric"` and `ran.gen`. The function `ran.gen` tells how to generate the bootstrap samples, and it takes two arguments. The first argument will be `data`. The second argument is anything else that you need to generate the samples, for example, estimates of parameters based on the orginal data. Also, `f` needs at least one argument which will be a simulated data set. Any additional arguments can be passed explicitly to `boot`.

## Solutions to Exercises

1. We could start by estimating  $\theta$  by the M.L.E.,  $1/\bar{X}$ . Then we would use the exponential distribution with parameter  $1/\bar{X}$  for the distribution  $\hat{F}$  in the bootstrap. The bootstrap estimate of the variance of  $\bar{X}$  is the variance of a sample average  $\bar{X}^*$  of a sample of size  $n$  from the distribution  $\hat{F}$ , i.e., the exponential distribution with parameter  $1/\bar{X}$ . The variance of  $\bar{X}^*$  is  $1/n$  times the variance of a single observation from  $\hat{F}$ , which equals  $\bar{X}^2$ . So, the bootstrap estimate is  $\bar{X}^2/n$ .
2. The numbers  $x_1, \dots, x_n$  are known when we sample from  $F_n$ . Let  $i_1, \dots, i_n \in \{1, \dots, n\}$ . Since  $X_j = x_{i_j}$  if and only if  $J_j = i_j$ , we can compute

$$\Pr(X_1^* = x_{i_1}, \dots, X_n^* = x_{i_n}) = \Pr(J_1 = i_1, \dots, J_n = i_n) = \prod_{j=1}^n \Pr(J_j = i_j) = \prod_{j=1}^n \Pr(X_j^* = x_{i_j}).$$

The second equality follows from the fact that  $J_1, \dots, J_n$  are a random sample with replacement from the set  $\{1, \dots, n\}$ .

3. Let  $n = 2k + 1$ . The sample median of a nonparametric bootstrap sample is the  $k + 1$ st smallest observation in the bootstrap sample. Let  $x$  denote the smallest observation in the original sample. Assume that there are  $\ell$  observations from the original sample that equal  $x$ . (Usually  $\ell = 1$ , but it is not necessary.) The sample median from the bootstrap sample equals  $x$  from the original data set if and only if at least  $k + 1$  observations in the bootstrap sample equal  $x$ . Since each observation in the bootstrap equals  $x$  with probability  $\ell/n$  and the bootstrap observations are independent, the probability that at least  $k + 1$  of them equal  $x$  is

$$\sum_{i=k+1}^n \binom{n}{i} \left(\frac{\ell}{n}\right)^i \left(1 - \frac{\ell}{n}\right)^{n-i}.$$

4. For each bootstrap sample, compute the sample median. The bias estimate is the average of all of these sample medians minus the original sample median, 201.3. I started with a pilot sample of size 2000 and estimated the bias as 0.545. The sample variance of the 2000 sample medians was 3.435. This led me to estimate the necessary simulation size as

$$\left[ \Phi^{-1} \left( \frac{1 + 0.9}{2} \right) \frac{3.435^{1/2}}{0.02} \right]^2 = 23234.$$

So, I did 30000 bootstrap samples. The new estimate of bias was 0.5564, with a simulation standard error of 0.011.

5. This exercise is performed in a manner similar to Exercise 4.

- (a) In this case, I did three simulations of size 50000 each. The three estimates of bias were  $-1.684$ ,  $-1.688$ , and  $-1.608$ .
- (b) Each time, the estimated sample size needed to achieve the desired accuracy was between 48000 and 49000.
6. (a) For each bootstrap sample, compute the sample median. The estimate we want is the sample variance of these values. I did a pilot simulation of size 2000 and got a sample variance of 18.15. I did another simulation of size 10000 and got a sample variance of 18.87.
- (b) To achieve the desired accuracy, we would need a simulation of size

$$\left[ \Phi^{-1} \left( \frac{1 + 0.95}{2} \right) \frac{18.87^{1/2}}{0.005} \right]^2 = 2899533.$$

That is, we would need about three million bootstrap samples.

7. (a) Each bootstrap sample consists of  $\bar{X}^{*(i)}$  having a normal distribution with mean 0 and variance  $31.65/11$ ,  $\bar{Y}^{*(i)}$  having the normal distribution with mean 0 and variance  $68.8/10$ ,  $S_X^{2*(i)}$  being  $31.65$  times a  $\chi^2$  random variable with 10 degrees of freedom, and  $S_Y^{2*(i)}$  being  $68.8$  times a  $\chi^2$  random variable with 9 degrees of freedom. For each sample, we compute the statistic  $U^{(i)}$  displayed in Example 12.6.10 in the text. We then compute what proportion of the absolute values of the 10000 statistics exceed the 0.95 quantile of the  $t$  distribution with 19 degrees of freedom, 1.729. In three separate simulations, I got proportions of 0.1101, 0.1078, and 0.1115.
- (b) To correct the level of the test, we need the 0.9 quantile of the distribution of  $|U|$ . For each simulation, we sort the 10000  $|U^{(i)}|$  values and select the 9000th value. In my three simulations, this value was 1.773, 1.777, and 1.788.
- (c) To compute the simulation standard error of the sample quantile, I chose to split the 10000 samples into eight sets of size 1250. For each set, I sort the  $|U^{(i)}|$  values and choose the 1125th one. The simulation standard error is then the square-root of one-eighth of the sample variance of these eight values. In my three simulations, I got the values 0.0112, 0.0136, and 0.0147.

8. The correlation is the ratio of the covariance to the square-root of the product of the variances. The mean of  $X^*$  is  $E(X^*) = \bar{X}$ , and the mean of  $Y^*$  is  $E(Y^*) = \bar{Y}$ . The variance of  $X^*$  is  $\sum_{i=1}^n (X_i - \bar{X})^2/n$ , and the variance of  $Y^*$  is  $\sum_{i=1}^n (Y_i - \bar{Y})^2/n$ . The covariance is

$$E[(X^* - \bar{X})(Y^* - \bar{Y})] = \frac{1}{n} \sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y}).$$

Dividing this by the square-root of the product of the variances yields (12.6.2).

9. (a) For each bootstrap sample, compute the sample correlation  $R^{(i)}$ . Then compute the sample variance of  $R^{(1)}, \dots, R^{(1000)}$ . This is the approximation to the bootstrap estimate of the variance of the sample correlation. I did three separate simulations and got sample variances of  $4.781 \times 10^{-4}$ ,  $4.741 \times 10^{-4}$ , and  $4.986 \times 10^{-4}$ .
- (b) The approximation to the bootstrap bias estimate is the sample average of  $R^{(1)}, \dots, R^{(1000)}$  minus the original sample correlation, 0.9670. In my three simulations, I got the values  $-0.0030$ ,  $-0.0022$ , and  $-0.0026$ . It looks like 1000 is not enough bootstrap samples to get a good estimate of this bias.

- (c) For the simulation standard error of the variance estimate, we use the square-root of Eq. (12.2.3) where each  $Y^{(i)}$  in (12.2.3) is  $R^{(i)}$  in this exercise. In my three simulations, I got the values  $2.231 \times 10^{-5}$ ,  $2.734 \times 10^{-5}$ , and  $3.228 \times 10^{-5}$ . For the simulation standard error of the bias estimate, we just note that the bias estimate is an average, so we need only calculate the square-root of 1/1000 times the sample variance of  $R^{(1)}, \dots, R^{(1000)}$ . In my simulations, I got  $6.915 \times 10^{-4}$ ,  $6.886 \times 10^{-4}$ , and  $7.061 \times 10^{-4}$ .
10. For both parts (a) and (b), we need 10000 bootstrap samples. From each bootstrap sample, we compute the sample median. Call these values  $M^{*(i)}$ , for  $i = 1, \dots, 10000$ . The median of the original data is  $M = 152.5$ .
- Sort the  $M^{*(i)}$  values from smallest to largest. The percentile interval just runs from the 500th sorted value to the 9500th sorted value. I ran three simulations and got the following three intervals: [148, 175], [148, 175], and [146.5, 175].
  - Choose a measure of spread and compute it from the original sample. Call the value  $Y$ . For each bootstrap sample, compute the same measure of spread  $Y^{*(i)}$ . I choose the median absolute deviation, which is  $Y = 19$  for this data set. Then sort the values  $(M^{*(i)} - M)/Y^{*(i)}$ . Find the 500th and 9500th sorted values  $Z_{500}$  and  $Z_{9500}$ . The percentile- $t$  confidence interval runs from  $M - ZY$  to  $M + ZY$ . In my three simulations, I got the intervals [143, 181], [142.6, 181], and [141.9, 181].
  - The sample average of the beef hot dog values is 156.9, and the value of  $\sigma'$  is 22.64. The confidence interval based on the normal distribution use the  $t$  distribution quantile  $T_{19}^{-1}(0.95) = 1.729$  and equals  $156.9 \pm 1.729 \times 22.64/20^{1/2}$ , or [148.1, 165.6]. This interval is considerably shorter than either of the bootstrap intervals.
11. (a) If  $X^*$  has the distribution  $F_n$ , then  $\mu = E(X^*) = \bar{X}$ ,
- $$\sigma^2 = \text{Var}(X^*) = \frac{1}{n} \sum_{i=1}^n (X_i - \bar{X})^2, \text{ and}$$
- $$E([X - \mu]^3) = \frac{1}{n} \sum_{i=1}^n (X_i - \bar{X})^3.$$
- Plugging these values into the formula for skewness (see Definition 4.4.1) yields the formula for  $M_3$  given in this exercise.
- (b) The summary statistics of the 1970 fish price data are  $\bar{X} = 41.1$ ,  $\sum_{i=1}^n (X_i - \bar{X})^2/n = 1316.5$ , and  $\sum_{i=1}^n (X_i - \bar{X})^3/n = 58176$ , so the sample skewness is  $M_3 = 1.218$ . For each bootstrap sample, we also compute the sample skewness  $M_3^{*(i)}$  for  $i = 1, \dots, 1000$ . The bias of  $M_3$  is estimated by the sample average of the  $M_3^{*(i)}$ 's minus  $M_3$ . I did three simulations and got the values  $-0.2537$ ,  $-0.2936$ , and  $-0.2888$ . To estimate the standard deviation of  $M_3$ , compute the sample standard deviation of the  $M_3^{*(i)}$ 's. In my three simulations, I got 0.5480, 0.5590, and 0.5411.
12. We want to show that the distribution of  $R$  is the same for all parameter vectors  $(\mu_x, \mu_y, \sigma_x^2, \sigma_y^2, \rho)$  that share the same value of  $\rho$ . Let  $\boldsymbol{\theta}_1 = (\mu_{x1}, \mu_{y1}, \sigma_{x1}^2, \sigma_{y1}^2, \rho)$  and  $\boldsymbol{\theta}_2 = (\mu_{x2}, \mu_{y2}, \sigma_{x2}^2, \sigma_{y2}^2, \rho)$  be two parameter vectors that share the same value of  $\rho$ . Let  $a_x = \sigma_{x2}/\sigma_{x1}$ ,  $a_y = \sigma_{y2}/\sigma_{y1}$ ,  $b_x = \mu_{x2} - \mu_{x1}$ , and  $b_y = \mu_{y2} - \mu_{y1}$ . For  $i = 1, 2$ , let  $\mathbf{W}_i$  be a sample of size  $n$  from a bivariate normal distribution with parameter vector  $\boldsymbol{\theta}_i$ , and let  $R_i$  be the sample correlation. We want to show that  $R_1$  and  $R_2$  have

the same distribution. Write  $\mathbf{W}_i = [(X_{i1}, Y_{i1}), \dots, (X_{in}, Y_{in})]$  for  $i = 1, 2$ . Define  $X'_{ij} = a_x(X_{ij} + b_x)$ ,  $Y'_{ij} = a_y(Y_{ij} + b_y)$  for  $j = 1, \dots, n$ . Then it is trivial to see that  $\mathbf{W}'_2 = [(X'_{21}, Y'_{21}), \dots, (X'_{2n}, Y'_{2n})]$  has the same distribution as  $\mathbf{W}_2$ . Let  $R'_2$  be the sample correlation computed from  $\mathbf{W}'_2$ . Then  $R'_2$  and  $R_2$  have the same distribution. We complete the proof by showing that  $R'_2 = R_1$ . Hence  $R'_2$  and  $R_1$  and  $R_2$  all have the same distribution. To see that  $R'_2 = R_1$ , let  $\bar{X}_1 = \sum_{j=1}^n X_{1j}$  and similarly  $\bar{Y}_1$ ,  $\bar{X}'_2$  and  $\bar{Y}'_2$ . Then  $\bar{X}'_2 = a_x(\bar{X}_1 + b_x)$  and  $\bar{Y}'_2 = a_y(\bar{Y}_1 + b_y)$ . So, for each  $j$ ,  $X'_{2j} - \bar{X}'_2 = a_x(X_{1j} - \bar{X}_1)$  and  $Y'_{2j} - \bar{Y}'_2 = a_y(Y_{1j} - \bar{Y}_1)$ . Since  $a_x, a_y > 0$ , it follows that

$$\begin{aligned} R'_2 &= \frac{\sum_{j=1}^n (X'_{2j} - \bar{X}'_2)(Y'_{2j} - \bar{Y}'_2)}{\left( \left[ \sum_{j=1}^n (X'_{2j} - \bar{X}'_2)^2 \right] \left[ \sum_{j=1}^n (Y'_{2j} - \bar{Y}'_2)^2 \right] \right)^{1/2}} \\ &= \frac{a_x a_y \sum_{j=1}^n (X_{1j} - \bar{X}_1)(Y_{1j} - \bar{Y}_1)}{\left( \left[ a_x^2 \sum_{j=1}^n (X_{1j} - \bar{X}_1)^2 \right] \left[ a_y^2 \sum_{j=1}^n (Y_{1j} - \bar{Y}_1)^2 \right] \right)^{1/2}} \\ &= R_1. \end{aligned}$$

## 12.7 Supplementary Exercises

### Solutions to Exercises

- For the random number generator that I have been using for these solutions, Fig. S.12.7 contains one such normal quantile plot. It looks fairly straight. On the horizontal axis I plotted the sorted

Figure S.12.7: Normal quantile plot for Exercise 1 in Sec. 12.7. A straight line has been added for reference.

- pseudo-normal values and on the vertical axis, I plotted the values  $\Phi^{-1}(i/10001)$  for  $i = 1, \dots, 10000$ .
- The plots for this exercise are formed the same way as that in Exercise 1 except we replace the normal pseudo-random values by the appropriate gamma pseudo-random values and we replace  $\Phi^{-1}$  by the

quantile function of the appropriate gamma distribution. Two of the plots are in Fig. S.12.8. The plots are pretty straight except in the extreme upper tail, where things are expected to be highly variable.

Figure S.12.8: Gamma quantile plots for Exercise 2 in Sec. 12.7. The left plot has parameters 0.5 and 1 and the right plot has parameters 10 and 1. Straight lines have been added for reference.

3. Once again, the plots are drawn in a fashion similar to Exercise 1. This time, we notice that the plot with one degree of freedom has some really serious non-linearity. This is the Cauchy distribution which has very long tails. The extreme observations from a Cauchy sample are very variable. Two of the plots are in Fig. S.12.9.

Figure S.12.9: Two  $t$  quantile plots for Exercise 3 in Sec. 12.7. The left plot has 1 degree of freedom, and the right plot has 20 degrees of freedom. Straight lines have been added for reference.

4. (a) I simulated 1000 pairs three times and got the following average values: 1.478, 1.462, 1.608. It looks like 1000 is not enough to be very confident of getting the average within 0.01.  
 (b) Using the same three sets of 1000, I computed the sample variance each time and got 1.8521, 1.6857, and 2.5373.  
 (c) Using (12.2.5), it appears that we need from 120000 to 170000 simulations.

5. (a) To simulate a noncentral  $t$  random variable, we can simulate independent  $Z$  and  $W$  with  $Z$  having the normal distribution with mean 1.936 and variance 1, and  $W$  having the  $\chi^2$  distribution with 14 degrees of freedom. Then set  $T = Z/(W/14)^{1/2}$ .
- (b) I did three separate simulations of size 1000 each and got the following three proportions with  $T > 1.761$ : 0.571, 0.608, 0.577. The simulation standard errors were 0.01565, 0.01544, and 0.01562.
- (c) Using (12.2.5), we find that we need a bit more than 16000 simulated values.
6. (a) For each sample, we compute the numbers of observations in each of the four intervals  $(-\infty, 3.575]$ ,  $[3.575, 3.912)$ ,  $[3.912, 4.249)$ , and  $[4.249, \infty)$ . Then we compute the  $Q$  statistic as we did in Example 10.1.6. We then compare each  $Q$  statistic to the three critical values 7.779, 9.488, and 13.277. We compute what proportion of the 10000  $Q$ 's is above each of these three critical values. I did three separate simulations of size 10000 each and got the proportions: 0.0495, 0.0536, and 0.0514 for the 0.9 critical value (7.779). I got 0.0222, 0.0247, and 0.0242 for the 0.95 critical value (9.488). I got 0.0025, 0.0021, and 0.0029 for the 0.99 critical value (13.277). It looks like the test whose nominal level is 0.1 has size closer to 0.05, while the test whose nominal level is 0.05 has level closer to 0.025.
- (b) For the power calculation, we perform exactly the same calculations with samples from the different normal distribution. I performed three simulations of size 1000 each for this exercise also. I got the proportions: 0.5653, 0.5767, and 0.5796 for the 0.9 critical value (7.779). I got 0.4560, 0.4667, and 0.4675 for the 0.95 critical value (9.488). I got 0.2224, 0.2280, and 0.2333 for the 0.99 critical value (13.277).
7. (a) We need to compute the same  $Q$  statistics as in Exercise 6(b) using samples from ten different normal distributions. For each of the ten distributions, we also compute the 0.9, 0.95 and 0.99 sample quantiles of the 10000  $Q$  statistics. Here is a table of the simulated quantiles:

$\mu$	$\sigma^2$	Quantile		
		0.9	0.95	0.99
3.8	0.25	3.891	4.976	7.405
3.8	0.80	4.295	5.333	8.788
3.9	0.25	3.653	4.764	6.405
3.9	0.80	4.142	5.133	7.149
4.0	0.25	3.825	5.104	7.405
4.0	0.80	4.554	5.541	8.635
4.1	0.25	3.861	5.255	8.305
4.1	0.80	4.505	5.658	8.637
4.2	0.25	4.193	5.352	8.260
4.2	0.80	4.087	4.981	7.677

- (b) The quantiles change a bit as the distributions change, but they are remarkably stable.
- (c) Instead of starting with normal samples, we start with samples having a  $t$  distribution as described in the exercise. We compute the  $Q$  statistic for each sample and see what proportion of our 10000  $Q$  statistics is greater than 5.2. In three simulations of this sort I got proportions of 0.12, 0.118, and 0.124.
8. (a) The product of likelihood times prior is

$$\exp\left(-\frac{u_0(\psi - \psi_0)^2}{2} - \sum_{i=1}^p \tau_i \left[ \beta_0 + \frac{n_i(\mu_i - \bar{y}_i)^2 + w_i + \lambda(\mu_i - \psi)^2}{2} \right] \right)$$

$$\times \lambda^{p/2+\gamma_0-1} \exp(-\lambda\delta_0) \prod_{i=1}^p \tau_i^{\alpha_0+[n_i+1]/2-1},$$

where  $w_i = \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2$  for  $i = 1, \dots, p$ .

- (b) As a function of  $\mu_i$ ,  $\tau_i$ , or  $\psi$  this looks the same as it did in Example 12.5.6 except that  $\lambda_0$  needs to be replaced by  $\lambda$  wherever it occurs. As a function of  $\lambda$ , it looks like the p.d.f. of the gamma distribution with parameters  $p/2 + \gamma_0$  and  $\delta_0 + \sum_{i=1}^p \tau_i(\mu_i - \psi)^2/2$ .
- (c) I ran six Markov chains for 10000 iterations each, producing 60000 parameter vectors. The requested posterior means and simulation standard errors were

Parameter	$\mu_1$	$\mu_2$	$\mu_3$	$\mu_4$	$1/\tau_1$	$1/\tau_2$	$1/\tau_3$	$1/\tau_4$
Posterior mean	156.9	158.7	118.8	160.6	486.7	598.8	479.2	548.4
Sim. std. err.	0.009583	0.01969	0.02096	0.01322	0.8332	0.8286	0.5481	0.9372

The code at the end of this manual was modified following the suggestions in the exercise in order to produce the above output. The same was done in Exercise 9.

9. (a) The product of likelihood times prior is

$$\exp\left(-\frac{u_0(\psi - \psi_0)^2}{2} - \sum_{i=1}^p \tau_i \left[ \beta + \frac{n_i(\mu_i - \bar{y}_i)^2 + w_i + \lambda_0(\mu_i - \psi)^2}{2} \right] \right)$$

$$\times \beta^{p\alpha_0+\epsilon_0-1} \exp(-\beta\phi_0) \prod_{i=1}^p \tau_i^{\alpha_0+[n_i+1]/2-1},$$

where  $w_i = \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2$  for  $i = 1, \dots, p$ .

- (b) As a function of  $\mu_i$ ,  $\tau_i$ , or  $\psi$  this looks the same as it did in Example 12.5.6 except that  $\beta_0$  needs to be replaced by  $\beta$  wherever it occurs. As a function of  $\beta$ , it looks like the p.d.f. of the gamma distribution with parameters  $p\alpha_0 + \epsilon_0$  and  $\phi_0 + \sum_{i=1}^p \tau_i$ .
- (c) I ran six Markov chains for 10000 iterations each, producing 60000 parameter vectors. The requested posterior means and simulation standard errors were

Parameter	$\mu_1$	$\mu_2$	$\mu_3$	$\mu_4$	$1/\tau_1$	$1/\tau_2$	$1/\tau_3$	$1/\tau_4$
Posterior mean	156.6	158.3	120.6	159.7	495.1	609.2	545.3	570.4
Sim. std. err.	0.01576	0.01836	0.02140	0.03844	0.4176	1.194	0.8968	0.7629

10. (a) The numerator of the likelihood ratio statistic is the maximum of the likelihood function over all parameter values in the alternative hypothesis, while the denominator is the maximum of the likelihood over all values in the null hypothesis. Both the numerator and denominator have a factor of  $\prod_{i=1}^k \binom{n_i}{X_i}$  that will divide out in the ratio, so we shall ignore these factors. In this example, the maximum over the alternative hypothesis will be the maximum over all parameter values, so we

would set  $p_i = X_i/n_i$  in the likelihood to get

$$\prod_{i=1}^k \left(\frac{X_i}{n_i}\right)^{X_i} \left(1 - \frac{X_i}{n_i}\right)^{n_i-X_i} = \frac{\prod_{i=1}^k X_i^{X_i} (n_i - X_i)^{n_i-X_i}}{\prod_{i=1}^k n_i^{n_i}}.$$

For the denominator, all of the  $p_i$  are equal, hence the likelihood to be maximized is  $p^{X_1+\dots+X_k}(1-p)^{n_1+\dots+n_k-X_1-\dots-X_k}$ . This is maximized at  $p = \sum_{j=1}^k X_j / \sum_{j=1}^k n_j$ , to yield

$$\left(\frac{\sum_{j=1}^k X_j}{\sum_{j=1}^k n_j}\right)^{\sum_{j=1}^k X_j} \left(1 - \frac{\sum_{j=1}^k X_j}{\sum_{j=1}^k n_j}\right)^{\sum_{j=1}^k (n_j - X_j)} = \frac{\left(\sum_{j=1}^k X_j\right)^{\sum_{j=1}^k X_j} \left(\sum_{j=1}^k (n_j - X_j)\right)^{\sum_{j=1}^k (n_j - X_j)}}{\left(\sum_{j=1}^k n_j\right)^{\sum_{j=1}^k n_j}}.$$

The ratio of these two maxima is a positive constant times the statistic stated in the exercise. The likelihood ratio test rejects the null hypothesis when the statistic is greater than a constant.

- (b) Call the likelihood ratio test statistic  $T$ . The distribution of  $T$ , under the assumption that  $H_0$  is true, that is  $p_1 = \dots = p_k$  still depends on the common value of the  $p_i$ 's, call it  $p$ . If the sample sizes are large, the distribution should not depend very much on  $p$ , but it will still depend on  $p$ . Let  $F_p(\cdot)$  denote the c.d.f. of  $T$  when  $p$  is the common value of all  $p_i$ 's. If we reject the null hypothesis when  $T \geq c$ , the test will be of level  $\alpha_0$  so long as

$$1 - F_p(c) \leq \alpha_0, \text{ for all } p. \quad (\text{S.12.12})$$

If  $c$  satisfies (S.12.12) then all larger  $c$  satisfy (S.12.12), so we want the smallest  $c$  that satisfies (S.12.12). Eq. (S.12.12) is equivalent to  $F_p(c) \geq 1 - \alpha_0$  for all  $p$ , which, in turn, is equivalent to  $c \geq F_p^{-1}(1 - \alpha_0)$  for all  $p$ . The smallest  $c$  that satisfies this last inequality is  $c = \sup_p F_p^{-1}(1 - \alpha_0)$ . To approximate  $c$  by simulation, proceed as follows. Pick a collection of reasonable values of  $p$  and a large number  $v$  of simulations to perform. For each value of  $p$ , perform  $v$  simulations as follows. Simulate  $k$  independent binomial random variables with parameters  $n_i$  and  $p$ , and compute the value of  $T$ . Sort the  $v$  values of  $T$  and approximate  $F_p^{-1}(1 - \alpha_0)$  by the  $(1 - \alpha_0)v$ th sorted value. Let  $c$  be the largest of these values over the different chosen values of  $p$ . It should be clear that the distribution of  $T$  is the same for  $p$  as it is for  $1 - p$ , so one need only check values of  $p$  between 0 and  $1/2$ .

- (c) To compute the  $p$ -value, we first find the observed value  $t$  of  $T$ , and then find  $\sup_p \Pr(T \geq t)$  under the assumption that the each  $p_i = p$  for  $i = 1, \dots, k$ . In Table 2.1, the  $X_i$  values are  $X_1 = 22$ ,  $X_2 = 25$ ,  $X_3 = 16$ ,  $X_4 = 10$ , while the sample sizes are  $n_1 = 40$ ,  $n_2 = 38$ ,  $n_3 = 38$ ,  $n_4 = 34$ . The observed value of  $T$  is

$$t = \frac{22^{22} 18^{18} 25^{25} 13^{13} 16^{16} 22^{22} 10^{10} 24^{24}}{73^{73} 77^{77}} = \exp(-202.17).$$

A pilot simulation showed that the maximum over  $p$  of  $1 - F_p(t)$  occurs at  $p = 0.5$ , so a larger simulation was performed with  $p = 0.5$ . The estimated  $p$ -value is 0.01255 with a simulation standard error of 0.0039.

11. (a) We shall use the same approach as in Exercise 12 of Sec. 12.6. Let the parameter be  $\theta = (\mu, \sigma_1, \sigma_2)$  (where  $\mu$  is the common value of  $\mu_1 = \mu_2$ ). Each pair of parameter values  $\theta$  and  $\theta'$  that have the

same value of  $\sigma_2/\sigma_1$  can be obtained from each other by multiplying  $\mu$ ,  $\sigma_1$  and  $\sigma_2$  by the same positive constant and adding some other constant to the resulting  $\mu$ . That is, there exist  $a > 0$  and  $b$  such that  $\theta' = (a\mu + b, a\sigma_1, a\sigma_2)$ . If  $X_1, \dots, X_m$  and  $Y_1, \dots, Y_n$  have the distribution determined by  $\theta$ , then  $X'_i = aX_i + b$  for  $i = 1, \dots, m$  and  $Y'_j = aY_j + b$  for  $j = 1, \dots, n$  have the distribution determined by  $\theta'$ . We need only show that the statistic  $V$  in (9.6.13) has the same value when it is computed using the  $X_i$ 's and  $Y_j$ 's as when it is computed using the  $X'_i$ 's and  $Y'_j$ 's. It is easy to see that the numerator of  $V$  computed with the  $X'_i$ 's and  $Y'_j$  equals  $a$  times the numerator of  $V$  computed using the  $X_i$ 's and  $Y_j$ 's. The same is true of the denominator, hence  $V$  has the same value either way and it must have the same distribution when the parameter is  $\theta$  as when the parameter is  $\theta'$ .

- (b) By the same reasoning as in part (a), the value of  $\nu$  is the same whether it is calculated with the  $X_i$ 's and  $Y_j$ 's or with the  $X'_i$ 's and  $Y'_j$ 's. Hence the distribution of  $\nu$  (thought of as a random variable before observing the data) depends on the parameter only through  $\sigma_2/\sigma_1$ .
- (c) For each simulation with ratio  $r$ , we can simulate  $\bar{X}_m$  having the standard normal distribution and  $S_X^2$  having the  $\chi^2$  distribution with 9 degrees of freedom. Then simulate  $\bar{Y}_n$  having the normal distribution with mean 0 and variance  $r^2$  and  $S_Y^2$  equal to  $r^2$  times a  $\chi^2$  random variable with 10 degrees of freedom. Make the four random variables independent when simulating. Then compute  $V$  and  $\nu$ . Compute the three quantiles  $T_\nu^{-1}(0.9)$ ,  $T_\nu^{-1}(0.95)$  and  $T_\nu^{-1}(0.99)$  and check whether  $V$  is greater than each quantile. Our estimates are the proportions of the 10000 simulations in which the value of  $V$  are greater than each quantile. Here are the results from one of my simulations:

$r$	Probability		
	0.9	0.95	0.99
1.0	0.1013	0.0474	0.0079
1.5	0.0976	0.0472	0.0088
2.0	0.0979	0.0506	0.0093
3.0	0.0973	0.0463	0.0110
5.0	0.0962	0.0476	0.0117
10.0	0.1007	0.0504	0.0113

The upper tail probabilities are very close to their nominal values.

12. I used the same simulations as in Exercise 11 but computed the statistic  $U$  from (9.6.3) instead of  $V$  and compared  $U$  to the quantiles of the  $t$  distribution with 19 degrees of freedom. The proportions are below:

$r$	Probability		
	0.9	0.95	0.99
1.0	0.1016	0.0478	0.0086
1.5	0.0946	0.0461	0.0090
2.0	0.0957	0.0483	0.0089
3.0	0.0929	0.0447	0.0112
5.0	0.0926	0.0463	0.0124
10.0	0.0964	0.0496	0.0121

These values are also very close to the nominal values.

13. (a) The fact that  $E(\hat{\beta}_1) = \beta_1$  depends only on the fact that each  $Y_i$  has mean  $\beta_0 + x_i\beta_1$ . It does not depend on the distribution of  $Y_i$  (as long as the distribution has finite mean). Since  $\hat{\beta}_1$  is a linear function of  $Y_1, \dots, Y_n$ , its variance depends only on the variances of the  $Y_i$ 's (and the fact that

they are independent). It doesn't depend on any other feature of the distribution. Indeed, we can write

$$\hat{\beta}_1 = \frac{\sum_{i=1}^n (x_i - \bar{x}_n) Y_i}{\sum_{j=1}^n (x_j - \bar{x}_n)^2} = \sum_{i=1}^n a_i Y_i,$$

where  $a_i = (x_i - \bar{x}_n) / \sum_{j=1}^n (x_j - \bar{x}_n)^2$ . Then  $\text{Var}(\hat{\beta}_1) = \sum_{i=1}^n a_i^2 \text{Var}(Y_i)$ . This depends only on the variances of the  $Y_i$ 's, which do not depend on  $\beta_0$  or  $\beta_1$ .

- (b) Let  $T$  have the  $t$  distribution with  $k$  degrees of freedom. Then  $Y_i$  has the same distribution as  $\beta_0 + \beta_1 x_i + \sigma T$ , whose variance is  $\sigma^2 \text{Var}(T)$ . Hence,  $\text{Var}(Y_i) = \sigma^2 \text{Var}(T)$ . It follows that

$$\text{Var}(\hat{\beta}_1) = \sigma^2 \text{Var}(T) \sum_{i=1}^n a_i^2.$$

Let  $v = \text{Var}(T) \sum_{i=1}^n a_i^2$ .

- (c) There are several possible simulation schemes to estimate  $v$ . The simplest might be to notice that

$$\sum_{i=1}^n a_i^2 = \frac{1}{\sum_{j=1}^n (x_j - \bar{x}_n)^2},$$

so that we only need to estimate  $\text{Var}(T)$ . This could be done by simulating lots of  $t$  random variables with  $k$  degrees of freedom and computing the sample variance. In fact, we can actually calculate  $v$  in closed form if we wish. According to Exercise 1 in Sec. 8.4,  $\text{Var}(T) = k/(k-2)$ .

14. As we noted in Exercise 13(c), the value of  $v$  is

$$\frac{5/3}{\sum_{i=1}^n (x_i - \bar{x}_n)^2} = 3.14 \times 10^{-3}.$$

15. (a) We are trying to approximate the value  $a$  that makes  $\ell(a) = E[L(\theta, a)|\mathbf{x}]$  the smallest. We have a sample  $\theta^{(1)}, \dots, \theta^{(v)}$  from the posterior distribution of  $\theta$ , so we can approximate  $\ell(a)$  by  $\hat{\ell}(a) = \sum_{i=1}^v L(\theta^{(i)}, a)/v$ . We could then do a search through many values of  $a$  to find the value that minimizes  $\hat{\ell}(a)$ . We could use either brute force or mathematical software for minimization. Of course, we would only have the value of  $a$  that minimizes  $\hat{\ell}(a)$  rather than  $\ell(a)$ .

- (b) To compute a simulation standard error, we could draw several (say  $k$ ) samples from the posterior (or split one large sample into  $k$  smaller ones) and let  $Z_i$  be the value of  $a$  that minimizes the  $i$ th version of  $\hat{\ell}$ . Then compute  $S$  in Eq. (12.2.2) and let the simulation standard error be  $S/k^{1/2}$ .

16. (In the displayed formula, on the right side of the  $=$  sign, all  $\theta$ 's should have been  $\mu$ 's.) The posterior hyperparameters are all given in Example 12.5.2, so we can simulate as many  $\mu$  values as we want to estimate the posterior mean of  $L(\theta, a)$ . We simulated 100000  $t$  random variables with 22 degrees of freedom and multiplied each one by 15.214 and added 183.95 to get a sample of  $\mu$  values. For each value of  $a$  near 183.95, we computed  $\hat{\ell}(a)$  and found that  $a = 182.644$  gave the smallest value. We then repeated the entire exercise for a total of five times. The other four  $a$  values were 182.641, 182.548, 182.57 and 182.645. The simulation standard error is then 0.0187

## R Code For Two Text Examples

If you are not using *R* or if you are an expert, you should not bother reading this section.

The code below (with comments that start `#`) is used to perform the calculations in Examples 12.5.6 and 12.5.7 in the text. The reason that the code appears to be so elaborate is that I realized that Exercises 8 and 9 in Sec. 12.7 asked to perform essentially the same analysis, each with one additional parameter. Modifying the code below to handle those exercises is relatively straightforward. Significantly less coding would be needed if one were going to perform the analysis only once. For example, one would need the three functions that simulate each parameter given the others, plus the function called `hierchain` that could be used both for burn-in and the later runs. The remaining calculations could be done by typing some additional commands at the *R* prompt or in a text file to be `sourced`.

In the first printing, there was an error in these examples. For some reason (my mistake, obviously) the  $w_i$  values were recorded in reverse order when the simulations were performed. That is,  $w_4$  was used as if it were  $w_1$ ,  $w_3$  was used as if it were  $w_2$ , etc. The  $\bar{y}_i$  and  $n_i$  values were in the correct order, otherwise the error could have been fixed by reordering the hot dog type names, but no such luck. Because the  $w_i$  were such different numbers, the effect on the numerical output was substantial. Most notably, the means of the  $1/\tau_i$  are not nearly so different as stated in the first printing.

The data file `hotdogs.csv` contains four columns separated by commas with the data in Table 11.15 along with a `header` row:

```
Beef,Meat,Poultry,Specialty
186,173,129,155
181,191,132,170
176,182,102,114
149,190,106,191
184,172,94,162
190,147,102,146
158,146,87,140
139,139,99,187
175,175,107,180
148,136,113,,
152,179,135,,
111,153,142,,
141,107,86,,
153,195,143,,
190,135,152,,
157,140,146,,
131,138,144,,
149,,,,
135,,,,
132,,,
```

The commas with nothing after them indicate that the data in the next column has run out already, and `NA` (not available) values will be produced in *R*. Most *R* functions have sensible ways to deal with `NA` values, generally by including the optional argument `na.rm=T` or something similar. By default, *R* uses all values (including `NA`'s) to compute things like `mean` or `var`. Hence, the the result will be `NA` if one does not change the default.

First, we list some code that sets up the data, summary statistics, and prior hyperparameters. The lines that appear below were part of a file `hotdogcmc-example.r`. They were executed by typing

```
source("hotdogmcmc-example.r")
```

at the *R* prompt in a command window. The `source` function reads a file of text and treats each line as if it had been typed at the *R* prompt.

```
# Read the data from a comma-separated file with a header row.
hotdogs=read.table("hotdogs.csv",header=T,sep=",")
# Compute the summary statistics
# First, the sample sizes: how many are not NA?
n=apply(hotdogs,2,function(x){sum(!is.na(x))})
# Next, the sample means: remember to remove the NA values
ybar=apply(hotdogs,2,mean,na.rm=T)
# Next, the wi values (sum of squared deviations from sample mean)
w=apply(hotdogs,2,var,na.rm=T)*(n-1)
# Set the prior hyperparameters:
hyp=list(lambda0=1, alpha0=1, beta0=0.1, u0=0.001, psi0=170)
# Set the initial values of parameters. These will be perturbed to be
# used as starting values for independent Markov chains.
tau=(n-1)/w
psi=(hyp$psi0*hyp$u0+hyp$lambda0*sum(tau*ybar))/(hyp$u0+hyp$lambda0*sum(tau))
mu=(n*ybar+hyp$lambda0*psi)/(n+hyp$lambda0)
```

Next, we list a series of functions that perform major parts of the calculation. The programs are written specifically for these examples, using variable names like `ybar`, `n`, `w`, `mu`, `tau`, and `psi` so that the reader can easily match what the programs are doing to the example. If one had wished to have a general hierarchical model program, one could have made the programs more generic at the cost of needing special routines to deal with the particular structure of the examples. Each of these functions is stored in a text file, and the `source` function is used to read the lines which in turn define the function for use by *R*. That is, after each file has been “sourced,” the function whose name appears to the left of the = sign becomes available for use. Its arguments appear in parentheses after the word `function` on the first line.

First, we have the functions that simulate the next values of the parameters in each Markov chain:

```
mugen=function(i,tau,psi,n,ybar,w,hyp){
#
# Simulate a new mu[i] value
#
(n[i]*ybar[i]+hyp$lambda0*psi)/(n[i]+hyp$lambda0)+rnorm(1,0,1)/sqrt(tau[i]*
(n[i]+hyp$lambda0))
}
taugen=function(i,mu,psi,n,ybar,w,hyp){
#
# Simulate a new tau[i] value
#
rgamma(1,hyp$alpha0+0.5*(n[i]+1))/(hyp$beta0+0.5*(w[i]+n[i]*(mu[i]-ybar[i])^2+
hyp$lambda0*(mu[i]-psi)^2))
}
psigen=function(mu,tau,n,ybar,w,hyp){
#
# Simulate a new psi value
#
(hyp$psi0*hyp$u0+hyp$lambda0*sum(tau*mu))/(hyp$u0+hyp$lambda0*sum(tau))+
```

```

rnorm(1,0,1)/sqrt(hyp$u0+hyp$lambda0*sum(tau))
}

```

Next is the function that does burn-in and computes the  $F$  statistics described in the text. If the  $F$  statistics are too large, this function would have to be run again from the start with more burn-in. One could rewrite the function to allow it to start over from the end of the previous burn-in if one wished. (One would have to preserve the accumulated means and sums of squared deviations.)

```

burnchain=function(nburn,start,nchain,mu,tau,psi,n,ybar,w,hyp,stand){
#
# Perform "nburn" burn-in for "nchain" Markov chains and check the F statistics
# starting after "start". The initial values are "mu", "tau", "psi"
# and are perturbed by "stand" times random variables. The data are
# "n", "ybar", "w". The prior hyperparameters are "hyp".
#
# ngroup is the number of groups
ngroup=length(ybar)
# Set up the perturbed starting values for the different chains.
# First, store 0 in all values
muval=matrix(0,nchain,ngroup)
tauval=muval
psival=rep(0,nchain)
# Next, for each chain, perturb the starting values using random
# normals or lognormals
for(l in 1:nchain){
  muval[l,]=mu+stand*rnorm(ngroup)/sqrt(tau)
  tauval[l,]=tau*exp(rnorm(ngroup)*stand)
  psival[l]=psi+stand*rnorm(1)/sqrt(hyp$u0)
# Save the starting vectors for all chains just so we can see what
# they were.
  startvec=cbind(muval,tauval,psival)
}
# The next matrices/vectors will store the accumulated means "...a" and sums
# of squared deviations "...v" so that we don't need to store all of the
# burn-in simulations when computing the F statistics.
# See Exercise 23(b) in Sec. 7.10 of the text.
muacca=matrix(0,nchain,ngroup)
tauacca=muacca
psiaccca=rep(0,nchain)
muaccv=muacca
tauaccv=muacca
psiaccv=psiaccca
# The next matrix will store the burn-in F statistics so that we can
# see if we need more burn-in.
fs=matrix(0,nburn-start+1,2*ngroup+1)
# Loop through the burn-in
for(i in 1:nburn){
# Loop throught the chains
  for(l in 1:nchain){
    muacca[l,]=muval[l,]
    tauacca[l,]=tauval[l,]
    psiaccca[l]=psival[l]
    muaccv[l]=muval[l,]^2
    tauaccv[l]=tauval[l,]^2
    psiaccv[l]=psival[l]^2
    fs[i,2*ngroup+1]=fs[i,2*ngroup+1]+(muacca[l,]-muacca[l,])^2
    fs[i,2*ngroup+2]=fs[i,2*ngroup+2]+(tauacca[l,]-tauacca[l,])^2
    fs[i,2*ngroup+3]=fs[i,2*ngroup+3]+(psiaccca[l]-psiaccca[l])^2
  }
}

```

```

# Loop through the coordinates
for(j in 1:ngrup){
# Generate the next mu
  muval[1,j]=mugen(j,tauval[1],psival[1],n,ybar,w,hyp)
# Accumulate the average mu (muacca) and the sum of squared deviations (muaccv)
  muaccv[1,j]=muaccv[1,j]+(i-1)*(muval[1,j]-muacca[1,j])^2/i
  muacca[1,j]=muacca[1,j]+(muval[1,j]-muacca[1,j])/i
# Do the same for tau
  tauval[1,j]=taugen(j,muval[1],psival[1],n,ybar,w,hyp)
  tauaccv[1,j]=tauaccv[1,j]+(i-1)*(tauval[1,j]-tauacca[1,j])^2/i
  tauacca[1,j]=tauacca[1,j]+(tauval[1,j]-tauacca[1,j])/i
}
# Do the same for psi
psival[1]=psigen(muval[1],tauval[1],n,ybar,w,hyp)
  psiaccv[1]=psiaccv[1]+(i-1)*(psival[1]-psiacca[1])^2/i
  psiacca[1]=psiacca[1]+(psival[1]-psiacca[1])/i
}
# Once we have enough burn-in, start computing the F statistics (see
# p. 826 in the text)
if(i>=start){
  mub=i*apply(muacca,2,var)
  muw=apply(muaccv,2,mean)/(i-1)
  taub=i*apply(tauacca,2,var)
  tauw=apply(tauaccv,2,mean)/(i-1)
  psib=i*var(psiacca)
  psiw=mean(psiaccv)/(i-1)
  fs[i-start+1,]=c(mub/muw,taub/tauw,psib/psiw)
}
}
# Return a list with useful information: the last value of each
# parameter for all chains, the F statistics, the input information,
# and the starting vectors. The return value will contain enough
# information to allow us to start all the Markov chains and
# simulate them as long as we wish.
list(mu=muval,tau=tauval,psi=psival,fstat=fs,nburn=nburn,start=start,
n=n,ybar=ybar,w=w,hyp=hyp,nchain=nchain,startvec=startvec)
}

```

A similar, but simpler, function will simulate a single chain after we have finished burn-in:

```

hierchain=function(nsim,mu,tau,psi,n,ybar,w,hyp){
#
# Run a Markov chain for "nsim" simulations from initial values "mu",
# "tau", "psi"; the data are "n", "ybar", "w"; the prior
# hyperparameters are "hyp".
#
# ngroup is the number of groups
ngrup=length(ybar)
# Set up matrices to hold the simulated parameter values

```

```

psiex=rep(0,nsim)
muex=matrix(0,nsim,ngroup)
tauex=muex
# Loop through the simulations
for(i in 1:nsim){
# Loop through the coordinates
  for(j in 1:ngroup){
# Generate the next value of mu
    temp=mugen(j,tau,psi,n,ybar,w,hyp)
    mu[j]=temp
# Store the value of mu
    muex[i,j]=temp
# Do the same for tau
    temp=taugen(j,mu,psi,n,ybar,w,hyp)
    tau[j]=temp
    tauex[i,j]=temp
  }
# Do the same for psi
temp=psigen(mu,tau,n,ybar,w,hyp)
psi=temp
psiex[i]=temp
}
# Return a list with useful information: The simulated values
list(mu=muex,tau=tauex,psi=psiex)
}

```

Next, we have a function that will run several independent chains and put the results together. It calls the previous function once for each chain.

```

stackchains=function(burn,nsim){
#
# Starting from the information in "burn", obtained from "burnchain",
# run "nsim" additional simulations for each chain and stack the
# results on top of each other. The
# results from chain i can be extracted by using rows
# (i-1)*nsim to i*nsim of each parameter matrix
#
# Set up storage for parameter values
muex=NULL
tauex=NULL
psiex=NULL
# Loop through the chains
for(l in 1:burn$nchain){
# Extract the last burn-in parameter value for chain l
  mu=burn$mu[l,]
  tau=burn$tau[l,]
  psi=burn$psi[l]
# Run the chain nsim times
  temp=hierchain(nsim, mu, tau, psi, burn$n, burn$ybar, burn$w, burn$hyp)

```

```

# Extract the simulated values from each chain and stack them.
  muex=rbind(muex,temp$mu)
  tauex=rbind(tauex,temp$tau)
  psiex=c(psiex,temp$psi)
}
# Return a list with useful information: the simulated values, the
#   number of simulations per chain, and the number of chains.
list(mu=muex,tau=tauex,psi=psiex,nsim=nsim,nchain=burn$nchain)
}

```

The calculations done in Example 12.5.6 begin by applying the above functions and then manipulating the output. The following commands were typed at the *R* command prompt >. Notice that some of them produce output that appears in the same window in which the typing is done. The summary statistics appear in Table 12.4 in the text (after correcting the errors).

```

> # Do the burn-in
> hotdog.burn=burnchain(100,100,6,mu,tau,psi,n,ybar,w,hyp,2)
> # Note that the F statistics are all less than 1+0.44m=45.
> hotdog.burn$fstat
      [,1]      [,2]      [,3]      [,4]      [,5]      [,6]      [,7]      [,8]
[1,] 0.799452 0.7756733 1.464278 1.831631 0.9673807 0.4030658 1.161147 2.727503
      [,9]
[1,] 0.548359
> # Now run each chain 10000 more times.
> hotdog.mcmc=stackchains(hotdog.burn,10000)
> # Obtain the data for the summary table in the text
> apply(hotdog.mcmc$mu,2,mean)
[1] 156.5894 158.2559 120.5360 159.5841
> sqrt(apply(hotdog.mcmc$mu,2,var))
[1] 4.893067 5.825234 5.552140 7.615332
> apply(1/hotdog.mcmc$tau,2,mean)
[1] 495.6348 608.4955 542.8819 568.2482
> sqrt(apply(1/hotdog.mcmc$tau,2,var))
[1] 166.0203 221.1775 201.6250 307.3618
> mean(hotdog.mcmc$psi)
[1] 151.0273
> sqrt(var(hotdog.mcmc$psi))
[1] 11.16116

```

Next, we `source` a file that computes values that we can use to assess how similar/different the four groups of hot dogs are.

```

# Compute the six ratios of precisions (or variances)
hotdog.ratio=cbind(hotdog.mcmc$tau[,1]/hotdog.mcmc$tau[,2],
hotdog.mcmc$tau[,1]/hotdog.mcmc$tau[,3],hotdog.mcmc$tau[,1]/hotdog.mcmc$tau[,4],
hotdog.mcmc$tau[,2]/hotdog.mcmc$tau[,3],hotdog.mcmc$tau[,2]/hotdog.mcmc$tau[,4],
hotdog.mcmc$tau[,3]/hotdog.mcmc$tau[,4])
# For each simulation, find the maximum ratio. We need to include one over
#   each ratio also.
hotdog.rmax=apply(cbind(hotdog.ratio,1/hotdog.ratio),1,max)

```

```
# Compute the six differences between means.
hotdog.diff=cbind(hotdog.mcmc$mu[,1]-hotdog.mcmc$mu[,2],
hotdog.mcmc$mu[,2]-hotdog.mcmc$mu[,3],hotdog.mcmc$mu[,3]-hotdog.mcmc$mu[,4],
hotdog.mcmc$mu[,4]-hotdog.mcmc$mu[,1],hotdog.mcmc$mu[,1]-hotdog.mcmc$mu[,3],
hotdog.mcmc$mu[,2]-hotdog.mcmc$mu[,4])
# For each simulation, find the minimum, maximum and average absolute
# differences.
hotdog.min=apply(abs(hotdog.diff),1,min)
hotdog.max=apply(abs(hotdog.diff),1,max)
hotdog.ave=apply(abs(hotdog.diff),1,mean)
```

Using the results of the above calculations, we now type commands at the prompt that answer various questions. First, what proportion of the time is one of the ratios of standard deviations at least 1.5 (ratio of variances at least 2.25)? In this calculation the vector `hotdog.max>2.25` has coordinates that are either TRUE (1) or FALSE (0) depending on whether the maximum ratio is greater than 2.25 or not. The `mean` is then the proportion of TRUEs.

```
mean(hotdog.rmax>2.25)
[1] 0.3982667
```

Next, compute the 0.01 quantile of the maximum absolute difference between between the means, the median of the minimum difference, and the 0.01 quantile of the average difference. In 99% of the simulations, the difference was greater than the 0.01 quantile.

```
> quantile(hotdog.max,0.01)
 1%
26.3452
> median(hotdog.min)
[1] 2.224152
> quantile(hotdog.ave,0.01)
 1%
13.77761
```

In Example 12.5.7, we needed to simulate a pair of observations  $(Y_1, Y_3)$  from each parameter vector and then approximate the 0.05 and 0.95 quantiles of the distribution of  $Y_1 - Y_3$  for a prediction interval. The next function allows one to compute a general function of the parameters and find simulation standard errors using Eq. (12.5.1), that is  $S/k^{1/2}$ .

```
mcmcse=function(simobj,func,entire=FALSE){
#
# Start with the result of a simulation "simobj", compute a vector function
# "func" from each chain, and then compute formula (12.5.1) for each
# coordinate as well as the covariance matrix. If "entire" is TRUE,
# it also computes the function value on the entire parameter
# matrix. This may differ from the average over the chains if "func"
# is not and average and/or if it does additional simulation.
# Also computes the avearge of the "func"
# values. The function "func" must take as arguments matrices of mu,
# tau, and psi values with each row from a single simulation. It
# must return a real vector. For example, if you want two
# quantiles of the distribution of  $f(Y_i, Y_j)$  where  $Y_i$  comes from group
```

```

# i and Yj comes from group j, func should loop through the rows of
# its input and simulate a pair (Yi,Yj) for each parameter. Then it
# should return the appropriate sample quantiles of the simulated
# values of f(Yj,Yj).
#
# k is the number of chains, nsim the number of simulations
k=simobj$nchain
nsim=simobj$nsim
# Loop through the chains
for(i in 1:k){
# Extract the parameters for chain i
  mu=simobj$mu[((i-1)*nsim):(i*nsim),]
  tau=simobj$tau[((i-1)*nsim):(i*nsim),]
  psi=simobj$psi[((i-1)*nsim):(i*nsim)]
# Compute the function value based on the parameters of chain i
  if(i==1){
valf=func(mu,tau,psi)
  }else{
valf=rbind(valf,func(mu,tau,psi))
  }
}
# p is how many functions were computed
p=ncol(valf)
# compute the average of each function
ave=apply(valf,2,mean)
# compute formula (12.5.1) for each function
se=sqrt(apply(valf,2,var)*(k-1))/k
#
# Return the average function value, formula (12.5.1), and covariance
# matrix. The covariance matrix can be useful if you want to
# compute a further function of the output and then compute a
# simulation standard error for that further function. Also computes
# the function on the entire parameter set if "entire=TRUE".
  if(entire){
list(ave=ave,se=se,covmat=cov(valf)*(k-1)/k^2,
entire=func(simobj$mu,simobj$tau,simobj$psi))
}else{
list(ave=ave,se=se,covmat=cov(valf)*(k-1)/k^2)
}
}

```

The specific function `func` used in Example 12.5.7 is:

```

hotdog13=function(mu,tau,psi){
#
# Compute the 0.05 and 0.95 quantiles of predictive distribution of Y1-Y3
#
  n=nrow(mu)
# Make a place to store the differences.

```

```

vals=rep(0,n)
# Loop through the parameter vectors.
for(i in 1:n){
# Simulate a difference.
  vals[i]=rnorm(1)/sqrt(tau[i,1])+mu[i,1]-(rnorm(1)/
sqrt(tau[i,3])+mu[i,3])
}
# Return the desired quantiles
quantile(vals,c(0.05,0.95))
}

```

Finally, we use the above functions to compute the prediction interval in Example 12.5.7 along with the simulation standard errors.

```

> hotdog.pred=mcmcse(hotdog.mcmc,hotdog13,T)
> hotdog.pred
$ave
      5%         95%
-18.57540  90.20092

$se
      5%         95%
0.2228034  0.4345629

$covmat
      5%         95%
5%  0.04964136  0.07727458
95% 0.07727458  0.18884493

$entire
      5%         95%
-18.49283  90.62661

```

The final line `hotdog.pred$entire` gives the prediction interval based on the entire collection of 60,000 simulations. The one listed as `hotdog.pred$ave` is the average of the six intervals based on the six independent Markov chains. There is not much difference between them. The simulation standard errors show up as `hotdog.pred$se`. Remember that the numbers in the first printing don't match these because of the error mentioned earlier.
